As mentioned, the significance of *philosophy of science* for science education is generally recognized today—though moreso among researchers than science teachers themselves (Duschl 1994, 1988; Hodson 2008; Matthews 1994a)—while philosophy per se is accorded much lesser importance, notwithstanding the limited forays by some researchers into its subfields, which can be acknowledged (e.g., language studies, post-structuralism, hermeneutics, scientific argumentation, "critical theory"). Why this situation has arisen and persists is an open question and would require its own socio-empirical research, and hence is not of immediate concern of this review. But it remains an important question that should be pursued as it could reveal much about our community, about how science education is perceived and undertaken. In other words, it aims at the core of the self-understanding of science education as profession and identity (Fensham 2004).

A familiar question posed by preservice and science teachers alike is: "What does philosophy have to do with science?" or more succinctly and less pejoratively "how can any sort of 'philosophy' contribute to helping my students better understand difficult *scientific* concepts?" Such questions implicitly assume of course a deep divide between science and philosophy, certainly between science education and philosophy.[9] While science teachers need not be openly hostile to philosophy, they certainly appear indifferent. Much responsibility can be laid at the door of the academy, its structure, culture, and teacher training. Their attitudes and preparation effectively expose much about how teacher identity is formed,[10] about preconceptions of knowledge, but also about the nature of university science education and scientific specialization, including the nature and influence of science textbooks.[11]

Classroom teachers tend to be more concerned with valuable but mundane matters of decision-making regarding immediate instruction, learning, and assessment. For them as pertains their professional duties and identity, these concerns have little if anything to do with philosophy—or so it would seem. A consequence of this disregard makes providing educational rationales of their thinking and practice a

---

[8] See the chapters in Bonjour and Sosa (2003) for a concise overview; Sect. 39.5.2.2 targets the former.

[9] That one must inevitably justify the value of philosophy for teachers and many researchers suggests a cultural predicament already exists concerning what constitutes "education" in our present age.

[10] Which includes essentially their "orientations" towards teaching, identified in science teacher education research as formative dispositions attached to identity (Van Driel and Abell 2010; Witz and Lee 2009)

[11] Probably the ongoing reality of the academic divide between the "two cultures" maintained as two solitudes in universities to this day (as described by C.P. Snow; Shamos 1995; Stinner 1989) contributes to the hostility or indifference since science teachers are not generally required to endure Arts faculty courses. All this in combination with the common negative *image* that academic philosophy is preoccupied with obtuse speculation, arcane technical jargon, and unresolved disputes are remote from everyday matters. Certainly quite different, encouraging evaluations can be had (Matthews 1994a; Nola and Irzik 2005).

challenge: "When planning lessons, teachers often struggle when asked to express how they decide what science content within a discipline is worth teaching. Rationales are post-hoc and rarely reflect deep thinking about the structure of the discipline, or how students learn …" (Clough et al. 2009, p. 833).[12] Their struggles become quite apparent when further asked to give an explicit account of their "philosophy of teaching" or "philosophy of learning." And this counts not just for content teaching and conceptions of learning but equally for providing truly *educational* objectives for either their individual courses or overall science education.[13] Seldom are the contextual aspects of teaching the subject matter made explicit even though *seven* competing "curriculum emphases" have been identified in science educational history (Roberts 1988). In effect, particular curricular emphases bear witness to buried educational philosophies. The teaching profession itself is mired in a scenario of what Roberts (2007) has astutely identified as two substantial conflicting "visions" of science education.[14] These facts alone warrant developing philosophical acumen for teachers.

If this picture as sketched is indicative of teacher training and science education culture, then emphasizing the significance of philosophy, especially philosophy of education, would require a "paradigm shift" in thinking. Exactly this sort of thing had been recommended by Jenkins (2000) for effective reform of that culture, although the present proposal would encompass a wider scope than was initially suggested.[15]

---

[12] They continue: "… Too often the selected textbook defines course scope, sequence, and depth implying that a textbook's inclusion of information, in part, legitimizes teaching that content. Textbooks also exert a significant influence on *how* content is taught…" (ibid).

[13] Many teachers would probably declare "science for all" or "scientific literacy" though seldom with awareness these slogans are replete with ambiguities—the latter goal even suffering inherent incompatibilities due to serious shifts in connotation, and this despite its ultimate prominence in worldwide "standards" documents (Jenkins 2009; Schulz 2009b; Shamos 1995). The science for all theme arguably partially appropriate for junior science nonetheless vanishes when specialty upper secondary or tertiary courses are reached, for here the status quo is maintained as "technical pre-professional training" (Aikenhead 1997, 2002, 2007). In this case an extreme narrowing of the "literacy" notion is found, HPSS aspects are distorted or abused, while the concealment of existent curriculum ideologies remains unrecognized in absence of educational philosophy (e.g., scientism, academic rationalism, "curriculum as technology" or social utility; Eisner 1992).

[14] In his comprehensive review, the categories "vision I" and "vision II" were postulated to account for two major competing images of science literacy behind many curricular reforms. The former designates those conceptions which are "internally oriented," that is, towards science as a knowledge- and inquiry-based discipline and including the image of science education as heavily influenced by the identity, demands, and conceptions of the profession. The latter vision, alternatively, is "outward looking," towards the application, limitation, and critical appraisal of science in society—the image influenced instead by the needs of society and the majority of students not headed for professional science-based careers. Here the question of the "social relevance" of the curriculum is paramount. He claims that while the second vision can encompass the first, the opposite is not true.

[15] For linked views, see Anderson (1992), Fensham (2004), Matthews (1994a/2014, 2002), and Schulz (2009a).

Philosophy in truth cannot be avoided, and not just for analyzing national "standards" documents, providing coherent rationales or detecting curricular ideologies. Science teachers inadvertently find themselves in its territory when confronted by diverse events, such as (i) explaining common scientific *terms* (like "law," "theory," "proof," "explanation," "observation"), or (ii) student-driven *quandaries* ("how do we know X?"; "do models reflect reality?"; "why are we studying this?", etc.), or (iii) when teacher and pupil together come across science-related public *controversies* (e.g., climate change, nuclear weapons, evolution versus intelligent design)—never mind popular beliefs and media reports (e.g., astrology or alien abductions). Such occurrences usually illustrate that "philosophy is not far below the surface" in any classroom (Matthews 1994a, p. 87). Moreover, the scientific tradition (as an integral part of Enlightenment culture) based on rationality, objectivity, and skepticism, which teachers have inherited, is equally challenged by strands of pseudoscience, irrationality, and credulity of the times (Hodson 2009; Slezak and Good 2011). How can teachers illustrate these differences, especially the distinction between valid and reliable knowledge claims from invalid ones (or natural from supernatural claims), without philosophical preparation? Yet it is not just the classroom, contemporary media discourse, or pop culture that is infused with questions, beliefs, claims, and counterclaims of philosophical significance, but likewise the evolution of science itself.

When science is seen historically, its development has always been interwoven with philosophical interests and debates, whether concerning epistemology, logic, metaphysics, or ethics (the major subfields of philosophy proper). A quick survey makes this evident: from debates on the nature of matter or motion in Ancient Greece to questions of logic, method, and truth with Galileo and Kepler during the Copernican revolution (or Descartes and Newton in the Enlightenment), also Lyell and Darwin concerning the age of the Earth or origin of species, respectively, in the nineteenth century (which saw the realist controversy about atoms in chemistry revived). Right down to our present age, philosophical controversies exist whether concerning the onto-epistemological debates in quantum mechanics or reduction in chemistry.[16]

The history of science, furthermore, is not simply a survey of fantastic discoveries, ideas, and theories as too many textbooks would imply, but is equally littered with discarded concepts and discredited theories (e.g., ether, epicycles, phlogiston, phrenology, caloric, Lamarck, Lysenkoism). Can teachers distinguish between quasi-histories and pseudo-histories or unmask how subject matter is organized to reflect the typical linear, non-controversial, and progressive accumulation of scientific knowledge, imitating the myth of "convergent realism?" (Kuhn 1970, 2000; Laudan 1981). The textbook's and one's personal view of scientific knowledge and

---

[16] It should not be forgotten that the seventeenth-century scientific revolution introduced "science" as a field of research and study under the academic umbrella of *Natural Philosophy* to distinguish it from the reigning scholasticism of the universities, hermeticism, and Neoplatonism. Our modern conception of the term and the severance of philosophy from science are of relatively recent origin. The division emerged historically as a development in intellectual thought and specialization, which evolved within European industrial society in the mid-nineteenth century.

its development both presume prior philosophical commitments (e.g., positivism? empiricism? naïve realism? critical realism? social constructivism?) (Duschl 1988; Säther 2003; Selley 1989; Smolicz and Nunan 1975).

Regarding ethics, one should not forget that Socrates was condemned on moral and religious grounds—as were Bruno, Galileo, and Darwin (though not exclusively). Eugenics, once the scientific "hard core" of the social Darwinism movement, was considered a legitimate topic of scientific research less than a century ago. Even modern physics cannot escape this subject, ever since Oppenheimer made the self-incriminating remark that physicists "had known sin" by developing the atomic bomb. The American philosopher C.S. Pierce had stated: "Find a scientific man who proposes to get along without any metaphysics . . . and you have found one whose doctrines are thoroughly vitiated by the crude and uncriticised metaphysics with which they are packed."[17] Studies in history, philosophy, and sociology of the sciences (HPSS) have made this claim abundantly apparent. These fields cannot be either ignored or glossed during science teacher education, but require time and attention for the emergence of an adequate PSE.

We have already noted the worth of philosophy (along with key aspects mentioned above) to lie in providing teachers with both (i) the perspective for synthesis of their educational enterprise by developing a PSE framework and (ii) making available to them in-depth studies termed "philosophies of." Linked to the latter, coming again to philosophy of science (appearing as the "PS" corner of the Fig. 39.1 triangle), teachers need to be made aware that in the past 20 years, new avenues of scholarship have been developing *within* the subfield itself to help them expand their foundational understanding of their specialty (e.g., philosophy of chemistry, philosophy of biology).[18] Here questions concerning major issues in subject matter content that bear directly on senior courses are being discussed. For example, there is dissention whether laws and explanations in biology and chemistry are of the same order and function as those in physics—normally taken for granted in PS literature.[19] Such "cutting-edge" philosophical research has acute ramifications for secondary and postsecondary education, expressly *subject epistemology*, including nature-of-science discourse (Irzik and Nola 2011; Jenkins 2009; Matthews 1998a).[20]

---

[17] Quoted in Matthews (1994a), p. 84.

[18] Scientists and philosophers alike have found it necessary to launch important new *subdisciplines* to address foundational questions and concerns arising from their scientific areas of expertise—notwithstanding those scientists who disparage the study of PS overall (e.g., Weinberg 1992). Philosophy of physics (Cushing 1998; Lange 2002), philosophy of chemistry (McIntyre 2007; Scerri 2001), and philosophy of biology (Ayala and Arp 2009) are becoming established research fields, including philosophy of technology (Scharff 2002), likewise lauded for teachers today (De Vries 2005).

[19] Refer to the respective chapter in this Handbook.

[20] Unfortunately it appears that science education worldwide and many science teachers themselves have tended not to keep abreast of these advances and what they possibly offer for curriculum design, instruction, and reform efforts. One might hope these subdisciplines offer, minimally, deeper and improved insights about subject content but, moreso, a better understanding of the essence of the discipline, the core of which teachers are required to inspire and impart to their

In addition to the above mentioned reasons, the worth of philosophy plainly lies in self-reflection. This means nothing less than to reassess one's own practice, educational ideas and aims; even going so far as to reevaluate one's own constructed sociocultural science teacher *identity*. Along with suggesting "philosophies of," Scheffler also argued that science teachers require philosophy as a "second-order" reflective capacity into the nature of their work, their understanding of science, and their educational endeavors. He considered this capacity analogous to the role philosophy of science plays when examining science:

> The teacher requires … a general conceptual grasp of science and a capacity to formulate and explain its workings to the outsider … No matter what additional resources the teacher may draw on, he needs at least to assume the standpoint of philosophy in performing his work … Unlike the researcher [or the academic] he cannot isolate himself within the protective walls of some scientific specialty; he functions willy-nilly as a philosopher in critical aspects of his role. (Scheffler 1970, p. 389)[21]

These proposals of Scheffler can equally be associated today with requirements to enhance teachers' "pedagogical content knowledge" (PCK: Abell 2007; Van Driel et al. 1998; Shulman 1987), which not only means developing *their epistemology* of science (Matthews 1994a/2014, 1997) but in addition their familiarity with philosophy of education topics (Matthews 2002; Schulz 2009a; Waks 2008). Again, Fig. 39.1 displaying the philosophy of science education (PSE) framework identifies these important aspects and illustrates how they are related to, and embedded within, the three corresponding dimensions of P, PS, and PE.

Philosophy in a nutshell then corresponds to the ancient Socratic dictum to examine oneself, and that "the unexamined life is not worth living." Transposing this motto, "the unexamined pedagogy is not worth doing"; in fact it is unsuccessful (as conceptual change research has uncovered)—if not harmful (i.e., indoctrination into scientism[22]).

Such an examination aligns with Kant's famous definition of Enlightenment as the emergence from one's self-imposed immaturity (due to reliance upon

---

students. Certainly these are less well known to science teachers and not canvassed by science education researchers to the extent of interest shown in the post-structuralist and "science studies" literature. See Allchin (2004), Collins (2007), Hodson (2008), Holton (2003), Kelly et al. (1993), Nola and Irzik (2005), Ogborn (1995), Roth and McGinn (1998), and Slezak (1994a, b).

[21] With such a faculty, teachers could better function in their role as *mediator* between the scientific establishment and their pupils, also between public discourse about science with pupils or adults not conversant either how science evolves or the nature of modern techno-science (see also Hodson 2009).

[22] The term "scientism" can be interpreted in different ways; most construe it negatively (Bauer 1992; Haack 2003; Habermas 1968; Matthews 1994a/2014). Nadeau and Desautels (1984) attribute five components. Irzik and Nola (2009) are careful to distinguish legitimate scientific worldviews from illegitimate *scientistic* ones: "A scientific worldview need not be scientistic. Scientism, as we understand it, is an exclusionary and hegemonic worldview that claims that every worldview question can be best answered exclusively by the methods of science… that claims to be in no need of resources other than science. By contrast, a scientific worldview may appeal to philosophy, art, literature and so on, in addition to science. For example, scientific naturalism can go along with a version of humanism in order to answer worldview questions about the meaning of life."

outside authority), the ability to freely make use of one's own faculty of reason, to "have courage to use your own understanding!"(Kant 1784). This ambition is inherent of course to the *liberal education tradition* (Anderson 1980; Carson 1998; Matthews 1994a; Stinner 1989), the objective sought after when teachers desire students "think for themselves"—easily an identifiable historical goal of science education (DeBoer 1991, 2000; Schwab 1978). This is inclusive of the newer critical thinking movement (Bailin 2002; Siegel 1988, 1989; Smith and Siegel 2004). The primary focus here, however, is upon the further development of teachers' critical thinking and competence and their own capacity to judge not only curricular and policy documents, but above all their pedagogy, epistemological assumptions, and educational beliefs (whether implied by their textbooks, e.g., naïve realism, inductivism, pseudo-history, or proposed by science educational literature, e.g., STEM, STSE, constructivism, postmodernism, science for social action). The topic of *critical thinking* is well-trodden ground in philosophy of education, although researchers seldom avail themselves of this literature (Bailin and Siegel 2003; Siegel 2003).[23]

Finally, as Wittgenstein (1953) stated, philosophy can even be *therapeutic*. Implied for our theme, this means it can alert science teachers to implicit *images* of science and philosophies of education they may hold unaware. Perhaps they have internalized these through practice or originally picked up through teacher training from university professors promoting their own pet educational ideas and theories. Indeed, the teacher may have developed strong opinions about HPSS or "social justice" topics, "but the point of education is to develop students' minds, which means giving students the knowledge and wherewithal to develop informed opinions" (Matthews 1997, p. 171). In any case, translating Pierce's statement above with science educators in mind, one can write: "Find a science educator who proposes to get along without any philosophy-of-education … and you have found one whose goals, perceptions and methods are thoroughly vitiated by a crude and uncriticised one with which they are packed."[24] While the textbook epistemology is often concealed, a teacher's epistemology and educational theory is usually pieced together during their career and rarely made explicit.

In summary, philosophy cannot be gone around, for as a discipline of critical inquiry, it allows analysis into curriculum, textbooks, learning, best practice, and identity. Relooking at our previous PSE triangle (Fig. 39.1), this includes (i) offering conceptual clarity; (ii) unmasking ideologies (social, political, educational); (iii) sorting out foundational aims, values, and teacher identities; (iv) providing perspectives and theoretical frameworks, as well as synoptic and integrative approaches; and (v) possibly even utilizing *creative* theorizing as solutions to pressing problems (discussed below on educational theory).

---

[23] Refer to the chapter contribution in this Handbook.

[24] What is being suggested here can be taken to correspond with a key objective of critical pedagogy, popularized by the Marxist teacher educator Paulo Freire (1970), their advance to "critical consciousness."

39.4 Philosophy of Education and Science Education

Philosophy of education, as mentioned, is a branch of philosophy. It seeks to address questions relating to the aims, nature, and problems of education. As a discipline it is "…Janus-faced, looking both inward to the parent discipline of philosophy and outward to educational practice … This dual focus requires it to work on both sides of the traditional divide between theory and practice, taking as its subject matter both basic philosophical issues (e.g., the nature of knowledge) and more specific issues arising from educational practice (e.g., the desirability of standardized testing)" (Siegel 2007). Thoughtful consideration of educational practice and assessing science curriculum is normally considered part of a teacher's professional competence; hence, some sort of philosophical thinking can be justifiably attributed to educators and researchers. What is of issue is the view that science educators can be encouraged to philosophize on a broader and systematic scale, and they can profit from philosophy of education (PE) studies (using their in-depth deliberations on theory and practice).

39.4.1 The Neglect of Philosophy of Education

If as Aristotle (1998) had intimated (by the opening quote) philosophy begins when one is filled with wonder—a state of being which can arise when confronted with some dilemma (hence one's *lack* of knowledge)—then the neglect to articulate a *systematic philosophy of* (PSE) for one's own science pedagogy (let alone the research field) causes one to ponder why so little effort and time have been invested into the subject. The consequences have not been a minor matter—confusion over educational *aims* including the "science literacy" debate, its meaning and competing "visions"[25]; science education's dependence on socio-utilitarian ideologies and competing group interests; science teachers' confusion about their identity and purpose, including the divide between belief and practice; etc.[26]

Jenkins (2001) has rightfully complained the research field is too narrowly construed and suffers from "an over-technical and over-instrumental approach" at the expense of other perspectives, such as neglecting historical studies. Although some recent research work can be taken as mitigating this charge (Gilead 2011; Jenkins 2007; Olesko 2006), even his perceptive critique had failed to mention the worth of

---

[25] Science education to this day has been unable to resolve the principal dilemma concerning the conflict of the two competing "visions" of its purpose (hence competing conceptions of "scientific literacy"). Roberts (2007, p. 741) admits the community must "somehow resolve the problems associated with educating two very different student groups (at least two)."

[26] Refer to Aikenhead (1997, 2007), Bybee and DeBoer (1994), Donnelly (2004), Donnelly and Jenkins (2001), Pedretti et al. (2008), Schulz (2009a), Shamos (1995), Witz and Lee (2009), and Yager (1996).

philosophical studies. The inertia of traditionalism[27] at the upper levels had prompted Jenkins surprising call for a "paradigm shift," as mentioned—but this is serious talk, nothing less than a plea for somber philosophical contemplation and reorientation. Even at the postsecondary level, the need to reform introductory science classes has received increased attention especially with some new findings in Physics Education Research (PER) indicating that the dominant textbook- and lecture-based instruction in large classrooms is unwittingly producing an antiscientific mind.[28] The appearance in time of three identified public "crises" regarding school science education (1957, early 1980s, late 1990s; Schulz 2009a) and the apparent inability of different "reform waves" to provide for major, long-lasting changes could in turn suggest that a shift towards a more concentrated educational-philosophical examination of the problems lies at hand. It can be argued that the general lack of consideration of educational philosophy and theory, that is, a *philo-educational failure*, could help account for why curricular reforms are particularly vulnerable to the political whims (or "ideologies") of various stakeholder groups, an enduring situation several researchers have taken notice of.[29] It could, for example, better inform policy deliberations when diverse stakeholders are at odds over what should "count" as science education (Fensham 2002; Roberts 1988).[30]

Fensham (2004) argues in his important book *Defining an Identity* that science education is still searching for ways to characterize its own "identity" as a

---

[27] Grade 11 and 12 specialist science courses continue to serve primarily a gatekeeping function for college and university entrance, and their purpose, structure, and content usually replicate first-year tertiary courses—their chief rationale is exclusively with "science for scientists," and not concerned with the large majority who will not specialize. In other words, as induction into pure academic science but at the neglect (if not deliberate omission) of discussing (never mind integrating), the epistemologies, social practices, and proper history of the sciences—otherwise termed *nature-of-science* perspectives (Hodson 2008; Irzik and Nola 2011; Lederman 2007; Matthews 1998a). Reform movements like *Science-Technology-Society* (STS), *Science-Societal Issues* (SSI), and (lately) scientific argumentation studies have been attempting to counter this dominant school paradigm for some time but continue to make only small inroads.

[28] Yet despite these disturbing findings, researchers in these newer fields of study (also Chemical Education Research) still struggle uphill for respect and acceptance in their academic departments, where educational studies and research continue to be afforded a low priority (Gilbert et al. 2004; Hestenes 1998).

[29] See Aikenhead (2006), Bencze (2001), Donnelly and Jenkins (2001), Fensham (2002, 2004), Roberts (1988), and Roberts and Oestman (1998). Laugksch (2000) draws attention to different social group interests in defining "science literacy." Ernest (1991) also identifies several interest groups as determinants of mathematics education.

[30] Fensham's (2002) paper "Time to changing drivers for scientific literacy" (movement away from the academic driver to "social" and industry-based drivers) provoked a lively response from researchers about the "educo-politics" of curriculum development, especially about what role academic scientists should play, if any (Aikenhead 2002; Gaskell 2002); such a suggestion though would reorientate science education back towards the recurrent (and contentious) "social relevancy" goal and the progressivism of Deweyan-type philosophy (Darling and Nordenbo 2003; DeBoer 1991)—whose educational theory is often concealed. It may even involve a Faustian bargain with industrial- and vocational-driven interests. Gaskell believes the risk is worth it. But given the complexity of techno-science and the great diversity of vocations and business interests today leaves one wondering if any sort of meaningful consensus on curriculum is achievable, even locally.

discipline. (His comprehensive survey canvasses the views and backgrounds of 76 prominent researchers in 16 countries, active from the 1960s to the present.) One would like to suppose that helping to define such an identity would include philosophy, especially a *philosophy of science education* (PSE). And it is not only the identity of the *discipline* that is of issue here, but as referred to in the previous section, that of the classroom professional as well. Hence, it might appear the time has come for science education to return to some philosophical ground work, to come to value philosophy of education (PE), and, in turn, for the research field to inaugurate and develop a new *fourth area* of inquiry—philosophic-historical. This one added next to the common three of quantitative, qualitative, and emancipatory, in support of arguments made previously by others for its development as a "mature discipline" (Good et al. 1985; Kyle et al. 1992).

But Fensham's book, with the sole entry of PE on one page alone (where the significance of Dewey is also cited), bears ample evidence of the disregard of this subject topic for researchers and science teachers alike.[31] One can infer from the evidence to date that the worth of any sort of meta-analysis of their discipline and pedagogy seems to hold little value for the majority, thereto the need to bring systematic educational-philosophical reflection to bear on research, curriculum, and teaching.

This claim is further evidenced by a simple perusal of research *Handbooks* published thus far, where the subject of philosophy of education (including topics "philosophy," "educational theory," "curriculum theory") is missing entirely (Fraser et al. 2012; Abell and Lederman 2007; Fraser and Tobin 1998; Gabel 1994). This absence is likewise attested by recent publications of European Handbooks of research in the field (Boersma et al. 2005; Psillos et al. 2003). Crossing over the other way, most handbooks or "guides" of philosophy of education (PE) exhibit the same paucity by avoiding science education, though art education, moral education, knowledge, feminism, postmodernism, critical thinking, and critical pedagogy as subjects remain prevalent.[32] Two exceptions exist: Curren (2003) and Siegel (2009). Comparing both fields, the claim is reinforced by an inspection of the respective leading research journals in both philosophy of education and science education for the past 30 years, which exhibit an almost complete disregard of the opposing field (barring exceptions). What one finds is that only a handful of philosophers write for the science education journals, and even fewer science educators publish in philosophy of education.[33]

---

[31] Fensham in fact suggests that it is the "dominance of psychological thinking in the area" which attests to why Dewey is *not* cited more frequently among respondents in the USA (still the most prominent philosopher of education linked with science education in North America).

[32] Important works are Bailey et al. (2010), Blake et al. (2003), Chambliss (1996a), and Winch and Gingell (1999).

[33] Authors in alphabetical order include Bailin, Burbules, Davson-Galle, Garrison, Grandy, Hodson, Matthews, McCarthy, Norris, Phillips, Scheffler, Schulz, Siegel, and Zembylas (see respective references).

If an examination of the preparation of science education researchers is any indication of the kind of academic preparation science teachers themselves receive (before they become researchers), then another look at Fensham's *Identity* book as commented on by Matthews (2009b, p. 23) is revealing. He notes that "the interviews reveal that the overwhelming educational pattern for current researchers is: first an undergraduate science degree, followed by school teaching, then a doctoral degree in science education" (citing Fensham 2004, p. 164). As Matthews observes, unfortunately "most have no rigorous undergraduate training in psychology, sociology, history or philosophy." Fensham himself comments that at best, "as part of their preparation for the development tasks, these teachers had opportunities to read and reflect on materials for science teaching in schools and education systems that were different from their own limited experience of science teaching."[34] Matthews concludes that Fensham's survey reveals an overall "uncritical adoption of idealist and relativist positions" among researchers and that poor academic preparation is a reason why "shallow philosophy is so evident in the field."[35] It certainly appears as if the inadequate science teacher preparation in philosophy of education is mirrored by the widely recognized fact of the inadequate preparation with respect to philosophy, history, and sociology of science.

39.4.2 Historical Background of Philosophy of Education and Science Education

With an eye fixed solely on the mutual historical developments of both fields, this neglect is rather difficult to explain especially because science education is after all about *education*, with natural focus on the science specialty. But philosophy and education have roots that are intertwined in history long past, convincingly traceable back to Plato (*Meno*; *Republic*). Every major philosopher in the Western tradition from Plato (in Ancient Greece) to Kant (European Enlightenment) to Dewey (modern industrial America) has proposed educational projects of some kind (Rorty 1998; Frankena 1965; Whitehead 1929). As Amelie Rorty correctly points out (1998, p. 1): "Philosophers have always intended to transform the way we think and see, act and interact; they have always taken themselves to be the ultimate educators of mankind." Understood in this way, Dewey was on the mark when he famously phrased the view that the *definition* of philosophy is "the theory of

---

[34] Matthews comments this may be the significant reason why the science education research literature "is dominated by psychological, largely learning theory, concerns" (ibid). Others have also cited the domination of psychology and conceptual change research (Gunstone and White 2000; Lee et al. 2009).

[35] The typical tendency is to adopt philosophical or ideological views from well-known authors outside the field but often not accompanied by critical appraisal of such authors: "… the work of Kuhn, von Glasersfeld, Latour, Bruner, Lave, Harding, Giroux and others is appropriated but the critiques of their work go unread: it is rare that science education researchers keep up with psychological and philosophical literature" (ibid, p. 35).

education in its most general phases" (1916, p. 331)—although most professional philosophers today would probably not construe it as such.

It was the Enlightenment's "project of modernity" (Habermas 1987)—first begun in the seventeenth century—that was expressly formulated as an *educational project* and which saw in the new science of the day an instrument for personal and sociopolitical liberation (Gay 1969; Matthews 1989). It is of course in full awareness of this intellectual and cultural heritage that postmodernists like Lyotard (1984) would outright dismiss the "grand narrative" of this project with its associated role and *image* of science as an emancipatory and positive force, including those science educators convinced by his critique (Loving 1997; Nola and Irzik 2005; Rorty 1984; Schulz 2007).[36] In fact the popularity of strands of post-structuralist Foucault, 1972/1989, 1980; Nola, and postmodernist thinking among some researchers bears witness to the recent discovery of the value of philosophy for the field (Zembylas 2000, 2006).

Looking much further back in time (again at the *Metaphysics)*, Aristotle identifies the man of knowledge—one who has attained expertise either via *techné* or *theoria* (instrumental or theoretical reason)—as the one who is plainly able to teach what he has learned and as such draws one distinguishing feature of the philosopher. To be a philosopher was to be a teacher. Conversely, to be a teacher implies one must do philosophy (of one form or other). Science educators seen in this light are inescapably located within a venerable philosophical tradition *along with* the newer scientific one which they usually and exclusively tend to associate themselves with—though, here too, not fully aware of the latter's cultural roots and significance.

The first mention of philosophy of education as a distinct field of study was in Paul Monroe's *Cyclopedia of Education*, published 1911–1913 (Chambliss 1996b). Philosophy of education, depending upon the given nation and its educational traditions, can be viewed as a relatively new discipline or not. As Hirst (2003, p. xv) points out, "philosophical inquiry into educational questions" was more established in the USA, Germany, and Scandinavia, whereas in the UK philosophy of education as a discipline first came into its own in the 1960s. It was dominated by analytic philosophy and accounts of schooling, although in ethics Kantianism was the major influence. In the USA, the *American Philosophy of Education Society* had already been founded earlier in 1941, along with the Deweyan journal *Educational Theory* in 1951. It was the pragmatist philosopher and educationalist John Dewey in his influential work *Democracy and Education* (1916/44) who had conceived of PE to be a study worked out on an experiential basis—in other words, that educational ideas were to be applied and tested in practice. He also considered that theory and

---

[36] Related to this topic is the question of what worldview(s) science assumes or requires in order to be sustained, hence which one(s) educators need to be supportive or cognizant of (Matthews 2009a). This further raises the question of the *universalism* of "Western science," whether or not its knowledge and truth claims are necessarily culturally confined, or merely *evolved*. Disputes over the interpretations of "multicultural science" will not be addressed here, but again science educators require philosophical training in order to adequately tackle these controversial topics. Philosophical treatment of this subject can be found in Hodson (2009), Matthews (1994a), Nola and Irzik (2005), and chapters in this Handbook.

practice were interdependent in a kind of feedback loop mutually learning from and reinforcing each other. This stood in contrast to the earlier views of the Englishman Herbert Spencer who instead conceived of education as an inductive science and where PE would serve as a kind of scientific method.

Alternatively, on the continent in Northern Europe, very different views about education had been developing. The ideas of Kant, Schiller, Herder, Herbart, and others had contributed to create the influential *Bildung* paradigm in the nineteenth century.[37] It has become established as the *Bildung/Didaktik* tradition whose conception of education dominates the German-speaking world and the Nordic countries.[38] Today this paradigm is not without its detractors, for by the 1960s this tradition had itself begun to clash with the "critical theory" of the Frankfurt school (Blake et al. 2003; Blake and Maschelein 2003; Smeyers 1994). It continues to engender much debate among educational thinkers and philosophers alike, both in Europe and English-speaking countries. Thereto, advocates of both traditions—Anglo-American "curriculum" and *Bildung/Didaktik*—came together in the 1990s to open dialogue comparing the relative benefits of each (Gundem and Hopmann 1998; Jung 2012; Vásquez-Levy 2002).

The *Bildung* paradigm itself actually represents an *educational metatheory* (Aldridge et al. 1992), a type of "grand theory" in education of which very few have been constructed in modern times (inclusive of Dewey and Egan; Polito 2005). It immediately raises the question of the worth and relation of educational theory to practice, whose merits are currently being contested in philosophy of education (Carr 2010).

The direct link between *Bildung* and science education[39] has been drawn only recently, notably in Fensham's *Identity* Book (2004) and by Witz (2000).[40] Fensham provides a highly informative discussion, explaining the concept and significance of *Bildung* when contrasting the Norse/German tradition with the content knowledge-driven Anglo-American tradition. He contends that a serious shortcoming of the so-called "curriculum tradition" of the English-speaking world is its consistent disregard of metatheory (discussed further below).[41] *He advises science education*

---

[37] The literature on *Bildung* and *Didaktik* is extensive. Some references to its historical development are Barnard (2003), Beiser (1998), Gadamer (1960/1975), and Schiller (1795/1993).

[38] "On the one hand, the concept *Bildung* describes how the strengths and talents of the person emerge, a development of the individual; on the other, *Bildung* also characterizes how the individual's society uses his or her manifest strengths and talents, a "social" enveloping of the "individual" (Vásquez-Levy 2002, p. 118). Given this interpretation, one could in fairness associate the values and aims of the *Bildung* tradition with two prevalent "curriculum ideologies" identified by Eisner (1992) as "rational humanism" and the "personal" stream within progressivism.

[39] Science education and *Bildung* in Germany have been examined by Benner (1990) and Litt (1963).

[40] One Canadian study involving science teachers had sought to fuse the *Bildung* ideal with the STS paradigm and cross-curricular thinking (Hansen and Olson 1996).

[41] "In the one, the maturing young person is the purpose of the curriculum. In the other, the teaching of subjects is the purpose. In the one case, disciplines of knowledge are to be mined to achieve its purpose; in the other, disciplines of knowledge are the purposes" (2004, p. 150).

should acquire one. The same arguments have long been raised in Germany by Walter Jung (2012).

Another interesting aspect about the *Bildung* paradigm can be noted: it exercised an indirect influence via Herbart's ideas on the philosopher-scientist Ernst Mach. While Mach's impact on Einstein's thinking is generally recognized, his educational ideas are hardly known in the English-speaking world. Already back in the late nineteenth century, he had been politically active for educational reforms, including improving teacher education, and is credited with founding and coediting the very first science education journal in 1887 *Journal of Instruction in Physics and Chemistry* (Matthews 1990b, 1994a). Siemsen and Siemsen (2009) argue his rediscovery at present could provide significant contributions to current European reform efforts.

On a final note, for the English-speaking nations, the USA was in the forefront of the establishment of both disciplines (science education and philosophy of education) that have developed in tandem—simultaneously but separately in the early twentieth century. One would think that because of this pedigree, and in some cases of clearly overlapping interests (as exhibited in the important case of Dewey), science education would be more cognizant, and science teacher training more reflective, of their common roots. Unfortunately, on this matter science education seems to suffer amnesia on both counts, for if it can be admitted that "philosophy of education is sometimes, and justly, accused of proceeding as if it had little or no past" (Blake et al. 2003, p. 1), then this certainly rings true of science education.[42]

The call for a philosophy *of* science education (PSE) is not only to raise awareness of this forgotten earlier period, but *to identify the need to create a subdiscipline within educational studies* that, although new, nonetheless has substantial historical roots going back into the science-educational but especially the philosophical-educational past.

Why science educators do not associate themselves just as intimately with philosophy of education is a fascinating question, one that cannot be pursued here. It almost certainly has a lot to do with several factors (such as the prestige of science in society, how disciplinary knowledge is structured, how their own university science education proceeded, and, not least, how they were trained as educational professionals).[43] What is called "foundations in education" courses, which usually include studies in the history and philosophy of education, are often optional for preservice science teachers, depending upon the prerequisites of their attending institutions.[44]

---

[42] Jenkins (2009) notes the same problem with reform movements and policy documents. This complaint (although dated but still relevant) was earlier attested by DeBoer in his Preface to his insightful *History of Ideas in Science Education* (1991).

[43] Roberts (1988, p. 48) draws attention to where teacher *loyalties* commonly lie: "The influence of the subject community is an especially potent force in science education. In general, the 'hero image' … of the science teacher tends to be the scientist rather than the educator [or philosopher]."

[44] Hirst (2008b) has recently complained that in some countries such as England, there are now moves afoot to delist such courses for teacher training altogether. It would not be a stretch to conclude that

39.4.3 Philosophy of Education Today

Coming at last to the present historical culmination, philosophy of education has today progressed to become a respectable, established subdiscipline in philosophy. It comprises evolving research fields, a sizeable literature, professorial chairs, professional associations (e.g. PES), and several leading journals.[45]

There now exists two *Handbooks* (Bailey et al. 2010; Siegel 2009) but also a *Guide* (Blake et al. 2003), *Companion* (Curren 2003), and *Dictionary* of key concepts (Winch and Gingell 1999). An *Encyclopedia* of PE is also on hand (Chambliss 1996a). These can be sought out by science educators to familiarize themselves with the current discussion, inclusive of disputes regarding different topics of individual interest to them. Several newer and older *Introduction* texts are also available (e.g., Barrow and Woods 2006/1975; Tibble 1966), including Carr (2003) and Noddings (2011). For educators seeking immediate information, several encyclopedia articles exist providing succinct, comprehensive overviews of PE (accessible online: Phillips 2008; Siegel 2007).

39.4.4 The Value of Philosophy of Education

Philosophical questions bearing on the different facets of science curriculum, teaching, and learning must be addressed and inspected by the thoughtful educator:[46] questions pertaining to (i) chief educational goals, content selection, and course objectives, or (ii) assessing learning theories, or (iii) bearing on nature-of-science- and techno-science-related issues—thereto, the character of scientific research, knowledge, and societal applications as related to curriculum or policy reforms. Hence, questions also pertaining to who enacts and benefits from such reforms with respect to interests and ideologies. And all this often in spite of, not because of, state-mandated and prepackaged "content knowledge" curricula:

> What are the aims and purposes of science education? What should be the content and focus of science curricula? How do we balance the competing demands of professional training versus everyday scientific and technological competences versus the past and present interactions of science with society, culture, religion and worldviews? What is the structure of science as a discipline and what is the status of its knowledge claims? What are the ethical constraints on scientific research and what are the cognitive virtues or intellectual dispositions

---

such a downgrade in the general value of philosophy-of-education cannot fail to negatively impact science teacher professional development.

[45] The leading journals of the English-speaking world are *Studies in Philosophy and Education, Educational Theory, Educational Philosophy and Theory,* and *Journal of the Philosophy of Education.*

[46] Some classroom case examples are Hadzigeorgiou et al. (2011), Kalman (2010), and Ruse (1990). Bailin and Battersby (2010), Giere (1991), and Kalman (2002) offer science teacher educators rich material for enhancing science subject-related critical thinking:

> required for the conduct of science? What is the meaning of key scientific concepts such a theory, law, explanation, and cause? (Matthews 2002, p. 342)

If it is indeed true, for example, that precollege and first-year college level science courses are primarily about "technical preprofessional training," then vital questions need to be asked about what differences should exist between training and education in science. It raises cultural, epistemological, and political questions about the nature of school science: whether, for instance, it is truly reflective of the nature of science (in some form) or more reflective instead about courses performing a "gatekeeping" function by limiting access to higher education (a sociopolitical role)—this in turn reflecting norms of school culture and assimilation (as critical pedagogy perspectives contend).[47] Does a hidden cultural bias exist (as "cultural studies" perspectives contend)? Should the worth of school physics and chemistry education, say, be mainly determined by "political/instrumental value" (prerequisites to college entrance courses; Aikenhead 2006)? If so, this would raise more disturbing questions about the nature of, or links between, socialization, training, and perhaps indoctrination (into scientism). There can be little doubt that in such cases a given "vision" of what constitutes "science education" is in place (with hidden "companion meanings"; Roberts and Oestman 1998).

At minimum it should raise questions about subject epistemology or the preeminent *value* placed upon a certain kind (Gaskell 2002). Such topics, though, have been a staple of PE disputes for quite some time—inclusive of deliberating the difference between hidden aims and genuine educational aims of curriculum and schooling (Apple 1990; Posner 1998), or the differences between education and indoctrination (Snook 1972). Not to forget, previous science education reforms have too often been associated with several past "crises" (as cited) which were themselves linked with wider socioeconomic problems in society: were these just pseudocrises manipulated by science education stakeholders and their interest groups? What educational values/views inform such groups and their policies?[48] Again, similar questions are addressed in PE.

39.4.4.1 Philosophy of Education and the Nature-of-Science Debate

Just focusing on one fundamental topic, the *nature-of-science* (NoS) debate, and zeroing in only on one aspect of this debate, the key question is: "who defines science for science educators?" The scientific experts within isolated academic disciplines (as is common)? Philosophers of science? Historians? Sociologists? Or those within cultural and women's studies? Postmodernist-type thinkers and critics?

---

[47] "Domination, resistance, oppression, liberation, transformation, voice, and empowerment are the conceptual lenses through which critical theorists view schooling and pedagogy" (Atwater 1996, p. 823).

[48] Different kinds of answers are provided by Aikenhead (2006, 2007), Apple (1992), Bencze (2001), Donnelly and Jenkins (2001), Gaskell (2002), Gibbs and Fox (1999), Klopfer and Champagne (1990), Roberts and Oestman (1998), Schulz (2009a), and Zembylas (2006).

Or possibly students and teachers themselves, according to some versions of social constructivist theory?

The NoS topic alone has been recognized as one chief aim of science education for over 50 years, yet to this day, there exists a poor record of achievement worldwide (Lederman 2007). This fact is due to several interrelated causes, not least of which is the entrenchment of traditionalism (conventional discipline-based paradigm)—but moreso the reality that NoS is itself a contested field in HPSS studies. The "science wars" (initially launched by the Sokal hoax 1996a, b) and their aftermath have made the issue public, and science teachers are inadvertently involved in a contest that is being fought in the academy.[49] Researchers can certainly be found on either side, running the gauntlet from "positivism to postmodernism" (Loving 1997; Turner and Sullenger 1999).[50]

These polarized camps have made the business of science education a messy and complicated affair—it has become increasingly difficult to navigate a pedagogical course between competing views "from diehard realism to radical constructivism" (Rudolph 2000, p. 404). At best consensus can be found that several common classroom *myths* must be exposed, including talk of "scientific method" (Bauer 1992; Feyerabend 1975; Hodson 1998; Jenkins 2007). Teachers clearly require substantial philosophical background to familiarize themselves with the issues, but even *if* consensus could be achieved (which seems unlikely), the question cannot be solely confined and determined on HPSS grounds. This decision would leave entirely untouched the related *pedagogical question* how that (would be) conception of science plays a role in the education of the student, as to what educational *aim(s)* school science is ultimately expected to achieve.[51] In other

---

[49] For examples of teachers caught in the debate, see Sullenger et al. (2000) and Witz and Lee (2009). For different perspectives on the debate in the academy, see Brown (2001), Giere (1999), Gross et al. (1995), Laudan (1990), Nola (1994), C. Norris (1997), Siegel (1987a, b), and Sokal and Bricmont (1998).

[50] Science educators continue to quarrel whether basic NoS statements *can* or *should* be defined, even where a measure of recognized consensus is said to exist—inclusive of those now written into global policy documents. The dispute centers on how to determine "consensus" (among which experts?), or questions regarding disciplinary distinctions, or about NoS cultural dependence on "Western" science and Enlightenment traditions, among others (Hodson 2008; Irzik and Nola 2011; Matthews 1998a; Rudolph 2000, 2002). Good and Shymansky (2001) make the case NoS statements found in "standards" documents like NSES and *Benchmarks* could be read from opposing positivist- or postmodernist-type perspectives.

[51] This viewpoint aligns to an extent with Hodson's view (2009, p. 20) except for the fact he ignores relating his desired outcomes to educational philosophy and theory: "In my view, we should select NOS items for the curriculum in relation to other educational goals … paying close attention to cognitive goals and emotional demands of specific learning contexts, creating opportunities for students to experience *doing* science for themselves, enabling students to address complex socio-scientific issues with critical understanding…." On what philo-educational grounds the selection is to be undertaken, we are not told though he considers students' "needs and interests" (overlap with progressivism?), views of experts ("good" HPSS—the Platonic knowledge aim?), and "wider goals" of "authentic representation" of science and "politicization of students." His lofty ambition for science education (thus his notion of "literacy"), however, includes too many all-encompassing and over-reaching objectives. These must clash and become prioritized (or so it seems) once his

words, for the educational setting, the question "what counts as science?" must be allied with "what counts as science education?"[52] The historian may have something to say (e.g., correcting pseudo-history in textbooks), at other times the philosopher of science (e.g., correcting misleading epistemology inherent to textbooks), other times the sociologist, etc., each depending upon the context of instruction and in coordination with desired educational objectives and policy deliberations of stakeholders.

The issue is precisely that subject content (inclusive of disciplinary structure) must be "problematized" during curriculum decision-making, and for *two* reasons:

(i) It must be broadened to function as a more authentic and appropriate knowledge base.
(ii) It must be transposed into a form that considers the culture and age developmental stage of learners along with desired educational aims (Englund 1998; Schulz 2011).

That the curriculum needs to be made problematic implies that a *philosophical* (and not just instructional) problem initially lies at hand which requires resolution. This problem lands us squarely in philosophy of education (PE) territory. It requires a close linkage of questions found in PS with those found in PE (the base of the triangle in Fig. 39.1). The philo-pedagogical problem concerns the appropriate or *best didactic transposition* of epistemic content knowledge (CK) into an appropriate form accessible to the learner in accordance with educational aims and theory.[53] There are some educational thinkers who argue this cannot be suitably achieved without educational *metatheory* (Carr 2010; Dewey 1916/1944; Egan 1997).

As an example, while a teacher's content knowledge (CK) in chemistry may need to be better informed by research in the philosophy of chemistry (one crucial component of PSE would involve stressing this factor), nonetheless a PSE is more concerned with how such CK can be made to fit with the requirements of an educational metatheory and its concern with the cognitive-emotive *developmental stage* of the learner, with respect to this subject matter. In other words, a teacher's CK and the curriculum are not at the forefront for learning science (although they are invaluable dimensions), as is commonly done. Rather, they are evaluated in light of philosophy of education and the learner's age developmental mind-frame as befits

---

three stated criteria for subordinating goals force them under his socio-techno-activist umbrella of politicizing students—the ghost of Dewey beacons.

[52] The focus here is on the normative nature of the question (i.e., what do policy documents, researchers, or theorists stipulate?), as opposed to the empirical (i.e., what is going on in classrooms now?).

[53] This important topic is too often overlooked in curriculum theory or in the science education literature. See Fensham (2004), Geddis (1993), Klafki (1995), Lijnse (2000), Schulz (2011), Vásquez-Levy (2002), and Witz (2000); Dewey, Mach, and Schwab all in their day also identified the issue that the logic of the discipline does not conform with the psychologic of learning the subject matter of the discipline. Thereto, Aikenhead (1996) has argued that learning science involves a culturally rooted "border-crossing" on the part of the student, to negotiate the transition from the personal "lifeworld" to the "school-science world."

what it means to *educate* a person in the sciences. This emphasis necessarily shifts the focus to the substance of a teacher's pedagogical content knowledge (PCK) and educational philosophy.

If, say, NoS knowledge is taken to be an *end* (an aim in itself), then an implicit "philosophy" would be "academic rationalism" (Eisner 1992)—whose objective could be associated with "knowledge-for-knowledge sake," building "mind" (possibly even critical thinking), and likewise similar-sounding ideals coupled to a typical knowledge-driven educational metatheory (Egan identifies it with Plato's historic project).[54] This *can* equally be squared with science teaching within the conventional academic paradigm, though providing subject content with *context* (Roberts "vision I"); on the other hand, NoS combined with "critical thinking" as *means* to create critical-minded citizenry to strengthen democracy in society would couple NoS teaching with Deweyan-type educational metatheory (Egan identifies this educational tendency with a form of socialization; Roberts "vision II"). There are tensions here which may not be reconcilable[55]—tensions also inherent to liberal education (e.g., aims for the individual and society can clash considerably); they are certainly topics of concerned debate in PE. Not to be forgotten, there are those who wish to teach NoS because it stands alone—the *intrinsic* worth to learn about authentic science (or science as a cultural force); others however see it subservient to other ends—for advancing critical thinking (itself), or chiefly addressing science-societal issues (Zeidler et al. 2005), or yet again, for emancipation (critical pedagogy) and sociopolitical action (Hadzigeorgiou 2008; Hodson 2009; Jenkins 1994).[56]

What is really of issue here, though hardly recognized, is how (and which) *epistemic aims* of science education (e.g., knowledge, truth, justification)[57] can or should be met, either apart from, or linked with, or perhaps subordinated to, other identified *moral* and *political* aims of education (e.g., autonomy, human flourishing, citizenship, social justice).[58] A common and depressing feature of several reform programs (e.g., STS, SSI, sociopolitical activism) is the notable confused state of their several suggested educational aims. Moreover, it can be asserted that such avowed and increasingly popular projects for science education as identified presuppose educational metatheory of some kind, whose existence is either assumed or overlooked.[59] Engagement with philosophy of education debates about,

---

[54] See discussion on the topic of epistemic aims by Adler (2002), Hirst (1974), and Robertson (2009).

[55] See discussion in Egan (1997) and Pring (2010). Smeyers (1994) discusses the European account.

[56] Driver et al. (1996, pp. 16–23) offer five rationales for teaching NoS in classrooms, yet they either assume or overlook their dependence upon different, prior educational theories.

[57] See Nola and Irzik (2005), Robertson (2009), and Siegel (2010) for discussion of these subjects.

[58] See Brighouse (2009) and Pring (2010) for discussion of these subjects. Donnelly (2006) only scratches the surface of the problem with his defined dual clash between "liberal" and "instrumental" educational aims behind community reforms.

[59] This remark also targets research concerning situated cognition models, where it has often been asserted; practice was either *prior* to theorizing or *without* theory. See critiques of Roth by Sherman (2004, 2005).

and analyses of, *indoctrination* can be an antidote to such political-activism programs simply replacing unthinking science lessons with uncritical acceptance of whatever causes teachers or researchers might be energized about. As Erickson has stated (2007, p. 33), the science education community "needs to develop pedagogical models that make explicit the normative premises about aims" in its discourse on scientific literacy.[60] Whenever the topic of educational aims arises, the neglect and need of philosophy of education become only too evident.[61] The time has come for the community to strive for clarity and prioritization concerning which fundamental aims the field can and should achieve (Bybee and DeBoer 1994).

In any event, NoS raises foundational *philo-educational* questions: "What is the ultimate aim of science education?" (or, e.g., of physics education?). "What does it *mean* to be educated in science?" "How is such an education related to human flourishing?" These should ideally be addressed before the subsidiary question "what do we educate people in science *for*?"—often the common starting point of curriculum thinking and policy decision-making, which begins first with the prior value, with its linked presumption of the overall importance, of *social utility*. (The difference so stated is one of choosing between deontologic or teleologic rationales.) The former should not be approached as "mere academic questions" during teacher preparation, for they aim at the heart of what the profession and teacher identity is all about. Yet it should be clear that they cannot be answered without reference to educational philosophy and theory—while the utility rationale, alternatively, presupposes a particular one. In other words, it requires of the science educator a *philosophical valuation* of subject content and aims and an awareness of the broader educational purpose of the science educational field, including some personal positioning among available educational/curriculum theories (Scott 2008).

39.4.5 Overview of Philosophy of Education Subjects and Questions

It is the view of the present author that teachers as well as researchers when becoming more conversant with the ideas and disputes as argued by philosophers of education will help them (at minimum) gain insight and perhaps (at maximum) resolve

---

[60] He continues: "Too often we try to simply derive pedagogical practices from theoretical positions on learning, or diversity, or language, or the latest research on the functioning of the brain, etc." (ibid).

[61] An example of the confusion which results in science education research when PE is ignored is the paper by Duschl (2008). Here empirical research from the learning sciences and science studies is confused with educational goals, which must be chosen on a normative basis. Such research may very tell us *how* students (and scientists) learn but expressly not *why and what* goals they *should* learn. And to argue for a "cultural imperative" is to *make* a normative claim extrapolated from such research—one is dabbling in PE without its recognition. Moreover, whether the avowed economic, democratic, epistemic, "social-learning" goals, etc. (as they have been historically articulated for the field) can be "balanced" as Duschl simply assumes is by no means obvious—PE debates show quite the opposite (Egan 1997; Levinson 2010; Schulz 2009a).

problems related to issues of *common interest* (the nature and kinds of aims; the nature of language and learning, knowledge and truth, educational theory; feminism, multiculturalism; education for citizenship; critical thinking; ideology, interests, and curriculum; indoctrination, etc.). The field of philosophy of education is a veritable mine of ideas, posed problems, and suggested solutions. This holds true whether the *approach* to PE is simply to:

(i) Study prominent philosophers and their views on education (e.g., Plato, Aquinas, Rousseau, Kant, Whitehead, Scheffler, Foucault)[62]

(ii) Study educational thinkers and their philosophical positions (e.g., Schiller, Herbart, Dewey, Peters, Freire, Hirst, Egan, Noddings)

(iii) Study sub-branches of philosophy and their relevance to education (e.g., philosophy of science, moral and political philosophy, or aesthetics)

(iv) Study "schools of thought" in education (e.g., idealism, realism, Thomism, Marxism, existentialism, critical theory, postmodernism)[63]

(v) Study the philosophical questions of ultimate concern (e.g., the nature of being, of knowledge and cognition, the ideal of an educated person, autonomy)

There is intellectual insight and pedagogical profit to be had in any of these approaches (Barrow 2010). For the more practical-minded science educator though, the approach to PE could imply instead a focus on specific, contemporary educational questions. Here Amélie Rorty's (1998, pp. 1–2) list of essential PE questions serves to illustrate the "down-to-earth" PE approach, when *transposed* onto science education:

> What are the directions and limits of public [science] education in a liberal pluralist society? … Should the quality of [science] education be supervised by national standards and tests? Should public [science education] undertake moral education?[64]… What are the proper aims of [science education]? (Preserving the harmony of civic life? Individual salvation? Artistic creativity? Scientific progress? Empowering individuals to choose wisely? Preparing citizens to enter a productive labor force?) Who should bear the primary responsibility for formulating [science] educational policy? (Philosophers, …, rulers, a scientific elite, psychologists, parents, or local councils?).[65] Who should be educated [in science]?[66] How does the structure of [scientific] knowledge affect the structure and sequence of learning? … What interests should guide the choice of [science] curriculum?

---

[62] To name just some in the Western tradition; Eastern and other traditions have of course their own major philosophers who have concerned themselves with education.

[63] A classic source of material for this orientation are the essays in Henry (1955).

[64] As those in the *SocioScientific Issues (SSI)*, reform movement today insists (Zeidler and Sadler 2008).

[65] See DeBoer (2000), Fensham (2002), Gaskell (2002), Jenkins (1994), and Roberts and Oestman (1998), for responses to such questions.

[66] Recall the ongoing past disputes between "science for scientists" and "science for all" perspectives on curriculum, goals, and policy (ByBee and DeBoer 1994; DeBoer 1991). The most recent STEM reform movement in the USA can be justifiably accused of redefining science education as "science for engineers."

It is quite clear that common questions and concerns exist and one would have expected more cross-disciplinary discourse than has heretofore existed.

On the other hand, it is not here being suggested that a consensus is to be found among philosophers of education on such questions. In fact there are important disagreements and even diversity of interest and approaches to the solutions, as different PE "schools of thought" display (analytic, existential, phenomenological, postmodern, critical theory, etc.). Indeed, philosophy more often "divides" than it unites, and as one contemporary education philosopher admits: "missing in the present world of diversity of interests is the classic sense of a quest for philosophic unity" (Chambliss 1996b). As Scheffler stressed, "philosophies of" are not forged by some harmony of agreed-upon, sealed discourses. Instead they

> do not provide the educator with firmly established views … on the contrary, they present him with an array of controversial positions. But this array, although it does not fix his direction, liberates him from the dogmatisms of ignorance, gives him realistic apprehension of alternatives, and outlines relevant considerations that have been elaborated in the history of the problem. (Scheffler 1970, p. 391)

The point is not that some sort of philosophical unity should be either expected or had among philosophers or science educators, although of course consensus on common fundamental issues is to be desired. Rather, the nature of the discourse and sophistication of the debate can help illuminate those problems and issues which science educators are confronted by and continue to struggle with or have misconstrued, have overlooked, or for too long avoided.

39.5 Some Major Philosophy of Education Perspectives and Science Education

39.5.1 Educational Theory and Science Education

To talk of "educational theory" is first of all to recognize that it has undergone shifts in meaning ever since Western philosophy began contemplating educational matters in Ancient Greece. For the sake of brevity (and hazarding oversimplification), one charts a course from there to the current age by noting how its worth and purpose have undergone several changes, not only when specifying what *aims* to target, but *who* should carry the prime duty, namely, either philosophers, educationalists, or empirical scientists (Carr 2010; Phillips 2009).

The priority in Antiquity (Plato, Aristotle, Cicero) was to establish the grounds for knowledge to improve moral virtue (the "Good") but conceived more along a priori philosophical lines—hence the emphasis on reason and rationality. This tendency took "an empirical turn" with Rousseau, progressivism, and the rise of the scientific Enlightenment. This science-inspired propensity has continued right down to the primacy of developmental psychology in our age, "the view that the study of human cognition, emotional and social growth and learning ought to be scientifically grounded" (Carr 2010, p. 38). Largely lost sight of along the way was the previous prominence of moral virtue required to remodel society—reclaimed later in different guises by Deweyan theory (of social adaptation or reconstruction), critical theory/pedagogy, and *Bildung*. The postwar positivistic, language-based "analytic revolution" in philosophy (or "linguistic turn" as Rorty opined) which arose in the US and England facilitated the "new" philosophy of education in the 1960s (e.g., Scheffler and R.S. Peters, respectively).

The "analytic school" in education had sought to improve teacher professionalism by augmenting the usual study of the "doctrines of the great educators" with added philosophical analytical skills to help sort out educational language and thinking (which they had diagnosed as incredibly confused). They also sought to combine their reform effort with guidance sought from research in the social sciences. It allowed for neat separation between the roles of philosopher and scientist, a dualism between theory and practice, and essentially pictured *educational theory as applied science* (a view Piaget held into the 1970s). Needless to say, the "post-analytic revolt" which came afterwards challenged and rejected many of the previous guiding views and assumptions, including its dualism, its epistemological objectivism and deficient language theory, and its philosophy of science (the so-called received view).

In its wake diverse, contemporary "schools of thought" (Barrow 2010) have championed various anti-theory, anti-foundationalist and assorted postmodernist, constructivist, and sociopolitical views. These in turn certainly suffer problems of their own (not to be appraised here), suffice to note others have recently come to reprieve the status of theory.[67] Its proponents not only take issue with anti-theory and postmodern-type arguments but also equally with previous analytic inspired views and dismiss the secondary reliance of educational theory on the social sciences, or worse, its reduction to a mere branch of the field (Carr 2010; Egan 1983, 2002, 2005).[68] They have reasserted the worth of philosophy to deliberate upon educational theory independent from constraints they see placed upon it, especially from scientific psychology.[69] They advocate in spirit that philosophy of education should once again claim its own unique, rightful place, neither accepting subordi-

---

[67] So that it may "engage in explorations of what [science] education might be or might become: a task which grows more compelling as the 'politics of the obvious' grow more oppressive. This is the kind of thing that Plato, Rousseau and Dewey are engaged in on a grand scale" (Blake et al. 2003, p. 15).

[68] Carr holds that educational theory might be better suited to ethics (moral reasoning) than with any sort of empirical science, which is not to dismiss the worth of some empirical work: "On closer scrutiny, it seems that many modern social scientific theories of some educational influence are often little more than normative or moral accounts in thin empirical disguise" (2010, pp. 51–2). This deduction leaves unanswered the important question as to what the proper role and value of empirical research for educational theorizing is to be. The topic is controversial and engenders debate in PE. See Egan (2002) and Hyslop-Margison and Naseem (2007) for a negative assessment and Phillips (2005, 2007, 2009) for a positive view.

[69] "We have suffered from tenuous inferences drawn from insecure psychological theories for generations now, without obvious benefit" (Egan 2002, pp. 100–101).

nate status nor intending to displace the social sciences, rather seeking complimentary standing.

On a related issue, because "theory" is often ill-defined in education (Thomas 1997) and usually strictly identified with learning theory in science education (e.g., Norris and Kvernbekk 1997), one needs to distinguish this term from "grand theory" or *metatheory*—the sort of thing Plato, Rousseau, and Dewey were concerned with (Schulz 2009a).[70] The original emphasis on the requirement for a metatheory in education had been discussed by Aldridge and associates (1992) following the proposal first put forth by Egan in the early 1980s encompassing his critique of "scientific psychology" and the demand educational studies stake out independent territory (Egan 1983). Such a theory could very well insist on the difference between psychological and educational development. *The essential merit of metatheory lies in creating curricular coherence, properly transposing subject content knowledge for the learner, and steering educational aims.*

Any educational metatheory must need be a normative one, for it seeks to *prescribe* an educational process to ultimately yield a certain outcome or *aim* (Hirst 1966). This is usually a kind of person or the ideal of what an educated individual should aspire to become given the values and dispositions to be cultivated and methods employed in the specified program (Frankena 1965). Further, it is in the worth of that final aim that the pedagogical methods of the educational project are justified, which traditionally have themselves been framed within the values and aspirations a society has deemed of ultimate importance: "The *value* of this end-product *justifies* the stages that lead towards its realization. Becoming a Spartan warrior justifies training in physical hardship. Becoming a Christian gentleman justifies exercise in patience and humility" (Egan 1983, p. 9; original italics).

In Western civilization a succession of diverse aims or ideals have historically followed since the time of Ancient Greece, and some of the greatest Western minds have been preoccupied with formulating various philosophies of education to define their respective ideal and suggest ways to realize it (Lucas 1972): Plato, the (philosopher-king) man of knowledge; Aristotle, the "good" or "happy" active citizen; Augustine and Aquinas, the Christian saint; Locke, the successful Christian mercantile gentleman; Rousseau and romanticism, the natural development of self-actualization; Kant, the autonomous individual, self-ruled by moral "good will"; and Dewey, personal and social "growth" through ever-changing experience, as the basis for democratic living.[71]

---

[70] Phillips (2002, p. 233) terms these "classic theories of teaching and learning."

[71] It should be noted that Dewey's aim is among the least predetermined of the others, although it could reasonably be argued that Kant's ideal is also dynamic insofar as he allows for education's dual aim, the "perfecting" of man *qua* man plus the improvement of society and "the human race." In addition, Frankena (1965, p. 156) also notes that such a dual aim in Dewey could considerably conflict—that the expected growth of the individual and society may clash—in anticipation of Egan's critique, which claims the clash is inevitable insofar as modern schooling is molded according to progressivist precepts. Alternatively, for Dewey, but also for Aristotle and Kant, such a possible conflict was thought to be reconcilable in principle.

Frankena (1965) insists any philosophy of education must ask itself three basic questions: *what* dispositions (or "excellences") to cultivate, *how* to cultivate them, and *why*?[72] When examining the position of the educational theorist Kieran Egan (1983), he seems to have these same in mind but reformulates and generalizes them with a slight shift in accent. Instead of using terms like "dispositions to be cultivated" and "ideal," he talks in terms of "end product" and "aims" while explicitly raising the important fourth component of *development*—it is of the essence of an educational *metatheory*, he writes, that it answers four key questions: what to teach (curriculum), how to teach (instruction), when to teach it (stages of learner development), and most importantly, why to teach it (specification of the end product, aim, or ideal). That said, the similarity in questions and intent is obvious.

Egan (1997) has further argued that *three* long-standing yet venerable and operative *ideas* in education (themselves inexorably embedded within science education) are undermining each other.[73] Schools in the West as educational projects are ineffectual primarily because they are caught between three chief objectives (or rationales) which successfully serve to check or undercut each others' intended aims: whether to teach science for (1) intellectual development (knowledge), or (2) for individual fulfillment (character), or (3) for socioeconomic benefit. (The first can be associated with the original knowledge-based educational project of Plato, the second with Rousseau, and the last is a cross-cultural and timeless expectation of most societies.)[74]

39.5.1.1 Educational Metatheory and Scientific Literacy

When science educational goals are examined historically, these three are ubiquitous; they persistently present themselves albeit in different guises, and they certainly can be identified throughout science educational reform history (Bybee and

---

[72] Such questions are actually the purview of what is demanded of an educational *theory*. Philosophy of education properly understood is a much broader field of inquiry that encompasses an analysis of such theories and questions (Peters 1966), which today usually overlaps with curriculum studies. Frankena seems to have been working with a constricted conception solely at the level of theory.

[73] Smeyers (1994) identifies the same quandary for Western European education.

[74] In brief, socialization conflicts with the "Platonic" (knowledge-focused) project because the former seeks the conformity to values and beliefs of society while the latter encourages the questioning of these; socialization also conflicts with the "Rousseauian project" since the latter argues that personal growth must conflict with social norms and needs. It sees growth and hence education in *intrinsic* terms instead of as utility for other socially defined ends. (Here exists the principal tension between the *Bildung* tradition and the dominating utility view of education and science literacy of the English-speaking world.) The Platonic and Rousseauian projects conflict because the former assumes an epistemological model of learning and development and the latter a psychological one. In the former "mind" is created and the aim is *knowledge*; in the latter it develops naturally, requiring only proper guidance, and the aim is *self-actualization*.

DeBoer 1994).[75] Considering the current controversies about prioritizing goals in science education, one may be surprised to learn that even educational debates have a long history. Once again, PE can offer insight into long-standing science educational dilemmas. Aristotle records:

> But we must not forget the question of what that education is to be, and how one ought to be educated. For in modern times there are opposing views about the task to be set, for there are no generally accepted assumptions about what the young should learn, either for virtue or for the best life; nor yet is it clear whether their education ought to be conducted with more concern for the intellect than for the character of the soul. (Aristotle, *Politics*, VIII ii: 1337a33; 1962/1981, p. 453)

It is remarkable to contemplate how his discussion mirrors the debate of values and aims that has steered science education since its inception in the nineteenth century. Consider if you will the conflicting meanings (post-WW2) of "science literacy,"[76] still identified as the overall objective of science education as discipline and practice: whether it is to be primarily understood as personal self-fulfillment (i.e., "virtue" as its own intrinsic worth) or for "critical citizenship" in a democracy (i.e., as instrumental worth; "the best life": STS), or rather solely for development of "mind" per se, as mastery of subject-based formal knowledge and as a tool for developing inductive (later redefined as "critical") reasoning (i.e., "intellect" development; science "processes": traditionalism; "scientific argumentation"). Lastly, whether it should encompass foremost moral development when arguing "socioscientific issues" (SSI) or "science education as/for sociopolitical activism" (i.e., "character of the soul"—always seen by Aristotle in terms of sociopolitical *activity*).

Note as well that the three fundamental goals underlying education (as elaborated above) can be identified here and mapped onto the corresponding conceptions of literacy and onto existing school science educational paradigms.[77] Some critical

---

[75] No one normally holds exclusively to one or the other, although usually one or the other is emphasized over the other two at a given time (depending upon the defined "crisis" at hand and under influence of respective social group interests), and the modern school and indeed many "standards" documents aim at a sort of *balance* between them. Roberts (1988), too, holds that "balance" is both desirable and achievable during public policy curriculum deliberations. Egan though insists that the attempts to achieve "balance" are illusory and must undermine the strengths of any one at the cost of the others.

[76] The term itself first came into use in the late 1950s. Initially broadly framed in terms of science, culture, and society relationships, it soon came however to mean learning technical, subject-specific knowledge: "This emphasis on disciplinary knowledge, separated from its everyday applications and intended to meet a perceived national need, marked a significant shift in science education in the post-war years. The broad study of science as a cultural force in preparation for informed and intelligent participation in a democratic society lost ground in the 1950s and 1960s to more sharply stated and more immediate practical aims" (DeBoer 2000, p. 588). By the 1980s the phrase had become commonplace: "Yet despite the problems of definition, by the 1980s scientific literacy had become the catchword of the science education community and the centerpiece of virtually all commission reports deploring the supposed sad state of science education" (Shamos 1995, p. 85).

[77] As can the seven "curriculum emphases" behind science curricula, identified by Roberts (1988)

observers had thus come to the conclusion that already by the late 1980s, the usefulness of the literacy concept had exhausted itself.[78] *We have a situation here where a discipline cannot agree on the most fundamental purpose and goal of its educational endeavor.*

One can therefore conclude, given this consistent mode of discourse about "science literacy," that the community is placed before one of *three* choices:

(i) *Exclusivist* option: one chooses either an already given or hoped for curricular paradigm; this could be the knowledge-based, specialist "vision I" literacy conception (the given: traditionalism) or, at the other end of the spectrum, opting for an "extreme" form of "vision II" (as Roberts (2007, p. 769) remarks), by redefining literacy as "collective praxis"—such as the (hoped for) image held by Roth and Barton (2004).

(ii) *Inclusivist* option: one agrees instead to hold fast to as many conflicting meanings as possible (e.g., Hodson 2009). Along with DeBoer (2000), one simply accepts the term stands for "a broad and functional understanding of science for general education purposes" (p. 594), and "because its parameters are so broad, there is no way to say when it has been achieved. There can be no test of scientific literacy because there is no body of knowledge that can legitimately define it. To create one is to create an illusion" (p. 597). Rather, only specific goals can be achieved in a piecemeal fashion, where his historically identified *nine* different conceptions are chosen as in a smorgasbord, attentive to the context of school culture and society wishes, and where "schools and teachers need to set their priorities" (ibid.). With this option, divergence is chosen. It is then assumed that "consensus about one definition throughout the worldwide science education community is a goal not worth chasing" (Roberts 2007, p. 736).[79]

(iii) *Abandonment* option: one chooses to reject the term as both useless and meaningless for educational purposes, along with Shamos (1995) and Solomon (1999).

In any case, if an educational metatheory is to be of service to science education, it must also acknowledge and address these options in the deadlock.[80] It may also

---

[78] Shamos has insightfully argued that its common conception tied to citizenship is fundamentally flawed, that the community is chasing a utopia, that it continues to refuse to accept the grounds why it has failed in achieving it, and finally that many rationales typically put forth to justify it are a *myth.*

[79] Option two although seemingly attractive on the surface does not seem viable, and one can imagine numerous problems associated with it. Just mentioning one, it assumes a degree of autonomy for schools and teachers which they generally lack and which in the climate of "accountability" and standardized testing and under the influence of powerful outside social groups would seem to check their ability to make the kind of choices DeBoer would like. A reversion to option one would in all likelihood result, namely, the default traditionalist position.

[80] A series of papers presented at a recent conference attempting to articulate "a more expansive notion of scientific literacy" illustrate the problems associated with this deadlock once more and why the sought-after solutions remain so elusive; discussions including educational theory and philosophy are conspicuously absent (Linder et al. 2007).

put into question the assumptions and scope of the discussion and even the entire character of the discourse which has heretofore been conducted (Schulz 2009b, 2011; Witz 2000).

39.5.1.2 Educational Metatheory and Advance of Science Education as a Research Field

Fensham's *Identity* book (2004), interestingly enough, also offers an important look at the role of theory (Ch.7) within the science education research community. He admits that the development of theory is a significant indicator of a discipline's advance as a research field:

> If the existence of theory and its development is a hallmark of a mature research field there is some evidence that the research in which the respondents have been engaged in science education has reached this point. On the other hand, the role that theory plays in the respondent's remarks was so variable that it is not possible to attach this hallmark in a simple way to much of their research. (Fensham 2004, p. 101)

With that admission he acknowledges that the usage of theory is restricted and there was little interest on the part of researchers to develop their theory of choice further. What is significant though is the range of *borrowed* theories from outside research fields that the researchers have heavily relied upon.[81] The spectrum stretches from social anthropology, ethnology, and cultural theory to psychology, cognitive science (e.g., information processing; schema restructuring), and philosophy of science (e.g., conceptual change theory).[82] He notes those researchers employing a "political framework" to curriculum, or concepts of power and ideology, shift the common focus of science education onto entirely different factors that influence science teaching and learning. Essential PE-type questions like "what counts as science education?" or "how are ideological meanings reproduced in science education?" are raised, but surprisingly not addressed with that perspective or discipline in mind. One observes rather that in all cases educational theory and philosophy of education nowhere make an appearance.

To the point of the subject at hand, Fensham does mention the topic of "grand theory" (p. 107). He writes that only *one* respondent had admitted to theorizing on this scale, namely, the biologist and educator Joseph Novak, who had earlier published *The Theory of Education* (1977).[83] Novak has today continued to hold, as

---

[81] "This borrowing can have the healthy effect of bringing new insights to bear on the problems of science education, but it can also lead to superficial descriptions that do not seem to be pushing for deeper understanding" (2004, p. 101). He fails to mention a *third* possibility that outside theories can do outright damage to education, as Egan (1983, 2002) argues for the cases of behaviorism, Piaget, and progressivism. The presumed relevance of cognitive science has lately come into question as well (Slezak 2007).

[82] Reliance upon psychology is clearly predominant, primarily Bruner, Gagne, and Piaget in the 1960s and 1970s and the significant role they played marking the revolt against behaviorism.

[83] This book, however, as is familiar today, is based on the psychologist Ausubel's quasi-neural theory of meaningful learning in combination with Toulmin's philosophy of science and principally restricted to learning theory.

Fensham comments, to the value of this theory and the belief that "theories in science education would be developed that have predictive and explanatory power, just as theories in the natural sciences have" (p. 106). This belief closely aligns educational theory with empirical theories in the natural or social sciences,[84] an arrangement both Hirst (1966) and Egan (1983, 2002) explicitly reject.

39.5.1.3 Educational Philosophy and Science Education as "Sociopolitical Activism"

One contemporary reform movement (spearheaded by some international researchers and popular with some policy advocates), namely, "science education as/for sociopolitical action," has been articulated with intentional philosophical perspectives. It could reasonably be interpreted as a rudimentary sort of "*philosophy of*" science education (PSE) as here elucidated (though granted, not formulated in this fashion). The position that science education *should* be oriented (if not exclusively so) to perform sociopolitical action is a normative claim argued on philosophical grounds, justified because of the apparent promise/claim of enhancing critical-minded citizenship and forwarding democracy. It patently stipulates categorical answers to the key questions: "What counts as scientific literacy?" "What counts as science education?" "What is it for?" Whether or not such a muscular and singularly focused PSE can do justice to the other historically identified aims associated as central to science education (including the *aesthetic* component of science; DeBoer 2000; Girod 2007), and therefore the best option for policy deliberations and reform, is a matter for some dispute—although a considered debate especially one involving philosophy of education (PE) is surprisingly lacking to date.[85]

That this sort of politicized PSE represents a "radical program" to challenge common school science education is understood (Jenkins 2009; Levinson 2010). Here our focus is to ask: is such a "program" an adequate PSE?[86] Science education, for example, could plausibly "do" sociopolitical action at times while rejecting "as" and "for." In any event, does politico-social activism as put forth substitute ideology

---

[84] It is admitted that Novak's writings offered an important counter-theory in support of the growing dissatisfaction with the dominance of Piagetian theory arising in the late 1970s (although some science educators continue to hold neo-Piagetian views). With the growth of conceptual change and constructivist research in the 1980s and the influence of Kuhnian philosophy-of-science, this dominance was gradually displaced in the research community. On the other hand, Erickson (2000) cautions there is much common ground between Piaget and the newer constructivist theories. Egan's cultural-linguistic metatheory (1997) is inclusive of learning theory but goes beyond it and outright rejects Piaget (Schulz 2009b).

[85] Leaving aside questions if its individual educational claims are either warranted or empirically validated. Strong advocates for this kind of politico-social activist PSE (just naming some researchers) are Hodson (2009) and Roth and Desautels (2002). Criticisms leveled against it are provided by Hadzigeorgiou (2008) and Levinson (2010).

[86] Does it fully take into consideration the three dimensions of the synoptic framework shown in Fig. 39.1?

for philosophy?[87] Does it presuppose educational metatheory? The present author would argue it must (although this feature is seldom articulated; i.e., social reconstruction). Stepping back, must *any* methodical PSE presuppose metatheory (of some kind)—or can it be gone around for, say, a list of rationales, principles, and exhortations? That debate has not yet begun, but would be welcomed.[88]

One of the responsibilities of a philosophy of science education (PSE) at the research level would be to expose educational theories (especially metatheories), as well as better clarify the relationships between such theories in PE and theories in other (empirical) disciplines (as to their nature, value, and limits), whether one of independence or interdependence.[89] In other words, a philosophical appraisal of several domains, such as conceptual clarification and the validity of borrowed ideas; scrutiny of epistemic and/or moral and political aims—their character and prioritization; analysis of the theory-practice dilemma; also the character, quality, and significance of kinds of assessments or tests employed (range of usefulness), etc.; and hence the question of boundaries, applicability, and relevance.

39.5.2 Epistemology, Knowledge, Understanding, and Hermeneutics

39.5.2.1 Epistemology, Belief, and Epistemic Aims

That science instructors and their technical textbooks are so concerned with accurate and exhaustive transmission of canonical scientific knowledge clearly reveals the central significance of epistemology to science education.[90] One can identify this preoccupation of academic sciences courses (a chief aim of school and college science) with the constricted and popular rendition of the customary *knowledge aim*.

---

[87] Roberts (1988, p. 50) had earlier cautioned the research community about the "*individual ideological preference* of professors of science education" which can "indoctrinate science teachers into believing that what counts as science education is the ideology of a single curriculum emphasis (or perhaps a few emphases)" (original italics).

[88] It seeks as well to address the common blurring of lines between "descriptive" and "normative" research work, the expectation *that* classroom research *should* change classroom teaching and learning, as Sherman (2005) points out, but strictly in accordance with a specified (ideological) program. This academic conflation may indeed be due to our culturally inherited situation, i.e., "if we can't be objective, we'll be openly ideological" (p. 205), but regrettably real "openness" is rare. The argument here in a nutshell is that science education avoids (c)overt ideology for candid philosophy.

[89] Such a conversation can be considered an extension of one already discussing the difference between epistemology and psychology (Duschl et al. 1990; Matthews 2000; Southerland et al. 2001) or critiquing the assumed validity of cognitive science theories for science education (Slezak 2007).

[90] For some time a major portion of science education research has in fact been focused on analyzing and critiquing the strengths and weaknesses of school science epistemology, whether of subject content, or of the student, or of the teacher.

Here is another area where PE discourse can provide relevance, for the knowledge aim or truth aim has been fundamental in the traditional view of education, including its *liberal* construal—notwithstanding significant attacks on that objective from different educational perspectives (e.g., progressivism, post-analytic, postmodernist).

> Although transmitting knowledge is not the only aim of education, it is surprisingly substantial in its ramifications. Because we can compare various educational practices to determine which ones better advance students' knowledge, the knowledge-aim offers educational guidance, justifies central educational practices, and exposes complexities in the educational policies it supports. (Adler 2002, p. 285)

Science teachers plainly assume their courses or textbooks provide (technical) knowledge, indeed substantially *true* knowledge—and for the most part, they would be correct (e.g., propositional knowledge of final form science; Duschl 1990).[91] Yet being philosophically inclined means giving pause to reflect on what *basis* this can be claimed (expertise of the authors? Authority of the scientific community?). HPSS-based reforms do insist, of course, that *content knowledge* (CK, of teacher or curriculum) requires expansion and corrections (e.g., historical and epistemological *context* to be properly understood and learned).[92] But stepping back and asking about justifying CK, or "what is knowledge?"[93], is to venture into both philosophy (P) and PE territory (the right segment of the triangle in Fig. 39.1). The kinds of answers to these questions have vital educational ramifications. How, for example, can one justify teaching evolutionary theory if its stake in knowledge and truth cannot be established against intelligent design claims? Or taking the "culture wars" into view, is cultural indigenous knowledge of nature *true* scientific knowledge? Are there other kinds? If so, how are they legitimated? How to best distinguish them from science?[94]

---

[91] This has also been referred to in the research literature as the "disciplinary view of knowledge" in contrast to "personal learner epistemology" and "social practice views of epistemology" (Kelly et al. 2012). The latter defers to science studies research and how knowledge is attained and justified through discourse practices within epistemic cultures (Knorr Cetina 1999). What is significant is that "within this perspective, knowledge is seen as competent action in a situation rather than as a correct, static representation of the world" (p. 286). What is not being acknowledged is that the two stated perspectives are themselves beholden to two different epistemological philosophies, namely, pragmatism and objectivism. While science education has traditionally been in the thrall of the second and is now expected to shift to the first, it could better take advantage of the respective benefits of each.

[92] Even when basic science "subject matter" is taught, it is always accompanied by some context that may operate covertly (e.g., preparatory, socio-utility, etc.). Such contexts have been called "meta-lessons" (Schwab), "curriculum emphases" (Roberts 1988), and "companion meanings" (Roberts and Oestman 1998).

[93] Also, what kind of science knowledge is of *most* worth (a key question of prioritizing subject content)?

[94] A very informative discussion on such questions, including examining beliefs, learning, knowledge, and critical inquiry pertaining to the aims of science education, can be found in Nola and Irzik (2005). The comments which follow can be considered supplemental to their work.

Students, when not just assuming the authority of the textbook or teacher, occasionally wish to have explained to them the grounds for knowing, grounds that can only partially be established when "doing science" (i.e., scientific inquiry). Four possible harmful *dispositions* to knowledge students can develop from science classrooms are cynicism, dogmatism, skepticism, and relativism, and Norris (1984) rightfully asks "can all these be avoided?" Teachers require philosophical intelligence not just for telling these apart, but awareness when they crop up during instruction and for strategies to overcome them.[95] Thankfully there already exists a tradition in PE that can assist them, which has sought to demonstrate the relevance of epistemology for education (Adler 2002; Carr 1998, 2009; Siegel 1988).

The standard account of knowledge is "justified true belief" (JTB), which stipulates three conditions in order for someone to say they "know X." For instance, science educators would not be satisfied if a student stated they "know" the Earth orbits the Sun but could not provide any evidence for this proposition. In this case the student has a *true belief* (two conditions met), but without justification could not be said to have attained knowledge. Even if philosophers have brought forth serious challenges to JTB[96], this doctrine of traditional epistemology still retains its value in assisting science teachers' thinking about the differences between knowledge, belief, and justifying conditions in the classroom as they arise (Southerland et al. 2001). It highlights the drawbacks of traditional instruction which can overstress the value of rote learning, algorithmic problem solving, and decontextualized subject content, especially if tied to a policy of exaggerated standardized testing (Hofer and Pintrich 1997; Mercan 2012).

JTB can equally shed light on other cases which can occur where knowledge and belief appear conflated, such as when a student has learned content but refuses to believe it (e.g., "I understand evolution, but I don't believe it"; "I can explain the Bohr model but don't believe atoms exist"). Southerland and associates (2001) have provided an overview of the differing conceptions and occasional clashing views concerning how "knowledge" and "belief" are employed as terms in the separate research fields of philosophy, educational psychology, and science education. They also raise the important pedagogical question whether science education should limit its aim to providing knowledge (or understanding) and not demand changing student beliefs (as required by conceptual change research). An interesting exchange of views between Smith and Siegel (2004) and Cobern (2000, 2004) on this topic illuminates that science teachers need to sort out not just their own presuppositions about knowledge and beliefs but require sensitivity to historical and cultural dimensions of these concepts while attending to philosophical arguments.

Within the field of science education research, Norris (1995, 1997) has analyzed how the JTB view of knowledge finds expression in the aim of *intellectual independence*, one key content-transcendent goal articulated since Dewey and progressivism.

---

[95] Certainly the relatively recent research studies to enhance *scientific argumentation* in the classroom also aim towards resolution of the issues and questions raised here, but are not of present concern.

[96] These will not be discussed here; instead see Siegel (2010) and Norris (1997).

He identifies several serious shortcomings of past and recent formulations of this goal (e.g., as found in constructivism and notions of scientific literacy). Norris notes especially the philosophical controversy surrounding the question to what extent, if any, non-experts can reason independently of experts' knowledge and community—hence, to what extent they can be justified to trust in authority and yield to scientists' judgments (and by association, their textbooks). The outcome of the dispute remains contested, but it appears some reliance is indeed unavoidable.

The degree to which intellectual independence is attainable (or not) has major ramifications for the character and educational aims of science education reform movements (like STS, SSI, HPS, social action). It could impose severe limitations, depending upon the stipulated objectives and overall ambition they desire to advance for the discipline, notably which independence-based goals they mistakenly assume school students can rightfully achieve.[97]

Returning to a previous point, Smith and Siegel (2004) in their paper had also named *understanding*—along with knowledge, and *not* (changing) belief—as primary goals for science instruction. The focus here though is not to address their position nor the dispute with Cobern (but noting its significance) rather to point out that "understanding" as both concept and goal has been largely overlooked in the research literature. Its merit with respect to epistemology and the traditional preoccupation with "knowledge" yields a checkered history, too (Toulmin 1972).[98] Yet its prominence does come to the fore in *philosophical hermeneutics* (Gadamer 1976, 1960) as well as Egan's educational metatheory. A systematic investigation of "understanding," its contrast to knowledge, and its merit for science education has yet to be presented.[99]

One fertile perspective on "understanding" has been provided by the late physicist and philosopher Martin Eger (1992, 1993a, b). He had insightfully shown the relevance of Gadamer's "philosophy of the humanities" for science education with regard to the *interpretation* of nature but especially of science *texts*. Hermeneutics, an age-old scholarly discipline, ties understanding to the ability to achieve personal meaning when interpreting text (utilizing the "hermeneutical circle" method). The significance of his ideas lies in offering an alternative approach to viewing science learning and knowing, drawing science education away from psychological and cognitive science perspectives and towards philosophy and the humanities (Bontekoe 1996; Donnelly 2001; Gallagher 1992). Today his ideas are finding useful expression in some research work (Borda 2007; Kalman 2011). He explicitly shifts the emphasis away from epistemology towards *ontology*, away from "knowing" in the

---

[97] Kuhn (1970) was skeptical about what science education could achieve in terms of developing independent thought and argued instead the conservative view of reinforcing the conventional paradigm—in part because this furthered "progress" and in part because students had no competence to do otherwise. Schwab held a different view and thought students could be educated to become "fluid inquirers" within and about a discipline. Siegel (1978) has admirably contrasted the two opposing positions.

[98] Mason's (2003) "*Understanding* understanding" is one of the few to explore the contrast.

[99] Some researchers have ventured into this territory; see, for example, Wallace and Louden (2003).

objectivist sense to interpreting, meaning, and being. This shift, or "interpretative turn" (Hiley et al. 1991), has not been entirely endorsed as regards questions surrounding the nature of language, ontology, and the relationship between epistemology and hermeneutics. The next section provides science educators with an unconventional but updated outlook regarding these major topics.

39.5.2.2 Epistemology and/Versus Hermeneutics

Any discussion involving philosophical hermeneutics recognizes two current state of affairs, namely, the ongoing unresolved dispute over the self-conception of philosophy and the so-called interpretative turn from epistemology *to* hermeneutics.

To the first, one identifies that the modern Anglo-analytic philosophical tradition has fractured into two differing schools of thought as to what the nature and role of modern philosophy *is* and can accomplish (represented by the opposing views of Dummett and Rorty; Bernstein 1983). This opposition is reflected as well in contrasting perspectives on language theory—which Charles Taylor has characterized as the *designative* and *expressive* traditions (Medina 2005, p. 39). That said, authors like Bernstein, Rorty, and Taylor nonetheless all comment on the convergence of thinking in both the Anglo-American and Continental traditions which reject *foundationalism* or the former project of grounding philosophy, knowledge, and language ("objectivism"), as Descartes, Kant, Russell, and the early Wittgenstein sought but failed to do.

With the current preoccupation of repudiating this formerly eminent epistemological tradition[100], the task of "overcoming epistemology" has come to mean different things to different thinkers (Baynes et al. 1987). Dewey and Bentley (1949), for instance, sought to overcome subject/object dualism with his pragmatic focus on "transaction," the active/practical behavior taking place between the knower and known. Taylor (1987) correctly views both Quine and Rorty as abandoning foundationalism (with the former attempting to "naturalize" epistemology), while he solely targets overcoming the conception of knowledge as *representation* that lies behind the ambition of the foundationalist project since Descartes:[101] "If I had to sum up this understanding in a single formula, it would be that knowledge is to be seen as correct representation of an independent reality.

---

[100] "Current attitudes toward foundationalism, as they have been since Descartes, are sharply divided. The minoritarian conviction (Chisholm, Apel, Habermas, Haack, Swinburne, and others) that some version of foundationalism is or is at least potentially viable is outweighed by the majoritarian belief that in the debate since Descartes, foundationalism has died a natural death and cannot be revived" (Rockmore 2004, p. 56).

[101] Rorty, of course, also surfaces representation, but he explicitly ties it to philosophy as a profession whose role as a foundational discipline (with its "theory of knowledge" being essentially a "general theory of representation") was to adjudicate all cultural knowledge claims, eventually including scientific ones. His view is comparable to Taylor's "To know is to represent accurately what is outside the mind; so to understand the possibility and the nature of knowledge is to understand the way in which the mind is able to construct such representation" (1979, p. 3).

In its original form it saw knowledge as the inner depiction of an outer reality" (p. 466).[102] One notes representation plays a significant role in science and science education, and Giere (1999) argues, in contrast, for its continued importance in science independent of foundationalism. Indeed, some philosophers and science educators have argued for a "fallibilist epistemology" as a viable alternative to opposing foundationalist and radical constructivist views of knowledge and belief (Siegel 2001, 2010; Southerland et al. 2001). The collection of papers in Carr (1998) intends to help guide curriculum policy beyond "rational foundationalism" and "promiscuous postmodernism." The discussions in these works can contribute to advancing teachers' epistemological conceptions and deliberations, whether concerning science, curriculum, or student learning.

The second aspect, as mentioned, acknowledges an "interpretative turn" to have taken place not only in philosophy (due initially to Heidegger 1977) but in the natural and social sciences as well (inclusive of language theory)—though granted, still subject to much dispute—that also seeks to move "beyond objectivism and relativism" (according to Bernstein 1983).[103] Such a move can be considered a shift in the philosophical emphasis entirely "from epistemology to hermeneutics," as both Rorty and Gadamer have claimed[104]; certainly it can be admitted the relation between the two modes of inquiry is contentious and differing conceptions of language inform both.

Furthermore, although there are many similarities in Rorty's and Gadamer's positions, there exist important differences as well as to the nature and task of epistemology and hermeneutics, which is instructive. For example, while Rorty would agree that Anglo-analytic philosophy of language has slowly come to abandon the notion of language as correct "picture of the world"[105], he would disagree with Gadamer's universalist perspective of philosophical hermeneutics (with its inherent view of language as the *medium* of all understanding). Both agree that hermeneutics is not to be considered a successor to epistemology, rather that it involves an entirely different approach to comprehend the world—indeed Rorty construes it as a kind of "paradigm shift" (one that is holistic, historicist, and pragmatic). While Rorty makes

---

[102] Taylor links the success of "knowledge as correct representation" standpoint with two factors: its link with the rise of mechanistic science in the seventeenth century, whose mechanized worldview overthrew the Aristotelean one with its notion of "knowledge as participation" ("being informed by the same *eidos*, the mind participated in the being of the known object, rather than simply depicting it," p. 467); secondly, the influence of Cartesian philosophy that insisted a new reliable "method" was required that could guarantee certainty of the representation. Yet this method entailed, unlike in philosophical antiquity, the reflective and critical cast of individual *mind* performing a subjectivist inward turn. Rorty's view is similar (1979, p. 248).

[103] He cites such authors as Rorty and Taylor (in philosophy), Gadamer (in language theory), and Kuhn and Hesse (in philosophy of science). Other philosophers of science endorsing hermeneutics are Heelan (1991) and Ihde (1998).

[104] See especially Rorty (1979, Chap. 7) and Gadamer (1989, p. 235).

[105] "Putnam now agrees with Goodman and Wittgenstein: to think of language as a picture of the world—a set of representations which philosophy needs to exhibit as standing in some sort of nonintentional relation to what they represent—is *not* useful in explaining how language is learned or understood" (1979, p. 295; original italics).

a sharp distinction between the two but sees them as complementary and mutually supportive (epistemology for "normal discourse" and hermeneutics for "abnormal"), Gadamer views them rather as antagonists: hermeneutics as the universal condition of understanding (and hence of *being; Dasein*)[106] but epistemology as a failed *epistéme*-based, historico-philosophical venture whose time has come and gone. The project has died and should be buried. Rorty correctly stresses that Gadamer had emphasized *Bildung* as historical enculturation (hence the crucial role of education) as a proper goal of hermeneutics—construed as an open project of how understanding takes place through interpretation and dialogue, a form of *intersubjectivity.* This is seen in contrast to "knowledge" possession and obsession of isolated, individual cognition (the foundationalist project), but he would not consent that such "understanding" entails knowledge. Rorty is clear that "knowledge" is fallible and constrained to the "normal discourse" of a particular (historical) sociocultural paradigm (explicitly referencing Kuhn's ideas).[107] But taking such a position on a *standard* of knowledge one can argue, alternatively, must implicate Rorty's outlook as committed to the epistemic assumptions of Cartesian foundationalism.[108]

There is certainly more that can be surveyed here in the debate about the shift "from epistemology to hermeneutics." Siegel (2010), for instance, takes issue with Taylor's arguments for "overcoming" epistemology, while Suchting (1995) criticizes many of the "lessons" supposedly drawn from hermeneutics. Several very important questions exist that still need addressing, such as if the common division between *explanation* and *understanding* is abandoned—which has long been accepted as *the* major difference between the natural and social sciences (Mason 2003)—and "interpretation" comes to characterize all human inquiry, does or should a "contrast class" exist in opposition to it? Thereto, how can or should one demarcate the lines between the humanities and the different sciences? Moreover, how does one adjudicate between better and worse interpretations? Is hermeneutics[109] really an alternative

---

[106] This hermeneutic perspective on learning and understanding corresponds with the newer epistemological perspectives of the field: "… increasingly, science education researchers are viewing meaning as public, interpreted by participants (and analysts) through interaction of people via discourse including signs, symbols, models, and ways of being" (Kelly et al. 2012, p. 288).

[107] Hence his complaint that one can distinguish between "systematizers" (those engrossed in normal discourse) and "edifying" philosophers (anti-foundationalists like Dewey and hermeneutic thinkers like Heidegger, Gadamer, who disrupt it) within the tradition—the latter whose status as "true" philosophers is often questioned by academic professionals.

[108] Rockmore (2004, p. 57) writes that Rorty maintains "a strict but wholly arbitrary distinction between epistemology and hermeneutics in order to equate the failure of foundationalism with a form of skepticism that cannot be alleviated through a hermeneutical turn." He accuses Rorty of still clinging to a standard of knowledge that he admits cannot be met. Rorty freely concludes that one can no longer hope to bring the mind in contact with the real and that *interpretation* must be the alternative, but just denies this will lead to knowledge in the conventional sense. Alternatively, Rockmore argues that "the main strategy for knowledge is, and always has been, interpretation" (ibid), not to be taken as tantamount to skepticism.

[109] This is not meant to imply this field of study is monolithic, and commentators commonly distinguish between "right-wing" (Gadamer) and "left-wing" (Derrida) factions. Yet such a categorization

paradigm to epistemology (as Gadamer and Rorty insist) or another albeit extraordinary version of epistemology itself, just not of the classical foundationalist sort (as Rockmore (2004) and Westphal (1999) contend)?[110]

There are fundamental issues and concerns identified here that a philosophy of science education (PSE) would equally need to consider and evaluate, which have necessarily arisen in the dispute between the advocates of epistemology, hermeneutics, and their different perspectives on language, knowing, and understanding.

39.6 Conclusion

Philosophy and philosophy of education continue to remain outside the mainstream of thinking in science education. The chief purpose of this chapter has been to bring them closer into the fold. Philosophy is, on the one hand, underappreciated and ignored by science teachers, on the other, occasionally raided, used, and abused by science education researchers. Philosophy of education by contrast (and when compared to philosophy of science) has the dubious distinction of being disregarded by both groups.

Philosophy as a discipline of critical inquiry enables teachers to develop a thoughtful, critical capacity to reflect upon curricular, epistemological, and popular media issues as they arise, whether during classroom discourse or professional policy deliberations. Philosophy is not far below the surface in any classroom, and in truth cannot be avoided. This holds especially when discussing common terms like “law,” “theory,” and “proof,” or justifying content knowledge, or analyzing national “standards” documents, or providing coherent educational rationales for their courses, or for detecting curricular ideologies and conveyed textbook myths (e.g., academic rationalism, indoctrination into scientism, epistemological positivism, historically defined convergent realism, evolution versus intelligent design arguments, ambiguities and hazards of modern techno-science, cultural and personal bias). Philosophy of education as a subdiscipline prepares a forum of informed analysis and discussion on a range of topics and issues that bear directly on science education as an educational project, which has deep roots in the historico-philosophical past.

---

is equally overly simplified. Those in educational studies—see Gallagher (1992)—distinguish four separate schools: conservative (Dilthey; Hirsch), moderate (Gadamer; Ricoeur), radical (Derrida; Foucault), and critical (Habermas; Apel).

[110] Rockmore maintains that the shift leads to a *redefinition* of epistemology, from “knowing the way the mind-independent world is” to “the interpretation of experience” which is justified by the standards in use in a given cognitive domain. In this reformulation “then epistemology as hermeneutics presents itself as a viable successor to the traditional view of epistemology—indeed as the most likely approach at the start of the new century” (p. 11). Westphal criticizes Rorty for failing to distinguish between classical epistemology and hermeneutics seen as a generic epistemological task, hence, to differentiate the replacement of only one type (foundationalism): “*hermeneutics is epistemology,* generically construed … it belongs to the same genus precisely because like them it is a meta-theory about how we should understand the cognitive claims of common sense, of natural and social sciences, and even metaphysics and theology” (p. 416; original italics).

A philosophy of science education (PSE) can be understood as a *synthesis* of (at least) three academic fields of philosophy (P), philosophy of science (PS), and philosophy of education (PE), each of which have distinctive contributions to make in its development. It can be interpreted as a "second-order" reflective capacity on the part of the teacher, as an extension of their pedagogical content knowledge. The research field requires this capacity to think deeper and more systematically about the unique educational dimensions of teaching and learning of science as philosophy, as profession, and as practice. It should be inaugurated as a new *fourth* area of research inquiry.

PSE is ultimately concerned with the explicit *problematizing* of school science and its epistemology for two substantive reasons: (i) to recognize the current inadequate portrayal as inauthentic science and so to improve the content knowledge (CK) of both the curriculum and teacher through HPSS studies and integration and (ii) to allow for the effective didactic transposition of subject content for the culturally rooted, age-appropriate learner in accordance with educational aims, philosophy, and theory.

Pertaining to performing useful functions, its value is taken as being *threefold:* it serves to, first of all, provide a platform for both researchers and practitioners (in their separate ways) to perform meta-analysis (critical function); secondly, to reconceptualize, remake, and reform curriculum and instruction (creative function); and lastly, to implement, as an example, effective critical thinking for teacher and student, appropriate to subject content and age level (pragmatic function). In the process it is understood such a philosophy when developed would be articulating in essence its meaning of "scientific literacy" and thus specifying and prioritizing essential objectives for science education. Whether or not it could successfully perform these functions without an explicit educational metatheory at hand is open to challenge and debate. In any event, it would ultimately aim at improving science education by broadening the research field and opening new territory for exploration, as well as assisting teachers in broadening their theoretical frameworks, sharpening their critical acumen, and enhancing their pedagogical content knowledge.

Roland M. Schulz is a researcher with the *Imaginative Education Research Centre (IERG)* at Simon Fraser University in Vancouver and a sessional instructor in science teacher education. He holds a Ph.D. in Curriculum Theory focusing on philosophy of education, philosophy of science, and science education. His undergraduate degrees are in physics and in physical science education. He has been active as a secondary science teacher, having taught physics and chemistry for many years in Canada and physics in Istanbul, Turkey. His research interests include science education reform, philosophy of education, teacher education, hermeneutics and language theory, and the use of narrative and models to incorporate the history and philosophy of science for improving curriculum and instruction. Previous publications have appeared in the international journals *Science & Education* and *Educational Philosophy and Theory.*

Chapter 40
Conceptions of Scientific Literacy: Identifying and Evaluating Their Programmatic Elements

Stephen P. Norris*, **Linda M. Phillips, and David P. Burns**

'Scientific literacy is a programmatic concept' (Norris and Phillips 2009, p. 271). Programmatic concepts have elements that point in a valued direction or name a desired goal. In the case of scientific literacy, it points to goals that educators, scientists, and politicians want for citizens and society. It should not be surprising, then, that scientific literacy is contested. Not everyone possesses the same sense of valued directions and desired goals, so different individuals and groups urge their views on others. The question raised in this chapter is, 'By what means can the programmatic elements of conceptions of scientific literacy be identified and evaluated?'

First, we provide a detailed analysis of the nature of programmatic concepts and provide examples of the programmatic elements found in conceptions of scientific literacy. Given that definitions of scientific literacy bear upon what is taught in science education, a lens is needed through which to identify and judge these programmatic elements. Specifically, what values underlie these elements and what theories of value might be brought to bear in assessing them? The answer to this latter question will compose the second major section of the paper in which we present an analysis of approximately 70 conceptions of scientific literacy found in the literature since the year 2000. We identify the goals that each of these conceptions of scientific literacy implies and uncover the programmatic elements that are used to justify these goals. Our purpose here is not to be exhaustive in presenting

---

conceptions of scientific literacy but to present a sufficiently wide range of views to have a good representation of goals and programmatic elements. Third, we point to a number of pitfalls in any attempt to make preferential selections among the programmatic elements of conceptions of scientific literacy.

40.1 Programmatic Concepts

Programmatic concepts are of notable importance in education because of education's practical orientation toward 'social practices and habits of mind' (Scheffler 1960, p. 19). Programmatic concepts 'are not recognizable as such by their linguistic form alone: reference to the context needs to be made' (Scheffler 1960, p. 19). A study of the context in which a concept is used can reveal whether the concept has the effect of implying practical consequences or whether it does not serve such a purpose. Thus, programmatic concepts require 'independent, practical evaluation' (Scheffler 1960, p. 21) because they can raise serious moral and practical issues.

Like any concept in education, we expect programmatic concepts to meet certain linguistic and logical standards such as consistency, suitableness, and non-arbitrariness. However, programmatic concepts carry the extra burden of expressing value choices that embody programmes of action. We thus understand that to evaluate a programmatic concept, such as scientific literacy, it is necessary to consider both its linguistic features and value implications. Thus, an overriding question that we shall consider is, 'What is promised as a result of adopting a particular conception of scientific literacy?' We shall argue that any adoption should follow, rather than precede, the evaluation of what is promised in terms of sound theories of value.

Robert Ennis (1969) claimed that a programmatic concept takes the form of a definition, but 'it is more than this' (p. 178). Ennis's is a key point of focus, because it reminds us that programmatic concepts are not neutral descriptions of usage, compared let us say to dictionary definitions, which are intended objectively to describe linguistic practice. Programmatic concepts are not neutral, because they both imply a programme of what should or ought to be done and support that programme with explicit or implicit terms embedded within the meaning of the concept. According to Ennis, a programmatic concept effectively is 'a proposal (that is, a request, or command, or entreaty, etc.) for adoption of a program or point of view' (p. 179). For example, part of the conception of scientific literacy offered by Millar and Osborne (1998) is that a scientifically literate person has 'sufficient scientific knowledge and understanding to … read simple newspaper articles about science…' (p. 9). In this concept, we can see both of Ennis's elements at work. First, the concept reads like a definition. Thus, we can raise the questions of fact: Is the definition accurate? Is this what people mean by 'scientifically literate person'? Second, the concept reads like a proposal: We should take scientifically literate people to be able to read simple articles about science; we ought not to settle for less. Thus, we can raise the value questions: Is this how we ought to think of scientifically literate people? Should we consider reading simple newspaper articles to be important to scientific literacy? Is being able to read simple newspaper articles about science sufficient? The answers to these questions are not straightforward, but what is important is to acknowledge that these two elements are entailed: the questions of fact and the questions of value.

Consider a concept of our own to see again these two elements working. We theorized a fundamental sense of scientific literacy that 'means comprehending, interpreting, analyzing, and critiquing [scientific] texts' (Norris and Phillips 2003, p. 229). So, we can ask, 'Is this what scientific literacy means?' – the factual question about usage. More important, however, is that we were making a proposal that the science education field ought to include this way of thinking about scientific literacy in setting curricular goals. So we can ask whether this is a sensible, worthwhile, and productive way to think of scientific literacy – the value questions about adoption.

One might wonder whether all concepts are programmatic to some extent. If they are not, what are some concepts that are not programmatic? Consider the chemical concept of an element – that is, a substance consisting of atoms, all of which have the same number of protons. To argue that the concept of element is programmatic requires showing how it expresses value choices that embody programs of action. It might be argued, for example, that the concept arose from the desire for simplicity in theories that explain the natural world. However, unlike the concept of scientific literacy, over which we can exercise almost limitless discretion in adjusting its meaning, the concept of element captures the very real state of affairs that the substance of the world comes in discrete types – such as gold, which has exactly and always 79 protons in its atoms. Consider the concept of π, that is, the ratio of the circumference of circles to their diameters. No doubt, the concept arose from thinking driven by a set of values, including perhaps curiosity. Yet, it is difficult to imagine alternative conceptions to π. Alternatives to programmatic concepts are not only easy to imagine but seem invited by programmatic concepts such as scientific literacy. The concept of π refers to an unalterable fact about a precise geometric shape – its meaning, as the unique ratio of circumference to diameter, is beyond debate (although its exact value is actually beyond knowing). Thus, although most, or perhaps all, of our concepts contain in their history some elements of judgement and choice based upon values, that does not make all of our concepts programmatic. Only those concepts whose value choices embody programs of action about which we can expect significant and indefinitely extended debate fall into the programmatic category.

To summarize: to advance a conception of education, of any sort, is a programmatic task. That is, we promote certain educational ideas for consideration because we assume that certain paths and goals of development and growth are more valuable than others. These assumptions are underpinned by a wide range of premises about what counts as epistemically, morally, or politically valuable. As a result of this reality in educational discourse and thought, responsible practice requires an awareness of, and justification for, these values that underlie our assumptions. Science education is no exception to bearing this burden of responsibility. Discussion of scientific literacy, in particular, would benefit from precisely the sort of analysis we are recommending.

40.2 Programmatic Elements in Conceptions of Scientific Literacy

Using Google Scholar™, we searched for articles published since 2000 using the search phrase ‘scientific literacy’. We identified 74 articles in which we could isolate a definition of scientific literacy. Within these 74 articles, we identified a subset of 62 for which we could classify either the scientific literacy objectives espoused, the justification for espousing those objectives, or both of these. That is, there are two main categories of value discussion at play in contemporary conceptions of scientific literacy. The first regards the value *classification* of the desired outcomes of scientific literacy. The second regards the value *justification* provided (or implied) for such desired outcomes. These two categories, it will be shown, serve to draw attention to the important value analysis required of various conceptions of scientific literacy.

40.2.1 Value Classifications of Desired Outcomes

A focused reading of the 62 sources yielded the observation that many in the field would expect: the outcomes of scientific literacy do not belong uniformly to one value category. Rather, we saw repeated use of a relatively small set of key concepts: knowledge, ability, understanding, independence, participation, appreciation, among several others. One can discern several groupings in this list. Knowledge and understanding are (loosely speaking) epistemological concepts dealing with a mental state someone might possess. One might possess, for example, an understanding of particular scientific propositions or have knowledge of how to calculate the propagation of errors of measurement. Ability likely is interpreted best as a capacity to engage in particular actions. Independence and appreciation, in contrast to the preceding two categories, are states of personal character. We describe persons as more or less independent, and we say that persons are more or less appreciative, with reference to descriptions of whom those persons are and of what they are said to do. One might have knowledge or ability without the concomitant disposition to do anything in particular to use them. Independence and appreciation are, on the other hand, dispositional ways of being (Riveros et al. 2012). It is for this reason that we find it valuable to categorize the proposed outcomes of scientific literacy into three categories of values: values regarding the states of *knowing* one might obtain, values regarding the *capacities* one might refine, and values regarding the personal *traits* one might develop. We call them all values because they refer to ends of science education that are judged desirable.

This schema, or closely related ones, has been identified by others. For example, Laugksch (2000) produced a similar division. After examining the historical development of conceptions of scientific literacy, he concluded that three categories of what it means to be scientifically literate are applicable: being learned, competent, and 'able to function minimally as consumers and citizens' (p. 82). His schema, similar to the one proposed by us above, denotes a move from possessing particular knowledge and understanding, to the possession of certain capacities, to the fulfilling of certain roles. This third category, it should be noted, is not explicitly dispositional (as our third category is). Laugksch maintained ability as the key element of the third category, rather than explicitly separating capacity from disposition to act. Nevertheless, it is difficult to imagine that he desires people who are *able* to function as citizens while being indifferent to whether they do function in that way. Thus, we believe that Laugksch likely had dispositions in mind when formulating his schema, even if he did not explicitly use dispositional language.

The division between knowledge, capacities, and traits of character is pedagogically significant because it draws attention to the unique status of these three forms of valuable outcomes. To say that students should know certain things is clearly pedagogically distinct from saying that they should be able to do certain things. To say that students should embody certain traits, and hence be certain sorts of persons, is strikingly different from both knowledge and capacity.

Table 40.1 indicates which categories of objectives, if any, were evident in each of the sources. We have indicated the presence of objectives with bullets. In those cases marked with a bullet, we are confident there is positive evidence that the referenced objective is included. In those cases without indicator bullets, we did not uncover positive evidence, but another read, or another reader, might find implied evidence present. The knowledge and capacity objectives were widely present, occurring in 59 and 60 of the sources, respectively. The traits objective was also represented well by 38 of the sources.

40.2.1.1 Knowledge

Even though nearly every source said that knowledge is a goal of scientific literacy, it was frequently difficult to find statements of exactly what knowledge was desired. Take, for example, the following statement from Foster and Shiel-Rolle (2011, p. 85): 'At its simplest, the concept of "scientific literacy" refers to the fundamental knowledge that the general public needs to understand about science so that individuals can use that information to make informed decisions regarding personal, civic, and economic matters…'. Such a statement provides a very general idea of the function that the scientific knowledge is intended to serve, but it provides no indication of what that knowledge actually is. Is the knowledge substantive scientific knowledge? Is it, as the words invite one to think, knowledge about science, rather than knowledge of substantive science itself? Later in the same article, however, when describing a summer science camp designed to 'enhance scientific literacy in rural communities' (p. 87), the authors are very specific about the sorts of knowledge required: for example, 'identify the four species of mangroves found within the Bahamas; understand how mangroves serve as nurseries for juvenile fish and stingrays … a basic geological understanding of cave formation in the Bahamas' (p. 90). One might then wonder whether this very specific knowledge is the sort that

Objectives- *K* knowledge, *Ca* capacities, *T* traits
Justifications- *L* liberal, *Cm* communitarian, *V* virtue, *P* principled, *U* utilitarian

is needed 'to make informed decisions regarding personal, civic, and economic matters' as the authors want scientific literacy to provide.

Lau (2009) recognizes that the expression 'scientific knowledge' can be used pejoratively, perhaps to mean content learned by rote: 'Local science educators found that the junior secondary science curriculum was dominated by scientific knowledge, leaving many important scientific processes and understanding of the nature of science untouched' (p. 1062). At times, Lau appears to prefer the term 'understanding' to pick out what is valuable for scientific literacy, but he especially presses the distinction between knowledge of science and knowledge about science. The former he sees as referring to the substantive content of science; the latter as referring to meta-scientific knowledge, that is, to knowledge about scientific knowledge.

40.2.1.2 Capacities

Gräber et al. (2001) suggest 'a competency based model of scientific literacy' (p. 209). Including neither knowledge nor traits on the face of it, but instead focusing on capacities, this could be one of the most radical positions in the field. When examined more closely, however, a three-way distinction similar to our own underlies their model. They suggest that scientific literacy is needed 'for the individual to cope with our complex world' (p. 209), and to shape the sort of scientific literacy needed for this task, three questions must be answered: What do people know? What can people do? What do people value? They answer each question with sets of competencies, even the question about knowledge, for which they cite the need for subject competence and epistemological competence. The subject and epistemological competence fit under knowledge as we define it. The competencies they include under their second question are what we mean by capacities: social competence, procedural competence, and communicative competence.

Capacities often shade into knowledge, depending upon how the nature of the capacity is formulated. For example, Bybee (2009) says the following: 'the student with less developed scientific literacy might be able to recall simple scientific factual knowledge about a physical system and to use common science terms in stating a conclusion' (p. 2). On the one hand, Bybee is speaking of capacities (being able to recall something, and using something); on the other hand, he is thinking about the factual and terminological knowledge a student has. We see no deep theoretical point in this discrepancy that arises from vagaries of English usage nor any important issue that hangs on settling it.

40.2.1.3 Traits

The traits we identified fell into two major groups: intellectual and moral traits, the second of which are often termed 'moral virtues'. Intellectual traits are characteristics of people that promote intellectual flourishing. These traits might include inquisitiveness, open-mindedness, and carefulness. Virtues are characteristics that promote moral flourishing. These virtues might include honesty, generosity, and courage. Clearly, there are connections between the categories because a virtue such as honesty is central to intellectual flourishing, and a trait such as open-mindedness can be seen as morally superior to its opposite. Evans and Rennie (2009) associate scientific literacy with traits when they say that it is the capacity 'to be interested in, and understand, the world around them … to be sceptical and questioning of claims made by others about scientific matters …' (pp. 25–26).

40.2.2 Value Justifications for Desired Outcomes

This is the point at which our second categorization becomes relevant. If it is the case that there are three broad sorts of valued outcomes being considered in discussions about scientific literacy, then these differing values might very well demand and attract differing forms of justification. Table 40.1 indicates that we identified two broad categories of justification for scientific literacy objectives: moral and political. 'Morality' can be used in a descriptive or normative sense. In the descriptive sense, 'morality' refers to a code of conduct put forward by or followed by a society. You might imagine an anthropologist observing and interacting with a society and from the data collected inferring the code of conduct adopted in that society. If the descriptive sense is taken to exhaust the meaning of what is moral, then what is moral simply refers to the code of conduct that any group or person adopts. If the descriptive sense is taken in this way, then it conflicts with the normative sense of 'morality'. In the normative sense, what is moral is taken to apply universally, that is, to all those 'who can understand it and govern their behavior by it' (Gert 2011, p. 1). In the normative sense, it is assumed that actual codes of behaviour do not necessarily capture what it means to be moral. Actual codes of behaviour can be analysed and critiqued for falling short on morality, where morality here is thought of as an ideal that exists outside human practices and to which those practices can be held accountable. In the normative sense, moral justifications can never be overridden by other non-moral considerations.

Moral justifications of the objectives of scientific literacy can thus refer either to codes of conduct that are actually adopted or to codes of conduct that are not adopted but which, upon reflection, ought to be adopted. In the first type of case, the moral justification would be cast in terms of whether the objective led to behaviour that was in accord with an accepted code. In the latter type of case, the justification would be cast in terms of whether the objective led to behaviour that was considered moral, regardless of its conformity to an accepted code. If the behaviour was in conflict with an accepted code, the justification would in effect be saying that the code was morally deficient.

On one account, political justifications reduce to moral ones. That is, a behaviour is politically justified if, and only if, it is morally justified. On another account, moral justification is a necessary but insufficient condition for political justification: a behaviour is justified politically, only if it is morally justified. Consider an example outside of science education. If it is accepted that it is morally wrong to kill other human beings outside of situations of immediate threat to one's own life, then no reference to possible beneficial consequences can ever provide a political justification sufficient to override the moral condemnation of the act.

Politics can be defined roughly as the method by which groups of people make collective decisions. In advanced societies, politics is largely about how governments function, the business of collective decision making having been assigned to governments for many of the societies' resources. In this light, a political justification can be seen as one that defends a particular distribution of resources or the means of that distribution. So conceived, political justification requires more than mere consent from those affected by the decisions taken. The justification requires the offering of publicly accessible reasons that can be understood and challenged. It is through the public display and vetting of reasons that the political decisions acquire legitimacy; legitimacy cannot be bestowed by acquiescence.

A tight connection between political and moral justification is difficult to avoid, because the distribution of limited resources needs to conform to a sense of justice. So, although the distribution of resources is a practical matter and the form that distribution takes can be defended in part on practical grounds, it is impossible to avoid questions of fairness in the distribution. Education is one of the limited resources that our society has available for distribution. Therefore, political justifications of decisions of how to distribute that resource must ultimately conform to the demands of justice and be seen as legitimate on the basis of the reasons used to defend them.

40.2.2.1 Types of Moral Justification

The most prominent form of moral justification we uncovered in this analysis was *utilitarian*, found in roughly one-half the cases. Classical utilitarianism holds that actions are good insofar as they produce the most overall happiness (McLachlan 2010) or the greatest good for the greatest number. Debates rage over what constitutes happiness and over whether happiness is the greatest good that is to be sought. Whatever the particulars, utilitarianism is a form of consequentialism, which is a family of views that holds that the goodness or morality of an action is to be judged by its effects. In the case of justifying the objectives of scientific literacy, utilitarianism is manifested primarily on economic grounds, via an analysis of the sort of literacy that contributes to a healthy economy and personal competitiveness in the job market. Laugksch (2000) notes, for example, that advanced economies require technologically skilled professionals and only a scientifically literate populace can produce such professionals. Scientific literacy, on this understanding, is good because it strengthens economies and personal economic competitiveness. These consequences are, presumably, thought to be conducive to overall good or to human happiness, bringing us back to the touchstone of utilitarianism. Thus, the moral justification for scientific literacy might be outlined as follows: a society is economically stronger in the long term when its citizens are educated to a certain level of scientific literacy. An economically strong society is better for the persons encompassed by it. Therefore, it is justified to pursue scientific literacy for citizens.

Foster and Shiel-Rolle (2011) provide a utilitarian argument for scientific literacy that is almost textbook in its adoption of the utilitarian view described above:

> The importance of developing a scientific literate society is multifaceted. First, increasing scientific literacy has been considered to be a critical strategy for maintaining a country's technological and economic standing … Second, [i]t is increasingly important to have a scientifically literate society to make informed decisions regarding policy development and

> its implementation. Lastly, … [s]cientifically literate international communities can … potentially use the scientific insight to improve their local agricultural and marine practices, economies and educational systems. (p. 86)

So, although they see the reasons for promoting scientific literacy as multifaceted, all of their reasons fall into the same category: utilitarianism.

Bybee (2008) provides the following utilitarian moral justification for scientific literacy in the context of environmental issues and PISA 2006:

> Scientific literacy is essential to an individual's full participation in society. The understandings and abilities associated with scientific literacy empower citizens to make personal decisions and appropriately participate in the formulation of public policies that impact their lives. Assertions such as these provide a rationale of scientific literacy as the central purpose of science education. Too often, however, the rationale lacks connections that answer questions such as "personal decisions—" *concerning what*?" "fully participate—*in what*?" or "formulate policies—*relative to what*?" One could answer these questions using contexts that citizens daily confront; for example, personal health, natural hazards, and information at the frontiers of science and technology. Two other domains stand out—national resources and environmental quality. (pp. 567–568)

Readers would be correct to object that this evidence is insufficient to establish that Bybee relies upon a utilitarian justification for scientific literacy. Thus, it is necessary to examine his text in greater detail. Further examination of his document leaves little doubt about the nature of his justification. For example, he frames four policies that are supported by fostering scientific literacy as he conceives of it. The first policy is the fulfilment of basic human 'physiological needs such as clean air and water and sufficient food' (p. 578). The second and third policies come down to the same justification. The second policy deals with 'maintaining and improving the physical environment' (p. 578), which is 'the common heritage of humankind, and they are essential to fulfilling basic needs' (p. 579). The third policy focuses on the wise use of natural resources, which 'is closely related to … fulfillment of both the physical environment and to fulfillment of basic needs' (p. 579). Finally, the fourth policy aims 'toward establishing a greater sense of community' (p. 579). As such, the fourth policy might appear to find its grounding in communitarianism. In addition, the policy refers to the reduction of 'prejudice, such as racism, sexism, ethnocentricism and nationalism' (p. 579). This aim leans toward some sort of principled justification of avoiding forbidden behaviour. However, it is clear that both the push for community and the reliance on principles are themselves grounded on the same urge to fulfil basic human needs: 'If fulfillment of human needs and improvement of the environment … are to become realities, we must increase community involvement… one of the first steps … is the elimination of prejudicial barriers to community' (p. 579). Thus, the second to fourth policies reduce to the first, which clearly is motivated on utilitarian grounds. Feinstein (2011) makes a very deliberate effort to argue that the utilitarian justification for scientific literacy is the most robust:

> This essay examines the idea that science education is useful in daily life . . . I focus on usefulness for two reasons. First, claims about the usefulness of science education are more testable than claims about its cultural, aesthetic, or moral value. In other words, when someone says science education is useful in a particular way, we should be able to find evidence for or against that claim, at least in theory. Second, the idea that science education is useful

> exerts a powerful political influence: People, particularly people with money and resources, seem to believe in it . . . It is important to specify what I mean by "useful in daily life," because that phrase has several possible interpretations. I am referring to the very specific notion that science education can help people solve personally meaningful problems in their lives, directly affect their material and social circumstances, shape their behavior, and inform their most significant practical and political decisions. (p. 169)

Feinstein's argument is very interesting. He claims to prefer utilitarian justifications because they are more testable than moral justifications. However, as we have shown, utilitarianism is one form of morality, namely, the form that focuses on the consequences of actions to decide on their morality, so Feinstein's attempt to separate the good from the useful fails to recognize that usefulness is just one way to interpret goodness. As Feinstein claims, consequences might also prove testable, supposedly making the judgement that science education is useful more clear-cut. Yet, the calculation is not so easy as Feinstein envisages. He sees usefulness as measured by helping people solve personally meaningful problems and by informing their most significant decisions. Deciding whether a problem is personally meaningful or a decision is of greatest significance also involves moral judgement that cannot be reduced to utility calculation.

The next most frequently found type of moral justification was based upon *principles*. Principled justification (deontology, in technical terms) concerns itself with what is morally forbidden, required, and permitted. It stands in contrast to varieties of consequentialism in that it holds that conformity to moral norms, such as particular duties or principles, makes actions morally praiseworthy (Alexander and Moore 2008). In its Kantian form, for instance, one seeks to ascertain the principle (or *maxim*) underlying a particular proposed action. This principle is then tested by asking if it could be applied universally, including to oneself. Praiseworthy actions, in Kantianism's simplified form, are those that satisfy these two tests. It is because of these reasons that deontologists hold that actions cannot be judged by their effects alone: according to this view, some actions are forbidden no matter how good their consequences might turn out.

Laugksch (2000) notes, for example, that it is often argued that citizens ought to be scientifically literate because they are affected by science, because they help to fund scientific research through tax dollars, and because they can participate in public deliberation when they are informed about scientific issues. In each of these cases, the fundamental justification is not that greater good is produced through scientific literacy (as in utilitarian justifications), but rather that certain principles are best satisfied when citizens are helped to become scientifically literate: such as, we should be informed about those matters that affect our lives, we should understand what we help to support through tax dollars, or that all citizens ought to participate in public decision making. These principles generally refer to conceptions of ethical governance. Since the criteria in this reasoning are most related to the satisfaction of certain ethical principles (such as democratic sovereignty), this sort of reasoning is best categorized as principled or deontological. Thus, a person holding that participation in public deliberation is a right might not be deterred in holding this view just because some people are not scientifically literate, are unable to participate in deliberations about scientific issues, but nonetheless show no ill effects from their lack of participation. Nor need the person be deterred by public deliberation that reached poorer choices than might be reached by a much narrower blue-ribbon panel. Once more, abiding by the principle is much more important than the consequences.

Bhathal (2011) makes the argument that Indigenous persons are underrepresented in science classes and in scientific careers, the implication being that this situation in principle is wrong. Although not explicitly argued by Bhathal, the underrepresentation seems to be thought of as a violation of the moral right to non-discrimination and equality. Bhathal describes a study in which 15 secondary school Aboriginal students were brought to a university six times during a semester to conduct projects in astronomy. The projects drew upon both Aboriginal astronomy and modern scientific astronomy and aimed to improve the students' scientific literacy. It is mildly curious to us that in the outcomes section at the end of the article, several utilitarian ends were cited in an apparent justification of the intervention that had taken place: students developed more positive attitudes toward science, gained knowledge of Aboriginal astronomy, were interested in the projects, and more were disposed at the end of the projects than at the beginning of them to continue with their high school education. Of course, all of these outcomes are positive and important. Our mild curiosity stems from the fact that none of these findings refers to the original justification for undertaking the projects, which was principle-based rather than based on utilitarian outcomes. Presumably, the justification runs as follows: the utilitarian ends achieved are indicators that teaching scientific literacy through astronomy addresses the underrepresentation of Aboriginal students in science, which is deplorable on principle. However, none of this argumentation is made explicit, so it is possible that we are putting words into the authors' mouths that they would not accept.

The same sort of principle-based justification is also present with respect to gender representation in George and Brenner (2010). As stated by the authors, 'The goal of the project was to create opportunities in college curricula that urge women to take science seriously whether or not they are science majors, to learn how science orders and explores the world, and to question it along the way' (p. 28). Although it is never put so explicitly, it seems the principle justifying this goal is that there ought not be a major difference in the representation of males and females in science. At the end of their report, the authors say: '… we cannot conclude that introducing feminist science studies improved the students' learning compared with a more traditional science course. Still, by introducing this course into the women's studies and science for the liberal arts curricula, we have built at least one two-way street across what has been an intimidating intellectual divide' (p. 34). Improving learning was a utilitarian goal of this project, but it was secondary by the authors' own admission. The primary goal was the increased representation of women in science. Thus, the authors seem to hold fast to their original principled stance in the previously quoted extract. Although the authors do not explicitly say, 'Even though we cannot show improved learning …', it appears that this is what they have in mind. That is, they can nevertheless claim success despite no evidence of improved learning because they have found evidence that their approach can successfully address lower female participation rates in science, their principled objection to which is their primary justification.

In addition to utilitarian and principled justifications, one also finds conceptions of scientific literacy supported by *virtue theoretical* arguments, though these are the least frequently appearing type of justification. Virtue theoretical arguments are about human character and excellence (Hursthouse 2010). As such, they stand in contrast to arguments about doing what one is obliged to do or acting so as to produce desirable consequences. Also as such, the virtuous person is not simply one who practises virtuous acts, such as truth telling. Rather, truth telling is practised because it is valued for its own sake. We also need to distinguish two broad categories of virtue: namely, moral virtue and intellectual virtue. Among the first category we might find benevolence, compassion, empathy, gentleness, and selflessness. Among the second category we might find detachment, determination, flexibility, open-mindedness, perseverance, and reliability. We do not mean these lists to be comprehensive or mutually exclusive. For example, open-mindedness is intellectually virtuous in the conduct of science because it can prompt the consideration of alternative explanations that might be more powerful than the one under consideration. Likewise, open-mindedness is morally virtuous in everyday dealings with others because it can lead to the respect of moral agents who nevertheless hold different views and practise different customs than oneself.

Laugksch (2000), for example, discusses 'the intellectual, aesthetic, and moral benefits of scientific literacy to individuals' (p. 86). He describes these mostly in terms of intellectual virtues such as 'cultivated mind' and 'educated person', and perhaps a moral virtue, 'not merely wiser but better' (p. 86). Notions of cultivation and betterment are, at their root, notions of human excellence. Scientific literacy, in this case, is valuable insofar as it contributes to making students better persons. This emphasis places his reasoning within the category of virtue theory and places the focus on individuals' characters as opposed to, say, their knowledge and capacities.

It is striking that Dillon (2009) noted the concern of members of the 2007 Linné Scientific Literacy Symposium to the effect that there was a lack of emphasis on virtue in school science: 'There is little flavour in school science of the importance that creativity, ingenuity, intuition or persistence have played in the scientific enterprise' (Members of the Linné Scientific Literacy Symposium 2007, p. 7). In the same discussion, Dillon notes a particular emphasis on virtue in the reformed science education curriculum of Turkey and remarks that this emphasis would be 'unusual to a Western European eye' (2009, p. 208). He exemplifies the unusual emphasis with the following desired outcomes among others: 'Self-disciplined (Self-controlled, prompt, self-evaluating, sincere, consistent)' (Taşar and Atasoy 2006, p. 9). All of these outcomes belong among those on lists of intellectual and moral virtues.

Murcia (2009) says that scientific literacy is 'about a way of thinking and acting' (p. 219). This statement suggests she might be providing a virtue justification for scientific literacy. Although in Table 40.1 we have marked this work as providing virtue justification for scientific literacy objectives, we are not completely confident that it does. Murcia develops a framework of scientific literacy and says: ‘The aim of this framework was to clarify the type of knowledge, roles and abilities required to act scientifically in a contemporary context’ (p. 218). Among her categories, one of the ‘roles’ is the one most closely related to the nature of character. She refers to the work of Ford and Forman (2006), who have named the roles of Constructor and Critiquer for scientifically literate people. The latter of these, in particular, is easily interpreted in terms of the intellectual virtue of criticalness, the former can perhaps be interpreted in terms of creativeness. We are tentative in these recommended interpretations of Murcia’s work because we are not sure that is what she meant. Nevertheless, interpretation in terms of intellectual virtue does make sense of this aspect of her work.

Although Holbrook and Rannikmäe (2009) call them ‘skills’, we take their ‘personal skills related to creativity, initiative, safe working’ (p. 283) to be personal qualities much the same as virtues. Similarly, although Dos Santos (2009) never uses the word ‘virtue’, his entire article is about a particular sort of virtue, namely, commitment: ‘The conclusions of those works [Freire’s] reveal a political commitment to struggle for liberation’ (p. 369); ‘students need to take part directly in SSI discussions, so they can interact with the world, discuss their living conditions, and become committed to social change’ (p. 374). The clear implication of these lines is to point to the desirability of a particular sort of character trait, that is, one of commitment to social change.

One article (Greenleaf et al. 2011) presented all three types of moral justification.

Regarding principled moral justification, there is a repeated emphasis on inequity and underrepresentation as a motivating force. Specifically, they note underrepresentation of certain cultural groups in science and inequity of resources and training for teachers. The core argument is that illiteracy and lack of scientific literacy are objectionable on the grounds that they foster inequity (a deontological concern when framed in this way). Here is an example excerpt:

> Withdrawing adolescents from instruction in science to remediate reading difficulties threatens to exacerbate historic inequities in achievement for populations of students traditionally underrepresented in the sciences … There is therefore increasing urgency to investigate how the integration of reading instruction into science learning at the high school level might advance the reading and science achievement of underachieving youth. (p. 649)

Utilitarian justifications are found straightforwardly. The article opens with the standard argument about how the health of the nation (the United States in this case) requires this sort of education for scientific literacy on grounds of both economic and democratic utility: ‘Our democracy and future economic well-being depend on a literate populace, capable of fully participating in the demands of the twenty-first century … Yet National Assessment of Educational Progress (NAEP) results indicate that most American youth lack the skills to successfully engage in the higher-level literacy, reasoning, and inquiry needed for an information-generating and information-transforming economy’ (p. 648).

Although they are the most ambiguous of the three sorts of justification found in this article, we believe a case can be made that Greenleaf et al. offer virtue justifications for scientific literacy. They refer on several occasions to dispositional outcomes, suggesting that they are concerned with individuals' characters, but they seem to go further and to frame some dispositions in virtue terms. For example, they explicitly say that they want 'resilient' learners and students with 'stamina' (pp. 657–658) and construct the issue as one of personal identity construction. When we use terms of personal excellence, and we note that we seek to have people develop into certain sorts of people, we have moved from discussion of ordinary cognitive and attitudinal traits to discussion of virtues, either prudential or moral.

40.2.2.2 Types of Political Justification

Approximately two-thirds of the articles appeal to political liberalism to justify their scientific literacy objectives. Liberal theory places a fundamental emphasis on the exercise of personal freedom. One ought to be free to determine for oneself important elements of personal belief and lifestyle (such as religious belief). Rawls (1993), for example, famously argued that a political community ought to be arranged so that free persons could participate in rational public debate and dialogue in spite of their diverse beliefs. The educational corollary to this position is that persons must be nurtured into the knowledge, capacities, and traits required to participate in such critical deliberation. When public questions regard scientific practice or regulation or depend on scientific knowledge and method, it follows that scientific literacy specifically is required. One might argue, therefore, that the requirement to support public democratic deliberation is not just a principled moral imperative (as we argued prior to this section) but is also a liberal political imperative.

Correia et al. (2010) provide a textbook case of a liberal justification for scientific literacy:

> Scientific literacy (SL) is necessary in post-industrial society to nurture an autonomous citizenry . . . We are negotiating a new contract between society and science, and all citizens must have the right and the ability to make their own judgments about the ethical aspects of scientific and technological issues. (p. 680)
>
> Scientific literacy is a novel requirement for producing informed and autonomous citizens in post-industrial societies. Moreover, it is necessary that a student achieve scientific literacy during his or her career in higher education to be able to achieve the education for sustainability. Universities striving to teach sustainability must graft a holistic perspective onto the traditional specialized undergraduate curriculum. This new integrative, inter/trans-disciplinary epistemological approach is necessary to allow autonomous citizenship, that is, the possibility that each citizen understand and participate in discussions about the complex issues posed by our contemporary post-industrial society. (p. 685)

Bybee (2009) expresses a clear emphasis on the capacity of individuals to take a position on personal and political decisions and to formulate arguments in support of it:

> . . . as people are presented with more, and sometimes conflicting, information about phenomena, such as climate change, they need to be able to access collective scientific knowledge and understand, for example, the scientific basis for evaluations . . . versus the

> basis for perspectives by individuals representing oil, gas, or coal companies. Finally, citizens should be able to use the results of scientific reports and recommendations about issues such as health, prescription drugs, and safety to formulate arguments supporting their decisions about scientific issues of personal, social, and global consequence. (pp. 3–4)

These examples from Correia et al. and Bybee are clear instances of liberal political justification because they explicitly emphasize individual decision-making capacity, not collective meaning or collective agency. It is worth noting that, even though most of the articles contained in our review have a liberal justification at play for the objectives of scientific literacy, these justifications were nearly always vague references to individual decision-making capacity rather than explicit invocations of liberal theory. We think it is fair to say that the scientific literacy literature assumes liberal politics in most cases, in contrast to defending liberalism.

Also, there is not always a clear divide between liberal justifications and moral ones. There seems to be a moral implication in O'Neill and Polman (2004) when they discuss why people need scientific literacy to understand their personal choices:

> We suggest that on a societal scale, schools would function more effectively if they covered less content, in ways that would allow students to build a deeper understanding of how scientific knowledge claims and theories are constructed. This would be of use to all students in their decision making outside of school, and beneficial to those pursuing postsecondary studies in science as well. (p. 237)

The primary justification here for teaching about the nature of science seems to be the assistance this knowledge would bring to decision making outside of school. This justification is phrased in fairly standard liberal civic terms, meaning something like 'all agents should be able to access and understand information relevant to their personal choices'. Such a justification can be interpreted as well in Kantian moral terms, which is not surprising given that liberal political theory has a strong deontological heritage. This often displayed union of political liberalism and Kantian ethics in education points to a linkage between the discussion in this section on types of political justification with the foregoing section on types of moral justification.

The most explicit uses of political theory in these articles were instances in which communitarians wanted to distance themselves from the assumption of liberal politics. About one-half of the articles appealed to communitarian justifications for scientific literacy. Liberalism in educational theory often is contrasted with communitarianism (e.g., Strike 2000). Liberalism holds primary the fair distribution of liberties and resources to enable the individual selection of forms of life to lead. Fairness according to communitarianism must be judged within traditions and thus can vary from society to society and from time to time. In communitarian political thought, the emphasis is placed primarily on the collective determination of the community, not on the autonomous choice of the individual. Sectarian schools are, for example, a prominent manifestation of communitarian religious thought. Rather than emphasizing individual choice and deliberation across communities, communitarian politics seeks to nurture a single community. Of course, given the presumption of communitarianism that standards of value are community-specific, communitarians in plural states must be prepared to accept many communities. Such political reasoning can be applied also to scientific literacy. When science educators speak of fostering scientific values, for instance, they are at least partially speaking about creating and nurturing a particular kind of shared community – in this instance, one based upon science. At its root, this is a communitarian stance.

There are two broad kinds of communitarianism reflected among the articles. The first is represented in articles like Dos Santos (2009). This article uses a Freirean approach to emphasize community meaning and knowledge. The point of the article is to advance the ways in which a particular community constructs its problems and knowledge. Dos Santos draws attention to the existence of landfills in many Brazilian cities to illustrate how Freirean pedagogy could turn this situation into an important science lesson. 'Teachers could take their students to visit landfills, to interview people that work there, and later discuss in the classroom how that community could change the situation' (p. 373). The assumption of the collective determination of the community in setting its future is quite explicit in this quotation. Consider another situation mentioned by Dos Santos in which a school is situated in a location without a sewer system. 'The search for solutions for this problem will inevitably point out the need of mobilizing the school, and local community for political actions aimed at providing that community with sewage' (p. 374). Again, we see the emphasis on community decision making and action as opposed, let us say, to individual decision making and action, such as individual home owners installing septic systems or composting toilets. Note also that the political theory at play in the Dos Santos' document is much more explicit than in nearly all of the examples that drew upon liberal theory.

The second kind of communitarianism found in the articles places an emphasis on drawing students into scientific culture. In articles such as these, scientific literacy is justified on the grounds that it draws people into science as a cultural act. Such a justification seems centrally communitarian and quite distinct from saying that scientific literacy is important because it fosters individual decision making. Cavagnetto (2010), for example, argues that skills in scientific argumentation and understanding scientific processes and principles are insufficient bases in scientific literacy. Such skill and knowledge do not initiate one into the culture of science, which can only be entered by engaging in scientific practices. So, the justification for teaching argumentation is not that it teaches argumentative skill, but that it introduces students into a fundamental practice of science: 'Therefore, the goal of argument instruction in the context of scientific literacy is not the transfer of argument skills but rather the transfer of an understanding of scientific practice' (p. 352).

40.3 Choosing Among Conceptions of Scientific Literacy

We have shown thus far that the programmatic elements of various conceptions of science literacy contain at least three categories of valued objectives: knowledge, capacities, and traits. These three categories of objectives are justified either

Table 40.2 Frequencies of political and moral justifications offered for each scientific literacy objective

	Political justifications		Moral justifications		
Objectives	L	Cm	V	P	U
Knowledge	40	26	9	15	27
Capacities	41	28	9	15	29
Traits	31	19	9	14	22

Key. L liberal, *Cm* communitarian, *V* virtue, *P* principled, *U* utilitarian

morally or politically. On the moral side, we documented utilitarian, principled, and virtue theoretical justifications. On the political side, we documented liberal and communitarian justifications. There is no necessary link between any particular category of valued objective and any particular form of justification, and we found no strong correlation in the data, as can be seen by checking the frequencies of types of justifications for each objective in Table 40.2. Nor is it the case that these justifications contradict one another, although they might in certain renditions. Thus, it is possible at least sometimes to use without contradiction more than one type of justification to support the same objective. One could support the development of valuable traits of personality not only on the grounds that they contribute to personal excellence (a virtue theoretical justification) but also because they enable persons to contribute to the overall social good (a utilitarian justification) or also because persons have a moral right to be so supported (a principled justification). Yet, we note that among moral justifications, fewer utilitarian justifications were provided for the trait objective than for other objectives, which makes sense if you consider moral traits to be favoured more for their desirability than their usefulness. These traits might enhance personal participation in democratic deliberation (a liberal justification), or they might allow one to appreciate scientific culture (a communitarian justification). However, we note that between the political justifications, there were fewer communitarian justifications for trait objectives than for other objectives, which makes sense if traits are viewed as individual accomplishments.

Our schema is not totally exhaustive of all the objectives and justifications that do or could exist, so it is possible to propose analytic divisions beyond what we have offered. Returning to the opening of the chapter, the point is that scientific literacy is highly programmatic. This programmatic character is manifested in different kinds of valued objectives and justifications for them. To understand what is at stake in debates about scientific literacy and to decide one's own position, one needs to identify the valued objectives and the justifications for them, to understand how each type of justification functions, and to critique each. The canvass we have done of several examples should provide some useful starting points for such identification, understanding, and critique.

Understanding how the goals of scientific literacy and their justifications are linked allows us better to understand scientific literacy itself, and it allows scholars of science education to ask more fruitful and illuminating questions about this educational ideal. As we have demonstrated, each form of justification focuses on certain aspects of value and not others. The choice of whether to accept a particular justification is educationally significant. The choice is not always easy, and the alternatives among various justifications are not always clearly distinguishable in terms of quality, although we hope that we have provided guidance for making such distinctions.

So how might choices be made among alternative versions of scientific literacy objectives and their possible justifications? Among all the possibilities of contrasting positions defined by crossing the three types of scientific literacy objectives with the five types of justifications, we will consider three contrasts for illustration. The first contrast is between political and moral justifications, the second within political justifications between liberal and communitarian justifications, and the third within moral justifications between virtue, principled, and utilitarian justifications. The entire domain is essentially contested, so that there are not always clearly right or even better positions, but, rather, a panoply of good positions with some clearly poor or not so good ones. This is the nature of the scientific literacy domain; there is no way to make the ambiguity and uncertainty disappear. The point is to identify which definition of scientific literacy comparatively speaking is most educationally significant.

40.3.1 Contrast Between Political and Moral Justifications

At a very general level of consideration, ignoring any specifics for the moment and assuming all other things are equal, moral justifications in the normative sense that we prefer, based as they are upon what is right, should trump political justifications, based as they are upon what is possible. Thus, a moral justification for a science curriculum directed toward a universal scientific literacy that respected gender and racial equality might be seen, all other things being equal, as stronger than a political justification for a curriculum that promoted scientific literacy for social activism. Similarly, aiming to foster individual intellectual and moral virtues such as curiosity, open-mindedness, and valuing fair tests might be seen, *ceteris paribus*, as a more important reason to foster scientific literacy than the creation of critical and informed citizens for the promotion of the democratic state. The *ceteris paribus* clause covers a host of nuance and qualifications. For moral justifications to trump political ones, they have to be sound moral justifications. Thus, for example, if the justification offered is based on providing a gender and racially equal scientific literacy, then the curriculum that is envisaged to do this must be able to result in that desired outcome, or the justification for using that curriculum to reach the desired objectives breaks down. Also, it is one matter to respect gender and racial equality in providing opportunity for scientific literacy development and quite a different matter to demand equal outcomes. Perhaps equal scientific literacy outcomes across gender and race is not the most morally desirable outcome. An argument is needed to make the case one way or the other and that argument needs to be assessed.

Perhaps the best position for science educators is to consider moral justifications offered for scientific literacy objectives before considering the political ones.

There is no calculus, unfortunately – a theme we will repeat – for choosing between strong moral and strong political justifications if they result in the recommendation of different objectives and curricula for obtaining them. The situation is even more complicated, as shown in the following section.

40.3.2 Contrast Within Political Justifications

The distinctions between moral and political justifications are not always so easy to make. The political justifications based on liberalism and communitarianism themselves draw upon moral theory. Liberalism celebrates justice for all in the service of individual autonomy. Communitarianism sees collective decision making as a higher good than individual choice. Theoretical arguments do not exist that can help us choose definitively between these positions. Making the situation more complicated is that proponents on either side often acknowledge the values advocated by the other.

A central feature of liberalism is its neutrality concerning conceptions of what is good. Individuals should be free to follow their own preferences so long as they do not impede others' freedom to follow their preferences, but liberalism makes no judgement on the quality of those preferences. On this conception, scientific literacy has to be seen as a tool to help individuals to choose and pursue their preferred life courses. Communitarians believe that goods must be rank ordered and that there are goods in common. On this view, scientific literacy is seen as one of the common goods that helps build a society.

Does liberal justice trump communitarian benevolence? Does scientific literacy for individual self-determination trump scientific literacy for social cohesion and progress? It is difficult for educators to choose between these positions, because we are used to understanding education itself as good for both individuals and for society. The situation is such that many educators have comfortably chosen both justifications as being sound. We know of no strict contradiction between the positions. Furthermore, we find it difficult ourselves as educators to conceive of a justification for scientific literacy objectives that did not take into account the benefits for both the individual and for the society. This position is not one that we can defend here, but one we are confident would serve well science education. Our comfort rests on several considerations. First, there is no scholarly consensus on which version of political and moral life among those we have discussed is the preferable. Second, although we believe that education cannot be neutral, we also believe that it is not the role of education to select only one version of political and moral life to espouse, if there is more than one viable alternative, which there is. Third, we do believe it is the role of education to introduce students to the various forms of political and moral life that find widespread justification within our society. After all, it is the generation that is now in school that will be the one that has to grapple with these difficult and age-old issues, and for this reason is the one in need of broad exposure to more than one formulation of democratic politics and ethical living.

40.3.3 Contrast Within Moral Justifications

Under certain moral justifications scientific literacy might be argued to be *intrinsically* good, while under others it might not be an ultimate good itself but be an *instrument* for the good. If scientific literacy is part of a flourishing human life (a virtue theoretical argument), then one might conceive of such literacy as a good thing on its own (intrinsically good). If scientific literacy is valuable only insofar as it helps the economy, then it is only an instrument to the good (in this case, wealth or employment and the happiness that flows from those benefits). Such a utilitarian justification leads to an entirely different vision of science education than the preceding virtue theoretical justification. Why, for instance, should we help students to become broadly informed about science when specialization is often more highly rewarded in the job market? The answer to this question, and many like it, requires one to make the kind of distinctions we have begun to introduce here.

This contrast is very similar to the one described in the previous section. Some moral theorists argue that happiness is the greatest good and that the best society is the one in which the total utility is maximized and that utility is spread as evenly as possible across all people. Other theorists argue that individual excellence, in the form of virtues, is the greatest good, and the best society is the one in which people are the most virtuous. We argue for reasons similar to those in the previous section that education cannot choose between virtue and utility. Education can choose moral over immoral or amoral behaviour, but it is not its role to favour one version of morality over another, if all those versions find strong justification within the scholarly community. Therefore, a version of scientific literacy that sought only utilitarian goals could be critiqued on the grounds that it ignored individual excellence; a version focussed entirely on fostering virtue could be faulted for ignoring other important goals, such as the contribution to social utility resulting from making an effort to become scientifically literate.

40.4 Conclusion

We find ourselves in a position of not being able to make, all things being equal, definitive choices among justifications for the objectives of scientific literacy. Education in a way is like liberalism – it cannot (or, perhaps better, should not) choose between comprehensive conceptions of the good. MacLeod (1997) provides an excellent account of the meaning of comprehensive conceptions of the good:

> Conceptions of the good are views about the nature and constitutive elements of a valuable life. Conceptions of the good may be comprehensive or partial. A comprehensive conception of the good attempts to delineate a complete account of the sources and nature of a good life. A partial conception of the good merely identifies particular activities or projects that contribute to the realization of human excellence. Commitment to a religion can constitute a comprehensive conception of the good since adoption of a faith is sometimes viewed as grounding the meaning of a person's entire life. The idea that the appreciation of

> fine music is a valuable human activity is likely to constitute only a partial conception of the good. Aesthetic appreciation is a possible component in a good life but it does not constitute a full account of the good life. (p. 529, fn 2)

Therefore, ideally, a true education would introduce students to as many comprehensive conceptions of the good as are available. Thus, regarding moral justifications for the objectives of scientific literacy, science education should not privilege either a virtue, principled, or utilitarian justification. Likewise, regarding political justifications, science education cannot favour either political liberalism or communitarianism. Rather, science education must recognize each of these versions of moral and political life as viable and must structure the goals of scientific literacy so as to promote each alternative or at least to make the alternatives available to students so as to keep their futures as open as possible. However, science education rightly can take a negative stand against justifications for scientific literacy that are based on partial conceptions of the good. Thus, for example, a justification for the objectives of scientific literacy based only upon their role in securing employment for the individual or economic prosperity for society does not appeal to a comprehensive conception of the good unless it situates employment and economic prosperity within a more thoroughgoing conception of the good life. For example, the employment and the prosperity might be seen to lead to happier, more fulfilling, and more self-directed lives than otherwise would be possible. Alternatively, they might be seen to promote the possibility for fuller communitarian living.

It may seem ironic that science education must be designed upon a liberal footing if it is to support more than a liberal political agenda and to make available for consideration by students more than one version of moral life. This is so because between the versions of political and moral life under consideration, only liberalism takes the view that it cannot uphold one comprehensive version of the good over another. Even communitarian-motivated education, such as sectarian education, if it is to count as education and not indoctrination, must acknowledge and make its students aware of alternative versions of the good. Nothing can count as a true education that deliberately attempts to circumscribe students' futures by trying to keep morally and politically defensible options hidden or, even worse, by trying to denigrate them. This programmatic stance is the proper one for any version of science education vying for our support.

Stephen P. Norris is Professor and Canada Research Chair in Scientific Literacy at the University of Alberta, Canada. He has undergraduate degrees in physics and in science education, a master's degree in science education, and a Ph.D. in the philosophy of education. He has published extensively in philosophy of education and science education for over three decades. During the last 20 years he has published extensively on interpreting scientific text. His most recent books are: a co-authored volume with Linda Phillips and John Macnab, *Visualization in mathematics, reading and science education* published by Springer; an edited volume, *Reading for evidence and interpreting visualizations in mathematics and science education* published by Sense; and a forthcoming volume, *Adapted primary literature: The use of authentic scientific texts in secondary schools*, co-authored with AnatYarden and Linda Phillips and to be published by Springer.

(Sadly Stephen Norris died in February 2014.)

Linda M. Phillips is Centennial Professor and Director of the Canadian Centre for Research on Literacy at the University of Alberta. She holds two undergraduate degrees and a master's from Memorial University of Newfoundland and a PhD in cognition and reading from the University of Alberta. She is the recipient of national and international awards for outstanding research, teaching, and service. She has served on several editorial boards including Reading Research Quarterly; and was the senior editor for the Handbook of Language and Literacy Development: A Roadmap from 0 to 60 Months. Linda has published books, chapters and articles in top tier language and literacy venues. Her current research includes: the development of a Test of Early Language and Literacy (TELL) for children ages 3–8 years; the study of children's reasoning when reading in conventional and dynamic assessment contexts; the exploration of scientific literacy (reading when the content is science); the study of emergent and family literacy; and the use of fMRI studies in understanding reading development.

David P. Burns is a Faculty Member in the Department of Educational Studies, Kwantlen Polytechnic University, Surrey, British Columbia, Canada. He began his career teaching high school social studies in Edmonton, Alberta, Canada. He received his M.Ed. and Ph.D. in Educational Policy Studies from the University of Alberta for his research on moral education. His research interests include philosophy of education, pedagogical ethics, moral education, educational law, environmental education, science education, and teacher education.

Chapter 41
Conceptual Change: Analogies Great and Small and the Quest for Coherence

Brian Dunst and Alex Levine

41.1 Introduction

Science enjoys a privileged and unique position in Western culture. One basis for this privilege is the widely held perception that science continually produces progressively more reliable knowledge about the way our world works. The success of any new tool inspires imitators, and so the epistemic success of science has inspired analogies to other processes of epistemic and conceptual growth and change, including those that presumably take place in the developing mind of the human child. Owing to a thread running throughout Thomas S. Kuhn's *Structure of Scientific Revolutions*, psychologists, as well as historians and philosophers of science, have proposed an assortment of theories for modeling conceptual change in both science and childhood over the last half-century. Many of these models assume a robust bidirectional analogy between conceptual change in childhood development and theory change in the history of science. This analogy suggests that the relevant kinds of changes that a child experiences while acquiring and revising her conceptual makeup are sufficiently similar to the relevant kinds of changes that a scientific community undergoes over the course of its historical progression.

Enabled by this analogy, philosophers and historians of science have helped themselves to the work of developmental psychologists, and likewise developmental psychologists have helped themselves to the work of philosophers and historians of science. The fact that, in any given discussion, the analogy is usually drawn in only one direction works to conceal a potentially vicious circularity: if the analogy lends significantly to insights and inferences in one domain (say, in drawing on an

analogy from research on conceptual change in childhood in devising philosophical accounts of historical theory change in science), while the codomain from which it draws its insights and inferences relies upon an inverse analogical mapping (from the philosophical explanation of historical theory change in science to research on conceptual change in childhood), we may worry whether, after all, all this theorizing amounts to more than mere theoretical circularity.

If we are to ground either of these domains in methodologically acceptable terms, we must examine and justify the hidden assumptions that underlie this apparent reciprocal analogy between theory change in science and conceptual change in development. For instance, we can investigate whether the availability of a particular learning strategy in childhood (or science) suggests its availability in science (or childhood).[1] If no such guarantee can be maintained, reliance on such analogies is surely excessive and mistaken. In this chapter, we will show that there is perhaps a more interesting and less problematic relation between two distinct and specific ways that researchers invoke the concept of analogy: *argument by way of analogy* and reference to *analogical reasoning*. These, we argue, are distinct objects of research, but there may be an inference allowing results from the domain of analogical reasoning to inform and adjudicate the legitimacy of the arguments by analogy to which philosophers, historians of science, and developmental psychologists have helped themselves. If such an inference is possible, it means that the circularity that threatens researchers in both camps may not be a *vicious* circularity after all. In this chapter, we develop the following preliminary hypothesis: both the analogical reasoning that takes place during conceptual change in childhood and the successful arguments from analogy deployed by scientists express a quest shared by many if not all epistemic subjects: the search for coherence.

In our first section, we consider some of the more influential treatments of the relationship between conceptual change in childhood and science in the conceptual change literature, drawing attention to the extent to which both historians of science and cognitive developmental psychologists, though articulating their approaches in different technical vocabulary, have focused on conceptual change as involving not merely a change in *concepts*, but in *conceptions*. The following section turns to models of analogical reasoning of the sort that have struck participants in the conceptual change literature as promising ways of accounting for conceptual change. In our final section, we turn to the *motives* of the epistemic subject (whether child or adult scientist) embarking on the project of conceptual change.

---

[1] A fairly straightforward example – one to which we will return later – is whether mechanisms for the adoption of novel conceptions that maximize conceptual coherence and internal consistency in childhood development are necessary or sufficient for the process of scientific theory change. Similarly, we may ask whether the kinds of theoretical "paradigm shifts" that have historically occurred in science constrain the types of conceptual mechanisms that can allow for successful conceptual change in development. Stella Vosniadou and her colleagues have done extensive empirical research on these issues (cf., e.g., Vosniadou 2007; Christou and Vosniadou 2005; Vosniadou et al. 2004).

41.2 Conceptual Change as Change in Conception

As one of us has argued elsewhere (Levine 2000), Kuhn considered his early work on theory change in science to be deeply resonant with developmental psychologist Jean Piaget's genetic epistemology. For his part, Piaget saw his stage theory of genetic epistemology as attempting "to explain knowledge, and in particular scientific knowledge, on the basis of its history, its sociogenesis, and especially the psychological origins of the notions and operations upon which it is based" (Piaget 1970, p. 1). Thus, Piaget too understood his own hypotheses on childhood development as deriving at least partially from an analogy to the ways in which scientific knowledge changes historically. One can then wonder to what extent the analogy to childhood development that Kuhn meant as a support for his wider position on scientific revolutions – and through which he reasoned in formulating this position – is ultimately rooted in Piaget's intuitions about scientific revolutions. The worry is that Kuhn's appeal to the developmental analogy might be nothing but an appeal to intuition, which would weaken his arguments substantially.

Kuhn's arguments may be salvaged if the analogy runs unidirectionally (viz., from childhood development to scientific theory change, but not vice versa). As Kitcher (1988) observes, the conceptual tools forged during childhood development are available for adult scientists in their theoretical (re)conceptualizations during scientific revolutions (as well as normal science); but it is less plausible that highly nuanced and complex scientific theories are available conceptual resources for developing children. Intuitively, this places developmental psychology as *epistemically* prior to the study of historical scientific change. Unfortunately for Kuhn, while many developmental psychologists may agree with this order of epistemic priority, Piaget did not – and Kuhn himself appears to have realized this. In a telling footnote in *Structure of Scientific Revolutions*, Kuhn approvingly cites Piaget's historical sensitivity: "Because they displayed concepts and processes that also emerge directly from the history of science, two sets of Piaget's investigations proved particularly important" (Kuhn 1996, p. vii). Presumably, Kuhn believed that the close relationship that Piaget saw between childhood development and theory change throughout the history of science was evidence in support of his own thesis. The two approaches likely appeared to Kuhn as mutually reinforcing and suggestive of a more broadly *coherent* theoretical picture – which itself would have lent itself to the plausibility of Kuhn's philosophical project.

For our purposes, a paradigm case of an account that addresses the relationship between Kuhnian scientific concept change and (psychological) conceptual change in individual agents may be found in Posner, Strike, Hewson, and Gertzog's 1982 paper, "Accommodation of a Scientific Conception: Toward a Theory of Conceptual Change." In it the authors construct their account to show how individual proto-scientists go about making radical changes in their central or "core" concepts (e.g., going from thinking of physics in terms of Newtonian mechanics to thinking in terms of Einsteinian relativity), but without revising more mundane or peripheral concepts and beliefs (such as the belief that it is in fact not raining outside right now). Thus, their argument points toward the now familiar differences between (mere) concepts and (full) conceptions. Briefly, a *concept* is one node within a conceptual framework, and a *conception* is the relatively modular constellation or web of relations that define a particular knowledge domain. "Force" is a concept within a "Newtonian Mechanical" conception of physics. Posner and colleagues rely heavily on the legitimacy of an analogy drawn *from* Kuhnian scientific change literature *to* the psychological processes involved in scientific learning.

Their use of this analogy is unidirectional. They wish to show that the processes involved in Kuhnian paradigm shifts from normal science, through a scientific revolution, and into a new paradigm *are of the same kind as* those taking place within novice students of science. Initially they draw the analogy between the kinds of process involved both in historical episodes of concept change and individual episodes of scientific learning – both are processes requiring changes to be made to "core" concepts. A "core" concept is one whose character is in some causal way determinant of an entire conception. Change a "core" concept and the result is that the entire conception is qualitatively affected.

Here Posner and colleagues appropriate Imre Lakatos's distinction between the *assimilation* of "recalcitrant" (anomalous) data by making changes to the "protective belt" of auxiliary hypotheses, methodologies, and beliefs and *accommodation* of the "research program" (including making changes to its "hard core") to the recalcitrant data. In the former (assimilation), current theoretical commitments, methodologies, and scientific practices provide the "background" upon which new concepts are to be understood. If the new concepts can be reconciled in a way harmonious with these background commitments, the new concept can become accepted into the general theoretical framework of the research program without any radical revision. In the latter (accommodation), the new concept cannot be reconciled with the background commitments harmoniously, and the new concept either poses a threat to the very identity or "hard core" of the research program or is dismissed as observational error. Posner and collaborators make analogical use of "assimilation" and "accommodation" in their account of scientific learning. Learners "assimilate" by using their current conceptual commitments as a basis or background in assessing new phenomena or concepts. When the new phenomena or concepts resist cohering with background conceptual commitments, they must instead be "accommodated."

Piaget (1953) also prominently features the concepts of assimilation and accommodation in his theory of genetic epistemology. For Piaget, the processes of assimilation and accommodation form a dialectically coupled adaptive system. An attempt at assimilation is an attempt to fit one's occurrent state of affairs to one's occurrent belief system. Piaget likened successful assimilation to successful biological adaptation. When assimilation fails as an adaptive mechanism or strategy, learners must attempt accommodation – changing their occurrent belief structure to fit with the occurrent state of affairs. Importantly, Piaget saw *both* processes of assimilation and accommodation as necessarily altering one's conceptual structure. Thus, any assimilation necessarily requires *some* accommodation, and any accommodation is accompanied by assimilation. This would seem to contrast with the Posner group's usage of "accommodation," unless we understand their emphasis as a matter of degree: the sense in which they use the term accommodation is said to occur only under conditions of radical revision in conceptual structure.

Borrowing from Stephen Toulmin (1972), Posner and colleagues refer to the causal interdependence between one's concepts and conceptions as one's "conceptual ecology." The issue central in their discussion is identifying the conditions and features of conceptual ecologies under which scientific learners come to *accommodate* new core concepts. Toward this end, they outline four primary conditions severally necessary and jointly sufficient for accommodation to occur:

1. There must be dissatisfaction with existing conceptions.
2. A new conception must be intelligible.
3. A new conception must appear initially plausible.
4. A new concept should suggest the possibility of a fruitful research program. (Posner et al. 1982, p. 214)

It should be clear that these conditions are meant to align to similar Kuhnian conditions for adopting a new scientific paradigm. These conditions would look something like the following:

1. There must be dissatisfaction with the existing theoretical scientific framework(s).
2. A new scientific paradigm must be intelligible.
3. A new scientific paradigm must appear initially plausible
4. A new scientific paradigm should suggest the possibility of a fruitful research program.

Each of these four conditions needs to be met in order for a new theoretical paradigm to be taken up by a scientific community. Kuhn famously belabored how difficult it is for a single person to bridge the divide between two paradigms. However, if Posner and colleagues' analogy is to hold, this is precisely what occurs in the process of conceptual accommodation. Drawing directly from Kuhn's arguments, Strike and Posner later argue that – for similar reasons – changes to one's scientific conceptions, or to core concepts, are likewise difficult: "If one assumes that misconceptions are similar to paradigms, these views provide obvious reasons why misconceptions will be resistant to change, even given contrary instruction" (Strike and Posner 1992, p. 153). This is one reason, they say, that explains why established misconceptions are so robust and persistent in the context of science learning.

Posner and colleagues identify other constraints that keep learners from assimilating (and thus push toward accommodation). These constraints are features of the learner's conceptual ecology that are particularly influential in deciding which concepts come across to the learner as the most plausible. Thus, their model of conceptual succession is recursive: the character of the current conceptual ecology casually influences or determines the successor conceptual ecology. In the case of core concept change, this means that there are conceptual ecological factors that constitutively factor into shaping the character of the new (successor) core concept(s).

There are two assumptions worth mentioning about the kind of learners that Posner and colleagues are talking about here: first, they are rational. The decision procedure involved in their account of core concept change depends on the learner's being capable of rationally weighing the evidence and choosing the best alternative on well-reasoned grounds. Thus, the authors assume with Allison Gopnik that science learners are already "little scientists." The second assumption is that conceptual knowledge is essentially representational. Elsewhere (Levine and Schwarz 1993; Brooks 1991), both of these assumptions have been problematized, but it is worth noting that the view Posner's group put forth is fundamentally tied to them.

With this in mind, the remaining conceptual ecology constraints are the character of the anomalies affecting current concepts, analogies, and metaphors used to make novel concepts intelligible; epistemological commitments such as current explanatory ideals and views about the character of knowledge; the metaphysical beliefs and concepts that make sense within the current conceptual ecology, whether knowledge in other fields coheres with new concepts; and the character of concepts in competition for accommodation. Given these myriad conflicting constraints, concept change is difficult. Whenever possible, learners will attempt to assimilate rather than accommodate new concepts. Only when assimilation doesn't work does accommodation become a practical possibility – and only when a novel concept can be seen as intelligible does accommodation become a plausible action.

Just as Kuhn later qualified his claims about incommensurability, Posner and colleagues qualify their claims about the processes involved with accommodation. Specifically, they preserve the possibility of partial accommodation, in which the process of accommodation is not a binary, all-or-none affair. This means that for any given conceptual core, there may be unresolved inconsistencies or incomplete explanations. It follows that accommodation needn't be abrupt. It may take some time to make all the revisions necessary to move from a change in core *concept* to a change in overall *conception*. Given the number of causal variables and interactions in a conceptual ecology, the process of accommodation will also most likely be nonlinear and involve a process of trial and error and revision in order to cohere the core and peripheral concepts of a conception.

All of these qualifications fit nicely with Kuhn's later (1970) amendments to his account of theory change in scientific communities wherein he makes room for external beliefs and values in playing a (nonlinear) causal role in the processes of theory adoption. As is now well known, Kuhn's later views downplayed radical incommensurability, which in turn opened the door for closer analogies between scientific practice and developmental psychology (cf., Hoyningen-Huene 1993; Levine 2000). There is no question that Posner and colleagues' account of core concept change as the causal inter-workings of a learner's conceptual ecology draws a strong analogy from the Kuhnian literature. Strike and Posner later write:

> We have been substantially influenced by those theories of rationality that have been developed by authors such as Kuhn, Toulmin, and Lakatos…the substantive conceptions (of Kuhn's paradigms and Lakatos' research programmes) suggest what are to count as problems and what is to count as relevant evidence. Indeed, they provide the perceptual categories by which the world is perceived…Such accounts of rationality can be easily turned into accounts of rational learning suitable for pedagogical purposes. (Strike and Posner 1992, pp. 151–2)

While Strike's and Posner's optimism is commendable, and their utilization of the general Kuhnian framework is interesting and fruitful as a research program, what remains to be seen is whether such a strong analogy is warranted. Are the kinds of learning experiences science learners undergo sufficiently like historical changes in scientific communities? In order to assess this question, we would do well to understand exactly what features are meant to be analogous and which aren't. And to do this, we must first get clear on the kind of relationship an analogy conveys.

41.3 Analogy

For the purposes of this chapter, we will be utilizing a variant of the Structure-Mapping approach to analogical reasoning originally developed by Dedre Gentner (1983). This approach employs a basic distinction between what it calls "source" and "target" domains. In discussing conceptual change in childhood or science, the domains are typically supposed to be conceptions or theories, together with modes of conceptual or theoretical change.[2] For ease of exposition, we will be employing the term "theory" to represent both scientific theories, as well as conceptions. The presumed analogy between theories operates as a functional mapping from the source domain to the target domain. Typically, the source domain is taken to constitute a more reliable object of knowledge than the target domain. These analogical mappings can accommodate different degrees of structural stringency. The strongest mapping, and upper bound, for stringency in an analogy is identity between source and target domains. If the domains are *identical*, the mapping is not appropriately called an analogy (rather, it is an endomorphism – a mapping from a domain back to itself). Short of identity, the next most stringent class of mappings is *isomorphisms*, mappings that maintain source domain relations among elements of the target domain.

Less stringent are *homomorphic mappings* for which the mapping function defines a transformation wherein some, but not all, of the relational structure is maintained. There are at least two interesting kinds of homomorphic structural mappings: those whose domains *differ in kind* and those whose domains *differ in degree*. In a homomorphic mapping between different kinds, the source and target domains

---

[2] This presupposition is typical of, though not exclusive to, "theory-theory" approaches to the developmental attainment of conceptual tools for dealing with human behavior, where the theory most children acquire is variously called "folk psychology" or "theory of mind." In such contexts, the debt owed to the history and philosophy of science is often explicitly acknowledged, as in the title of Piaget student Annette Karmiloff-Smith's (1988) essay, "The Child is a Theoretician, not an Inductivist." In another example, Allison Gopnik observed that the tendency of developmental psychologists to refer to a child's conceptual knowledge base as a "theory" is a reflection of the extent to which developmental psychology must be previously informed by the history of science. She writes (1996): "cognitive and developmental psychologists have *invoked the analogy of science itself*. They talk about our everyday conceptions of the world as implicit and intuitive theories, and about changes in those conceptions as theory changes" (Gopnik 1996, p. 485, emphasis added).

are taken to be independent knowledge stores. There are very few if any recognizable entities common to both source and target domains. Homomorphic mappings between domains that differ in degree are taken to draw from one conceptual knowledge store but in ways that preclude identity (allowing us to consider the source and target domains as effectively distinct).

A good example of an analogy whose source and target domains differ only in degree is Darwin's argument by analogy in *The Origin of Species*. There are two analogies that comprise the backbone of Darwin's argument. First is his analogy for the mechanism of evolution. He draws from the source domain of "artificial" selection (animal husbandry) whose effects were well known and documented to the target domain of "natural" selection which was to work via the very same functional mechanisms (selective retention of favorable characteristics) as artificial selection. The identity of the underlying mechanism of change in both domains (selection) suggests the difference between them is merely one of degree. What differs is the amount of time required for the phenotypic effects of either process to noticeably accrue and the physical means by which selective retention operates (human breeders selecting breeding pairs in artificial selection and random mutation and the "struggle for existence" in natural selection). Darwin applies a second analogy between the conventional taxonomic units *species* and *variety*. He argues by way of analogy that different varieties differ from each other just as different species differ from each other – that is, the differences (all around) are *of a* kind (not *in* kind). The only *difference* between variety-difference and species-difference is in the degree of phenotypic divergence. As Darwin puts it, "a well-marked variety may be justly called an incipient species" (Darwin 1859, p. 52).

Even less stringent than homomorphic mappings are *congruence relations*, which do not provide well-defined transformative functions directly between source and target domains, but for which an intermediate domain can be constructed. A pair of homomorphisms can then be given defining transformations from source to intermediate and from intermediate to target domains. Important in congruence relations is that transitivity strictly cannot be maintained through both transformations (viz., from source, through the intermediate, to the target domain). We will call the intermediate domain the *transfer domain*. The limiting case of analogical mapping is *disanalogy*, wherein there is no readily apparent congruence relation.

For present purposes, this taxonomy of analogies will serve two distinct but related functions. First, it will help us to get clear on the nature of the often invoked if seldom scrutinized analogy between conceptual change in science and conceptual change in childhood. Different sorts of analogy support different sorts of inference. If we suppose that the two domains of conceptual change are isomorphic, the analogy between cognitive development and the history of science ought in principle to support inferences in both directions with the risks outlined above. If, on the other hand, they are connected only by congruence relations, such risks are mitigated – but then arguments that invoke such an analogy carry significantly less weight than often assumed.

But our discussion of analogy serves a second purpose. Recognition of the prevalence and significance in the conceptual change literature, of an analogy between conceptual change in childhood and conceptual change in science, led us to consider the role of *argument* by analogy in general. Confusing matters is that within that same literature, processes such as *argument from analogy* and *analogical reasoning* have also been touted as playing central roles in the actual cognitive processes of conceptual change. Let us assume, for the moment, that whatever the precise nature analogy between childhood development and scientific change, it is close enough to allow us to treat argument from analogy *as a species of* analogical reasoning (Gentner 1983). In that case, the precise entailments of this analogy may well be illuminated by an account of the role of analogical reasoning in conceptual change. That is, by getting clearer on the ways in which analogical reasoning functions, we will be in a position to better understand whether arguments by analogy relating conceptual change in science and childhood development are as problematic as they seem.

Analogical reasoning is often used in mapping congruently related conceptual domains and, for the purposes of analysis, often requires carefully constructing a transfer domain. But how are transfer domains constructed? Or, to address our specific concerns more directly, how can a novel theory be discovered, developed, or changed? Many commentators (notably Susan Carey) think it is reasonable to suppose that this task necessitates some sort of "bootstrapping" process imaginatively drawing upon available cognitive resources. As we have seen, Posner and colleagues require that successor core concepts causally depend on the current state of one's conceptual ecology. There are many accounts of the possibilities and constraints constitutive of such available resources, though the proper exposition of even the most plausible of these theories is far too ambitious for the scope of this discussion (see instead, e.g., Carey 2009 and Strike and Posner 1992). Additionally, we may wonder whether the necessary bootstrapping process is systematic enough to give rise to what might plausibly be called a theory. It would be enough, for starters, to articulate a theory of analogical reasoning consistent with the constraints operating in any one of the domains of conceptual change, if not all of them at once.

As an example of the construction of a transfer domain, we consider an idealized analogy between the solar system and the atom, as Ernest Rutherford would come to understand it. For our source domain, we select the solar system as described by Newtonian mechanics. Presumably, we are constructing an analogy between the solar system (source domain) and the atom (target domain) in order to explain or understand some aspect of the atom that has previously escaped our grasp (viz., the experimental evidence that it is composed mostly of empty space). In such cases, an analogical transfer domain can be used as a cognitive resource to model the relevant aspects of the target domain. It should be noted that the reason we use the solar system–atom analogy as an example of a congruence mapping (rather than the stronger homomorphic mapping) is because much of the relational structure is not maintained between the two models. Electrons possess substantially different properties and behave in drastically different ways from planets in their orbits about the Sun. Since the analogical relation is more metaphorical than literal, we are put in a position of needing to "spell out" more precisely how the analogy is to work. To do this, we draw an intermediate analogy to some other domain that helps clarify the analogical relation in both domains. In general, the need for a transfer mapping is indicative of a congruence analogy for the precise reason that the difficulty or impossibility of an adequate direct mapping precludes a homomorphic approach.

Through a process of abstraction, we can compile a set of comparable attributes between the source and target domains. This set will comprise the transfer domain. First, let us state the source and target domains:

(S): The solar system contains less massive planets that centripetally orbit a more massive Sun, with most of the volume of the solar system occupied by empty space.

(A): The atom is comprised of constituents similar in various ways to positively and negatively charged particles (α and β particles) recently observed. The whole is largely transparent to energetic α particles (see Geiger and Marsden 1909; Rutherford 1911) and must thus be mostly empty.

We have purposefully worded these two descriptions so as to easily lend themselves to common abstraction. In vivo, the process of honing the language used for comparison would likely be a more complex process involving multiple steps, each utilizing analogical reasoning. One can imagine a child (or scientific community) working through a series of partial, transient, provisional, and defeasible analogical reasoning processes in order to formulate the *source* domain of a more general transfer mapping. Finding an effective transfer domain is likely a hard-won victory. Additionally, there may be many alternative abstractive partitionings of specific contexts or problem situations for each of (S) and (A). Our task is to create one, (T), for which we can simultaneously define homomorphic mapping functions from (S) to (T) and from (T) to (A). There needn't be one and only one mapping of this kind. It stands to reason that with a greater number of potential mappings comes increased likelihood of the successful construction of a transfer domain – as an increase in potential mappings corresponds to an increase in available cognitive resources (such as concepts, conceptions, and conceptual relations, among others). For the sake of this example, we now provide one such transfer domain:

(T): The model contains entities that orbit a central object, bound by an attractive force exerted from the central object on the orbiting entities.

We are now able to construct a pair of homomorphic mappings (analogies): one abstraction from (S) to (T) and one instantiation from (T) to (A). So long as we succeed at constructing such mappings, we are guaranteed to meet certain relevancy criteria – in fact, the transfer model itself functions as a minimal relevancy constraint for the analogical task.

Now that each of the source and target model can be expressed in terms of the abstract transfer model, we have grounds for inductive hypothesis testing to help determine whether the relevancy constraint established by the transfer domain survives further observation. By discovering relevant similarities and dissimilarities through this process, we have assembled a procedure by which we can come to understand the target domain better. The point is just that such analogical comparison establishes a mechanism for generating testable hypotheses. More generally, such a process of mapping from a source conception to a transfer conception and then again from the transfer conception to a target conception allows for a learner to make the requisite transition from one conceptual ecology to a new one – or to shift from a misconception to a correct conception. A larger worry remains with the question as to whether analogical transfer mappings are *actually employed* by children or scientific communities in vivo. Nancy Nersessian has argued that in at least some contexts of scientific modeling, this does occur (Nersessian 2008, pp. 206–207). However, it remains less obvious that childhood conceptual development employs such a mechanism.

Gentner and Markman have devoted significant attention to the structures and relations that impose psychological constraints on analogical reasoning. In particular, they understand analogy as dependent on our psychological abilities to "align" or to bring into attunement the basic structures (or gestalts) of the domains involved in the attempted analogy (Gentner and Markman 1997). They identify three specific psychological constraints on analogical reasoning:

1. *Structural consistency*: It must observe parallel connectivity and one-to-one correspondence. Parallel connectivity requires that matching relations must have matching arguments. One-to-one correspondence limits any element in one representation to at most one matching element in the other representation.
2. *Relational focus*: Analogies must involve common relations but need not involve common object descriptions.
3. *Systematicity*: Analogies tend to match connected systems of relations. The systematicity principle captures a tacit preference for coherence and causal predictive power in analogical processing. (Gentner and Markman 1997)

Important for Gentner and Markman are not only the *similarities* in structures but the *differences* as well – both similarities and differences are alignable. They understand analogical reasoning to involve an iterable process of connecting one domain to another. On the taxonomy we have developed here, what is interesting in Gentner's and Markman's "structural alignment framework" is that it implies that through the processes of analogical reasoning, we can *massively* and *in parallel* employ multiple *transfer mappings* in an iterable fashion – one transfer mapping after another, connected in serial. Presumably, the only stop to such a process occurs when some psychological state of relative equilibrium is reached. The question that remains is what the conditions for such equilibrium could be (i.e., *in what* is there equilibrium? External coherence? Internal consistency? Practical applicability?)

Susan Carey, for her part, writes extensively on the kinds of mechanisms required to satisfy what she believes are the constraints on childhood learning. For her, an innate conceptual core in conjunction with a "Quinean bootstrapping" process that incorporates available external resources is necessary for the possibility of coming to understand the kinds of complex scientific theories that members of our scientific communities clearly require. Carey is concerned with the conditions and constraints operative in cognitive development that allow (or in some cases prohibit) an agent to come to understand, for example, continuous rather than discrete conceptions of number. Such "theoretical" understandings underwrite the more complex scientific theories that utilize and employ them. So for Carey, theory development and construction always recursively operate on current cognitive resources, which include an agent's prior theoretical attainments, a mode of communication capable of translating from a standing theory (source) to a novel one (target), as well as physically and socially available resources (e.g., external tools for learning, teachers). In many cases, the "novel" theory is not truly novel in that it is included in some of the available resources; for example, teachers already possess a solid understanding of the target theoretical domain (cf., Carey 2009, pp. 413–445).

Crucial to Carey's and others' formulations of theory change is that incommensurability is always local. Largely in response to criticisms of *structure*, the later Kuhn came to think of theory incommensurability as analogous to localized problems of translatability between languages, in contradistinction to his early claims of global incommensurability (roughly analogous to Quinean radical indeterminacy of translation). Carey's "Quinean bootstrapping" process precludes global incommensurability and untranslatability in that more basic concepts, theories, language use, and practices remain relatively unaffected by specific theoretical alterations. For example, in the midst of a conceptual theory change from discrete to continuous number theories, a child's beliefs and theoretical understanding about colors may be unaffected at first. It is possible that a theoretical conceptual change causes a cognitive agent's understanding to undergo global change – but not all at once. Eventually, the child may come to understand difference in hue as a continuous difference, but perhaps not, and perhaps not at first. Carey is at pains to emphasize that the process of Quinean bootstrapping (and the associated conceptual change it enacts) is difficult, often incomplete, and takes a lot of time.

An alternative approach toward the dynamics and constraints involved in conceptual change is the "Multiple-Interaction" approach discussed by Nira Granott (1993). She suggests that highly important to factors formative in a learner's conceptual development are the kinds of social contexts and interactions fostered and engaged in by both novices and experts. Instead of referring to individual and isolated psychological processes, Granott proposes that analysis should reflect the *social* etiology of cognitive processes. Her model differentiates (as a matter of degree) first between collaborative and disruptive interactions. Second, she tracks the degrees and types of expertise involved in interactions and the degrees of involvement of each participant. Some of the categories involved in her multidimensional analysis include *mutual collaboration* between equal peers; *symmetric counterpoint* relationships between interactants who take varying approaches to solving the same problem; *parallel activity*, in which individuals attempt to solve a problem in a relatively isolated (but coordinated) way; *asymmetric collaborations* between novices and experts; and *asymmetric counterpoint* relationships between novices and experts. Granott acknowledges that such relationships may also turn disruptive and that there are myriad other social factors that affect conceptual development (such as expertise in irrelevant domains, social roles, gender, race, personal histories of previous interactions, dynamic personality traits). But the general point is that perhaps Quinean bootstrapping is not the only factor required in conceptual development or at least that it shouldn't be focused on to the exclusion of other social factors.

41.4 Coherence

Our discussion thus far has pointed to the significance of conceptual change not as a change in concepts but as a change in *conceptions*. Such change, we have argued, involves the construction of mappings across conceptual domains. We have yet to consider the epistemic subject's *motives* for constructing such mappings. With this third piece in place, we will finally be in a position to articulate the hypothesis we advertised at the beginning of this chapter concerning the relationship between conceptual change in childhood and science: both express the epistemic subject's quest for coherence.

In a well-known discussion, Paul Thagard has argued that in conceptual change, cognitive agents are often motivated by a need to cohere all theoretical beliefs. He defines, and for the purposes of this chapter, we follow him in defining, the notion of conceptual coherence as follows:

1. Conceptual coherence is a symmetric relation between the pairs of concepts.
2. A concept coheres with another concept if they are positively associated, i.e., if there are objects to which they both apply.
3. The applicability of a concept to an object may be given perceptually or by some other reliable source.
4. A concept incoheres with another concept, if they are negatively associated, i.e., if an object falling under one concept tends not to fall under the other concept.
5. The applicability of a concept to an object depends on the applicability of other concepts (Thagard 1992; Thagard et al. 2002; Thagard and Verbeurgt 1998).

Reconsidering the example of the transformation of color conceptions discussed previously, Thagard's notion of conceptual coherence (and incoherence) suggests that the developing agent's naïve theory of color was incommensurable (or "incoheres") with a new understanding of continuity in number as well as with phenomenal and empirical evidence (perhaps from recently seeing a rainbow and its continuous blending of hues). Kuhnian historians of science, as well as more recent contributors to cognitive developmental psychology, might see such motives at work in participants in the "crises" that accompany scientific revolutions. To Thagard, what makes a crisis is that incoherence appears as problematic for us both as individual subjects and as members of scientific communities – conceptual incoherence is something that begs for remedy. In this, way we may finally see an anchor for an appropriate transfer domain in a useful analogy between concept change in childhood development and theory change in scientific communities: in both cases, the primary motivation is to cohere our understanding about the world. We might understand this drive toward coherence as underwriting scientific methodology as well as childhood curiosity or even as the primary underlying thread in analogical reasoning – especially in congruence mappings necessitating the utilization of a transfer domain. The institutionalization of scientific practice is nothing over and above the value that each of its communities' members places on coherence. This valuation of coherence by each member of a scientific community is no different *in kind* from the importance attached to coherence by a curious child. If there is a difference between these two, it is of *degree* or in the mode of implementation; and the analogy between them remains strong. If there is no difference, the analogy collapses into an identity – the claim that children are engaged in precisely the same coherence-resolving activities as adult members of scientific communities.

Considered from the vantage point of research in conceptual change, learning scientific concepts is often understood as replacing one's state of confusion, misconception, or overly simplistic or "common sense" understanding of a knowledge domain with more complex or theoretically sophisticated newer models. Strike and Posner (1992), for example, regard the replacement process as necessarily involving cognitive dissonance between actively conflicting conceptions. Generally, such conceptual change is understood as the comprehensive replacement of entire conceptions within a particular knowledge domain, rather than the piecemeal replacement of individual concepts within an overall conceptual or theoretical structure whose structure is preserved (cf., e.g., Vosniadou and Brewer 1992; Carey 1985; Chi 1992; diSessa 1988; Posner et al. 1982). Such a conceptual structure is thought to undergo a process of holistic reorganization until a stable or consistent set of interrelated and more scientific conceptions is attained. Again, Strike and Posner (1992) see this process as a decision (of sorts) between competing conceptions – one of which provides a more intelligible, coherent, plausible, and fecund outlook for the knowledge domain than the alternatives.

More recently, there has been substantial debate about the extent to which conceptual change in childhood succeeds at fulfilling the conditions of intelligibility, coherence, plausibility, and fecundity. As recently canvassed by Rusanen and colleagues (2008), "There is [now] a large body of experimentally based literature where it has been argued that the difference between the consistency or coherence of the belief systems of novices and experts is one of degree, not of kind" (Rusanen et al. 2008, p. 65; cf., e.g., Vosniadou 2007; Christou and Vosniadou 2005; Vosniadou et al. 2004). Some researchers, for instance, have proposed that novice "explanatory frameworks" are themselves already internally coherent, consistent, and interrelated sets of beliefs in a sense evocative of Kuhnian "Paradigms" (Samarapungavan and Wiers 1997). Others, such as Chi and her colleagues, have argued that novice belief systems exhibit "ontological" conceptual coherence (Chi 1992; Chi and Slotta 1993; Slotta and Joram 1995). Alternatively, there are also those who disagree with these characterizations of novices' belief systems. Andrea diSessa (1993) and Smith et al. (1994), for instance, describe novice learning as relying not on coherent, systematic theories but rather as more or less unorganized, context-sensitive elements belief-like primitives that are systemically inconsistent and thus do not cohere. In diSessa's "knowledge-in-pieces" account, naïve physical knowledge is organized into phenomenological primitives or "p-prims" – a novice's simple explanations abstracted from experiences and uncritically accepted (diSessa 1983).[3]

---

[3] We are grateful to Anna-Mari Rusanen for pointing us toward many of the works cited in this paragraph.

There is much to be said about whether and to what extent the value of coherence is socially inculcated (perhaps as a resource for Quinean bootstrapping of concept change) during childhood development. But our discussion has perhaps more clearly shown that as a matter of both causal influence and epistemic priority, the relation between childhood development and historical theory change in science is something of a chicken-and-egg problem. One cannot be resolved without necessary reference to the other. If there is something, then, that underwrites the analogy between the two, it is that both developing children and scientific communities share the (perhaps often implicit) underlying valuing of coherence, which acts to regulate the quest for knowledge. So, while the particular material and conceptual resources available to developing children on the one hand (e.g., social and cultural educational tools, practices, and resources) and adult members of a scientific community (e.g., the institutions and the tools and practices deployed scientific research) on the other are clearly distinct and different from each other, the underlying coherence-seeking processes by which each domain operates contribute to genetically informing and reinforcing the same process in the other. Thus, this relationship between Kuhnian theory change in the history of science and developmental conceptual changes in children should perhaps not be seen or understood as an *argument by analogy* as much as a complex causal interrelationship in which both domains materially depend on *analogical reasoning*. Along with hosts of other cognitive and methodological resources, these analogical reasoning methods causally factor into and influence the relations that genetically inform and reinforce particular epistemic developments in both developing children and adult scientists.

His research interests include the interactive relationships between epistemic agents and their environments. He has recently received his doctorate in philosophy from the University of South Florida.

Alex Levine is Professor of Philosophy at the University of South Florida, Tampa. He earned his M.A. and Ph.D. in philosophy at the University of California, San Diego, and his B.A. in philosophy and mathematics at Reed College. His scholarship has contributed to the history and philosophy of science as well as to the philosophy of mind and includes several papers on the connections between the two fields pertaining to accounts of conceptual change. He has recently published two coauthored books on the reception of Darwinisim in Latin America, *From Man to Ape* (Chicago, 2010) and *Darwinistas* (Brill, 2012). He has also been active as a scholarly translator.

Chapter 42
Inquiry Teaching and Learning: Philosophical Considerations

Gregory J. Kelly

> *Indeed, the very word 'cognition' acquires meaning only in connection with a thought collective.*

42.1 Inquiry in Science Education Reform

Debates regarding science education go through various stages of reform, perceived change, and more reform (DeBoer 1991). These changes have centered on the extent to which students' interests, autonomy, and knowledge are balanced against the cultural knowledge of the legitimizing institutions. Dewey (1938a), Schwab (1960), Rutherford (1964), and more recently the (USA) National Research Council [NRC] (1996, 2011) have, in various ways, called for engaging students in the scientific practices of professional scientists. These calls for reform conceptualize inquiry differently, and each can be viewed as making a set of assumptions about knowledge, science, students, and learning – thus suggesting the need for examining epistemological issues in science teaching and learning. In this chapter I consider some of the opportunities afforded by an inquiry-oriented science education but also the constraints to successful implementation of inquiry in schooling.

Inquiry in science entails conducting an investigation into the natural or designed world, or even into the applications of scientific knowledge to societal issues. Such investigations typically concern a domain for which at least some of the participating inquirers do not know the results prior to the investigation. Dewey (1929, 1938a) characterized inquiry as dialectical processes emerging from problematic situations

aimed at reaching some resolution.[1] Inquiry has been characterized as engaging learners in scientifically oriented questions, formulating and evaluating evidence and explanations, and communicating results (National Research Council 1996). As such, inquiry is derived from views of knowledge, is underwritten by interpretations of knowledge, and instantiates perspectives on knowledge. Furthermore, the referent for what counts as inquiry activity need not be limited to the work of professional scientists, as other members of society can be viewed as engaging in scientific practices. Thus, inquiry science poses epistemological questions, and with a focus on science education, these questions can be addressed from a philosophy of science point of view.

Interesting questions arise as to whether inquiry science teaching is directed at learning knowledge and practices of science or at aspects of the nature of science or both. We can speak of learning science through inquiry, where inquiry is the means to learn knowledge and practice. Or we can view the pedagogy as inquiry about science where the intent is to communicate lessons about the nature of science. Often these perspectives on inquiry purposefully brought together, so that learning knowledge and practices through inquiry serves to inform students about science by engaging in the practices constituting scientific activity. I will refer to the dual purpose approach as teaching science as inquiry. As each of these views of inquiry presupposes views of scientific knowledge and thus manifests an epistemological orientation, we would expect to find implications of the philosophy of science for teaching science in this manner. Nevertheless, the relationship of inquiry teaching and philosophy of science is not straightforward.

42.2 Educational Challenges of Teaching Science as Inquiry

There are a number of important challenges to teaching science as inquiry. First, through many years of research and across different learning theories, it is clear that students need concepts to learn concepts. Students learn concepts in bunches, and these cannot be typically investigated one at time through (even careful) classroom-based practice activities or empirical investigations. Educators should not assume that students are able to induce sophisticated scientific concepts from empirical phenomena. While few educational programs explicitly assert that students construct knowledge in the absence of more knowing others, a number of perspectives suffer from this assumption, often under various banners such as hands-on learning, discovery, or radical constructivism (Kelly 1997). As some knowledge is required to learn, then inquiry approaches that situate the student at the center of investigation need to recognize that only with sufficient, relevant background knowledge can answerable questions be posed by students. Thus, inquiry approaches to science

---

[1] Dewey's (1938a) definition is as follows: "Inquiry is the controlled or directed transformation of an indeterminate situation into one that is so determinate in its constituent distinctions and relations as to convert the elements of the original situation into a unified whole" (pp. 104–105).

learning need to consider the importance of learning through engaging in activities and discourse of science with more knowing others.

A second challenge for inquiry instruction is that learning science entails more than learning the final-form knowledge of scientific communities (Schwab 1960; Duschl 1990). While propositional knowledge (*knowing that*) is important, knowing how to engage in scientific practices and how to make epistemic judgments ought not be neglected. Therefore, science learning should include conceptual, epistemic, and social goals (Duschl 2008; Kelly 2008). While much of inquiry has focused on students' engagement in practical or laboratory activities, pedagogies focused on socioscientific issues and science in social contexts pose important opportunities to learn through investigations in unknown domains (Sadler and Fowler 2006). Inquiry can arguably include evaluation of expertise, certainty, and reliability of scientific claims of others.

A third challenge to learning science as inquiry concerns the nature of the intended propositional or procedural knowledge (*knowing how*) in the curriculum. Science topics and community practices may be more or less appropriate for an inquiry approach. Some knowledge and practices may be attainable through student-centered approaches, while others require the direction of more knowing others. Clearly, at least some scientific practices can be learned only through intensive effort, which may require extensive participation in a community of learners. Other topics might be suited for other forms of instruction. Furthermore, methods of assessment, either formative or summative, need to be carefully chosen to match the learning goals appropriate to the knowledge sought.

Fourth, learning the conceptual knowledge, epistemic criteria, and social practices over time in science domains may require coordination of scope vertically (across grades over time) and horizontally (across subject matter areas at a given grade) across the curriculum. While academics find ways to separate disciplines, and there may be interesting epistemological distinctions, students experience schooling as a whole. Science may not be separate from views and knowledge of history, mathematics, reading, writing, and so forth. Thus, the challenge for teaching science as inquiry includes understanding how such approaches can be supported or undermined by other curricular decisions and pedagogies, both from within and from outside science programs.

Despite these challenges, inquiry teaching and learning have been advocated in different forms many times across generations (most recently, see NRC 2011). The potential for learning knowledge and practices of disciplines through engagement in purposeful activity has been recognized both as a means to learn science and as a way to develop student interest. The linguistic turn in philosophy and the continual rediscovery of the importance of learning through participation in discourse practices of epistemic communities have led educators to examine ways that inquiry can be enacted in various settings. This potential of engaging in discourse practices as inquiry has not always been realized, and there is still considerable debate about the nature of inquiry and its overall merits (Blanchard et al. 2010; Kirschner et al. 2006; Kuhn 2007; Minner et al. 2010). Much of the debate fails to recognize the relationship and disagreement among the learning goals, limited measures of assessment, and the purposes of education – that is, rhetorically, the interlocutors argue past each other. Much of this debate regarding differences in traditional and experiential education was identified in Dewey's (1938b) *Education and Experience*. Has the field advanced since? How can philosophy of science help? To address these issues, I consider some challenges for using philosophy of science in science education.

42.3 Challenges for Using Philosophy of Science to Inform Inquiry Science Teaching

Just as inquiry poses challenges because of the realities of teaching and learning science, drawing from the philosophy of science to inform science education poses challenges because of the nature of philosophy. Educators have called for developing philosophically informed science curricula (Hodson 2009). While this is a welcome perspective, in this section I examine the assumptions of the application of philosophy of science to science education and note that some of the difficulty lies not with educators' misunderstandings about philosophy but rather with the nature of philosophy as a discipline. I identify four dimensions of this difficulty.

First, the philosophy of science treats a number of technical issues that may not directly inform educational practices. Throughout the history of the philosophy of science, issues such as inference, perception, and abductive reasoning form the basis for a number of technical arguments conducted by specialists. These arguments are important for the development of the field of philosophy of science and may advance understanding about the nature of science, but do not necessarily lend themselves readily to educational applications. For example, one debate concerns arguments for an instrumental versus realist view of scientific theories (van Fraassen 1980; Boyd 1991): Do theories serve as predicting devices or rather do they refer to real objects in the natural world independent of our theory-dependent views of such objects? While there is something at stake in philosophy, and indeed plausibly for education, regarding instrumentalism and realism, the technical arguments do not necessarily lead to specific implications for education. For example, scientific realism and constructive empiricism recognize the strong theory dependence of scientific methods. Procedures and inferences about actions in the course of an investigation are dependent on the extant theoretical knowledge of the inquirers. This level of consensus may be enough to develop science curricula that propose reasonably informed experiences for students, without a final answer to the instrumentalist-realist debates. While the particulars of the debate may not have easy answers for education, there are useful tools and ways of thinking in philosophy of science that have merit for education.

Second, philosophy of science includes different perspectives and knowledge that change over time. As philosophy of science changes, educators need to work to understand those changes and update their own of philosophies of science. Furthermore, this effort will be complicated by the number of philosophical positions. For example, Laudan (1990) broadly identifies four major research traditions: positivist, realist, relativist, and pragmatist. Within any one of these perspectives, there is considerable variation. For example, Dewey's (1938a) pragmatism refers to science as an approach to reasoning; Toulmin's (1972) pragmatic point of view provides historical evidence from the history of science to examine conceptual change over time; Rorty's (1991) pragmatism seeks to change the nature of the conversation from technical philosophical debate to thinking about the usefulness of knowledge, be it science or other. Thus, the nature of philosophy of science is itself variable and like science fields experiences changes through research.

Third, philosophy of science has historically been normative and relatively apolitical (with a few exceptions, see Matthews 2009; Rouse 1996). Some of the central goals of philosophy of science concern questions about how science should be practiced, rather than the actual practices occurring in real settings. While some motivation for the study of scientific reasoning emerged from the realization of scientific knowledge as remarkably (and perhaps uniquely) reliable, the focus of philosophy of science has historically been on studying structure and change of scientific theories (Suppe 1977). Machamer (1998) characterized philosophy of science as concerned with the nature and character of scientific theories, the history and nature of inquiry, the value systems of scientists, and the effects and influences of science in society. While such a view expands beyond a focus on theory, the focus of the discipline has traditionally been normative – thinking about ways that reasoning should occur to lead to reliable results. This poses challenges to educators. Developing an inquiry orientation around socioscientific issues requires some consideration of the messy, ill-formed reasoning and ambiguity that surrounds science in society. Additionally, even in highly controlled settings, the reasoning patterns of students are likely to vary from the logical rigor demonstrated in philosophy. Therefore, models of conceptual change from science disciplines can at best be viewed as analogies for promoting thinking about student learning.

Fourth, the complexity of philosophy of science, and science studies more generally, particularly the empirical study of scientific practices (such as that found in the sociology and anthropology of science), poses challenges about how to characterize the nature of scientific knowledge and practices for students (Kelly et al. 1993). The rich debates within philosophy of science require specialized knowledge and an understanding of the history of ideas in this domain. Furthermore, the nature of science within philosophy changes. The complexities of science suggest that there is no one nature of science, but rather natures of the sciences (Kelly 2008), and that learning about the knowledge and practices of scientific disciplines requires engaging with such practices in particular domains (Rudolph 2000; Schwab 1960). Philosophy of science offers insight into knowledge in the various disciplines, but is not readily applicable to inquiry science teaching.

42.4 Philosophy of Science and Inquiry

I have argued that teaching science as inquiry poses a number of serious challenges. I have subsequently argued that drawing implications from the philosophy of science similarly for inquiry is problematic. But surely a field dedicated to understanding the bases of scientific knowledge should have something important to say to those seeking to teach science. Issues such as observation, experimentation, inference, and explanation seem relevant to learning about the workings of science. Yet, such practices pose challenges for novice learners who may not have the conceptual and epistemic bases to engage in such scientific practices in inquiry settings.

What can the philosophy of science offer? I argue that despite potential problems of implementation, philosophy of science contributes much, including methods for posing questions about science, models for serious thinking about science, understandings about aspects of scientific inquiry, and a skeptical orientation regarding ways that science is characterized in curriculum materials and instruction.

42.4.1 An Inquiry Stance Toward the Nature of Inquiry

Philosophy of science provides methods for posing questions about science, scientific activity, and values entailed in such inquiry. Philosophy of science steps back from the details of specific scientific investigations, debates, and controversies and seeks to examine the rational basis for theory choice. Over time, the characterization of theory change as depicted in philosophy of science has changed, and the debates continue. For example, certain versions of early understandings of logical empiricism sought to understand the logic of theory choice. This perspective attempted to view theories as predicting devices and focused on the cognitive content (often viewed as the empirical consequences) of particular theories. Alternatives of various sorts to this depiction emerged after Kuhn's (1962/1996) influential view of theories as connected to overarching paradigms that influence the nature of observation. Recognizing the importance of theories, beyond their empirical consequences, led to a number of developments in empiricism and scientific realism, along with various social constructionist views of science. Across the perspectives, philosophy of science continues to engage in inquiry into the inquiry processes of science.

Modeling inquiry into inquiry has two implications for science teaching and learning. First, question posing serves as a model for school science pedagogy and research into learning science as inquiry. For pedagogy, inquiry requires finding ways to pose questions and problems. Indeed, recognizing what is a good question to ask is often a key feature of inquiry. For research into inquiry, posing questions about the inquiry process and examining ways that inquiry changes over time can advance educational thinking about science education. Second, inquiry into inquiry in philosophy of science demonstrates the importance of thinking about epistemic practices within a community and the value of shared repertoires for investigations and argumentation.

42.4.2 Development of Understandings About Aspects of Scientific Inquiry

Philosophy of science may identify educational perspectives on science that are not readily available through causal observation, or even participation. Careful analysis of theory change, induction, and explanation in the field of philosophy of science can lead to understandings about the nature of science. Furthermore, increasingly philosophy of science is being influenced by the empirical study of scientific practice (Fuller 1988). These studies are informing philosophy of science in ways that bring further relevance to the consideration of inquiry approach in education. Four examples illustrate this case.

First, across perspectives in the philosophy of science, there is wide agreement about the theory dependence of scientific methods. Hypotheses are not tested one by one, but rather a set of auxiliary hypotheses are held constant for a given domain of knowledge for each investigation. Disagreements about results, say for a tested hypothesis, include evaluations of plausibility of the auxiliary hypotheses, as much as the meaning of empirical results for the tested hypothesis. Part of what is at stake in advancing knowledge is understanding how theory, methods, and specific results map onto the plausibility of background theoretical knowledge. Furthermore, such investigations are the product of persuasive arguments and knowledge emerging out of (often) strenuous debates. Thus, theory dependence advances in knowledge situated within a relevant epistemic community.

Second, scientists engage in social practices for years before learning to recognize phenomena from the point of view of the discipline (that is to "see as") (Goodwin 1994; Kuhn 1962//1996; Wittgenstein 1953/1958). Such socialization provides stability in the field and provides the basis for inquiry. Becoming a relevant observer or speaker or member generally requires a significant apprenticeship, as a new member of a community learns the practices and applied knowledge of the research area in question. This view builds on the work of Wittgenstein (1958) and has been shown from historical (Hanson 1958; Kuhn 1962/1996) and sociological (Collins 1985) perspectives. Importantly, engaging in social practices entails learning the discourse processes and nuanced meanings of a field. This has led to careful examination of the ways that discourse processes make visible events for observers (Lynch 1993).

Third, the use of models has become recognized as important for scientific inquiry (Giere 1999). Models in science are viewed as holding an internal structure that represent aspects of some phenomenon or mechanism (Machamer 1998). These models come in different sorts (e.g., analogous physical conditions, mathematical representations, idealized cognitive models) and serve different roles at various stages of knowledge construction (Schwarz et al. 2009). Modeling in science education draws from philosophy of science and cognitive theory. For example, Windschitl et al. (2008) proposed a view of science that focuses student discourse on learning scientific concepts. They identified several epistemic characteristics of scientific knowledge represented in models. Such models are "testable, revisable, explanatory, conjectural, and generative" (p. 943). Windschitl and colleagues propose a model-based inquiry approach that uses a set of conversations to organize knowledge, generate testable research questions, seek evidence, and construct an argument. This model-based approach to inquiry offers the possibility of moving students beyond learning only theoretical knowledge by situating them in a community that considers the epistemic criteria for scientific models (Pluta et al. 2011). Such a view is consistent with the dialogical perspectives in social epistemology.

Finally, the complexities and variety of activities that might count as science have made characterizing these activities as a whole increasingly problematic. While at one time physics may have served as a model of science, emerging views of science recognize important disciplinary differences. Furthermore, the disunity of science and the range of the many fields that can properly be called science require that understandings, such as the nature of science, and disciplinary inquiry, such as the philosophy of science, look at specific ways the actual work of science is accomplished. This issue has been brought to science education in reviews of the nature of science (Kelly et al. 1998) and in specific applications to disciplinary knowledge within fields of inquiry such as biology education (Rudolph and Stewart 1998), chemistry education (Erduran 2001), and geology education (Ault 1998).

42.4.3 Values of Scientific Communities

Philosophy of science identifies values undergirding scientific inquiry. Such values are relevant to inquiry in science education. As an illustrative example, I consider the identification of values in science and the importance of establishing discourse ethics for fair debate in science fields. Longino's (1990, 2002) social epistemology articulates ways that productive discourse can be accomplished in scientific communities. In her work Longino (1990) examined both constitutive values internal to scientific communities and contextual values that influence assumptions in science. Her work considered how values for discourse could be established to promote reason and objectivity given the deeply value-laden work of science. Her solution was to propose a set of four social norms for social knowledge (Longino 1990, 2002): The *venue* refers to the need for publicly recognized forums for the criticism of evidence, methods, assumptions, and reasoning. Everyday venues may include research meetings, conference presentations, and publications. *Uptake* refers to the extent to which a community tolerates dissent and subjects its beliefs and theories to modification over time in response to critical discourse. This value is somewhat contested, as in some areas dissent can be interpreted as not adhering to the best available explanation. *Publicly recognized standards* are needed as a basis for criticism of the prevailing theories, hypotheses, and observational practices. These standards contribute to framing debates regarding how criticism is made relevant to the goals of the inquiring community. One would expect public standards to evolve over time as research groups, communities, and disciplines develop new knowledge and practices. Finally, Longino (2002) argued for communities characterized by *equality of intellectual authority*. This equality needs to be tempered, so differing levels of expertise and knowledge are appropriately considered. While these are values identified as prescriptive for public discourse in science, such values may be applicable to inquiry in science education (Kelly 2008).

42.4.4 Developing Skepticism Toward Portrayals of Science in Curriculum Materials and Instruction

Philosophy of science can help educators promote a healthy skepticism regarding how science is characterized in curriculum materials and instruction. Inquiry in science education is often seen as a means to realizing understandings about the nature of science – importantly this often entails opportunities to raise issues about science (Crawford et al. 2000). Machamer (1998) characterizes the philosophy of science as "the discipline that studies the history and structure of inquiry" (p. 2). The study of inquiry, thus, should evince aspects of the ways that disciplinary knowledge is constructed, assessed, used, and communicated. These issues have been taken up in science education, relying on the philosophy of science and science studies more generally. A fundamental question is whether there can be a consensus view characterizing the nature of science as a set of declarative statements, or if inquiry can serve as a means for engaging in aspects of disciplinary practice where epistemological issues arise. For example, Rudolph (2000) cautions about assuming a generalized view of science or a standard set of assumptions about the nature of science, given the disciplinary differences and the heterogeneous practices across the workings of science in its many forms and disciplines. Irzik and Nola (2011) make similar arguments against a consensus view of the nature of science. Their perspective takes a family resemblance view to account for the many ways science differs across disciplinary perspectives. Importantly, these authors note that while actual inquiry practices vary, engaging in "data collecting, classifying, analyzing, experimenting, and making inferences" (p. 593) is central to developing understandings of science. Considerations of the criteria for which such practices are relevant to a given situation, and under what conditions, can lead to productive conversations about how to characterize science for the various educational purposes of different science education programs. For example, Van Dijk (2011) proposed that a family resemblance view of the nature of science offers the flexibility for the fields of science communication where promoting scientific literacy is a key goal. This perspective recognizes the disunity of science and argues against viewing science as a set of declarative statements, suggesting that such a perspective offers ways of communicating the nuances in the variation across images of science.

Allchin (2011) suggests that achieving a robust view of science requires abilities to make sense and assess the validity of scientific claims. As suggested in the preceding section on inquiry into inquiry, philosophy of science can model the reasoning needed to understand the complexities of science while supporting skepticism toward generalized statements about science. Allchin proposes methods for evaluating students' understanding through engaging students in case studies of assessment of scientific claims, thus showing how the substantive knowledge and explanatory ideals of a given discipline is related to the inquiry methods (Ault and Dodick 2010; Kelly et al. 2000). This view of inquiry entails engagement with knowledge of the natural, designed, or socioscientific worlds, for a given task, and thus takes the expanded view of inquiry (beyond just hands-on science) described in the introduction of this chapter.

42.5 Toward a Sociocultural Philosophy of Science for Education

42.5.1 Shift in Epistemic Subject from the Individual to a Collective

Philosophy of science has shifted the epistemic subject from the individual learner to the relevant social group (Fuller 1988; Longino 2002). Such a shift provides the basis for a thoroughly social view of knowledge and practice in science (Lynch 1993) and science education (Kelly and Chen 1999). There are clear curricular implications for a social epistemology. These include creating practical experiences that take into account the extant knowledge of the students, designing investigations that acknowledge the interpretative flexibility of empirical evidence, and situating decisions about experimental results and socioscientific issues in a dialogical process (Kelly 2008). The social basis of scientific knowledge has a long history. From Fleck's (1935/1979) thought collective, Wittgenstein's (1958) language games, Kuhn's (1962/1996) paradigms, to Toulmin's (1972) constellation of explanatory procedures, to Longino's (1990) shared values, a continuous thread runs through twentieth-century philosophy of science: the sociocultural basis for scientific progress.

There are many examples that illustrate the importance of the sociocultural basis of scientific progress. Three examples highlight some of the relationships with inquiry: the *sociohistorical contexts of scientific discovery*, the *acculturation of new members to a community*, and the *relevance of epistemic criteria and evaluation of knowledge claims*. Before reviewing their implications, it is important to recognize the distinction between the aims of scientific groups, which are orientated toward producing new knowledge, and the aims of education, which include acculturating novices into ways of understanding the natural world. Scientific and educational institutions have different purposes, and failing to recognize the differences confounds aspects of inquiry with discovery, learning, and so forth. Inquiry in science activity may lead to new knowledge. Inquiry in education serves to instruct members how to engage in relevant specific processes of investigation, use concepts in context, and develop means for understanding community practices. Under some circumstances, inquiry in educational settings generates new knowledge within the local community, thus showing some similarity with scientific communities.

Advances in science emerge from *sociohistorical contexts* where relevant groups of inquirers draw from extant knowledge, design and execute ways of collecting evidence, and propose solutions and evaluate solutions to outstanding, communally recognized problems. Fleck's (1935/1979) analysis of the science of syphilology provides a telling case. A variety of notions of the origins and causes of syphilis emerged from various social constituents. Religious, astrological, and medical communities proposed ways of understanding the origins and nature of the disease. The eventual development of the idea of syphilis as an infectious disease occurred through agonistic debates in which both the nature of the causal entity and the relevance of certain preconditions were simultaneously examined. For any experimental result to be taken as evidence, a whole set of preconditions and assumptions of the thought collective need to be taken into consideration. The eventual success of the identification of the infectious agent was the result of the collective effort of a community of health officials, whose contributions and work "cannot easily be dissected for individual attribution" (p. 41). The debate had to be won around the epistemic criteria for evidence – not just around the nature of the evidence from the different perspectives.

A second example of the epistemic shift relevant to inquiry for education is the manner that newcomers are acculturated into particular ways of seeing, communicating, and being. This realization about the substantive and important socialization into the ways of being in science counters forms of positivism (Ayer 1952) that based scientific progress on logic and objective experimental facts (although see Carnap 1950). These ways of being are dependent on the social practices of a relevant community (Mody and Kaiser 2008). Much of the work of apprenticeship for the ways of seeing, communicating, and being entails active participation in the practices of a relevant community. Learning to participate and become a member involves collective action. Understanding the ways that the language of a group operates, the nuances in meaning, and the path to modification in such meaning involves use of discourse in contexts. Furthermore, the completion of such an apprenticeship may be critical to being taken seriously by peers (Collins 1985).

A third example of social processes involved in scientific progress concerns the epistemic criteria for the evaluation of knowledge claims. Rather than viewing reasoning in science as a logical process of hypothesis testing, contemporary philosophy of science recognizes the dialectical processes of persuasion, debate, and critique. Indeed, scientific knowledge is social knowledge to the extent that knowledge claims are judged in relevant disciplinary communities. Longino (2002) and Habermas (1990) each have proposed norms for productive conversations in communities that respect alternatives but focus clearly on the strength of marshalling evidence. This leads to implications for inquiry centered on the social basis for decisions and the importance of using evidence in science. A dialectic approach to the construction of knowledge claims has plausible relevance to education. Nevertheless, such an approach needs to consider the local context and participants. Interesting questions about inquiry can be raised about students' developmental ages and abilities and variations regarding the science topic at hand.

42.5.2 Philosophy of Science and Learning

The relationship of philosophy of science and learning has been a central part of numerous developments in science education. One intersection occurred during a focus on constructivist learning in science education. Constructivism entered science education through a focus on students' ideas and understandings, building initially on Piaget (for review, see Kelly 1997). These learning theories and their close cousins, such as conceptual change theory, brought a welcomed focus on students' conceptions. Through careful attention to how students made sense of science phenomena, researchers were able to examine learning from the learners' point of view. This had a significant impact on science education and brought in philosophy of science. For example, the development of the alternative conceptions movement and conceptual change theory both used the work of Kuhn (1962/1996) and others to consider how students' constellation of conceptions served as framework for sensemaking. These foci led to pedagogy attending to students' sensemaking and provided opportunities for students to be actively involved in knowledge construction.

Despite the many positive contributions of constructivism to science education, there were two central philosophical problems. First, many forms of constructivism, particularly radical constructivism, set their epistemological commitments on the mind of the individual learner. This view conceptualized the problem of knowledge and learning as a cognizing subject making sense through exploration. This epistemological orientation ignored the important contributions from philosophy of language and other social views. Thus, by committing to a Cartesian subject, the constructivist orientation was ill equipped to integrate discourse and consider the value of social practice (Kelly 1997). Rather than viewing learning as socialization into a community, constructivists tended to view learning as changes in the cognitive structure of an individual mind. Second, some forms of constructivism confounded the construction of knowledge with ontological questions about reality and world making. Radical constructivism in particular was clear about its commitment to an idealist ontology and failed to understand the nuanced ways other ontological commitments could adhere to similarly reasonable pedagogies (see contributions in Matthews 1998).

A serious competitor to constructivist theories of learning emerged in the form of sociocultural theory. This view of learning conceptualizes the problem of learning as one of participation and appropriation of knowledge and practices of some relevant group. Central to this view is the important role of discourse processes through which everyday events are constructed (Kelly and Green 1998). By viewing learning as acculturation, the role of social processes and cultural practices are emphasized. From this point of view, as groups affiliate over time, they form particular ways of speaking, acting, and being that are defined by the group membership and evolve as the group changes (Gee and Green 1998; Kelly 2008; Kelly et al. 1998). Discourse practices established by the group become cultural tools for members to construct knowledge. These cultural tools, signs, and symbols mediate social interaction, which forms the basis for learning (Vygotsky 1978). Learning does not occur only for individuals because the cultural tools themselves serve as resources for members and evolve as members internalize the common practices and transform them through externalization (Engestrom 1999). Thus, this view of learning entails more than changes in the internalized cognitive structure of individual minds; instead, participants learn to be members of a group with common knowledge, identity, and affiliation through shared cultural practices that constitute membership in a community.

Sociocultural psychology and philosophy of science share some important central tenets and premises about science, knowledge, and inquiry. Both represent a shift in the epistemic subject from the individual learner or scientist to the relevant epistemic *community*, the relevance of agency within the potential created by a social language, and the value of dialectical processes for proposing, evaluating, and testing knowledge claims. Perspectives from Vygotsky (1978) and neo-Vygotskians (Cole and Engestrom 1993) evince the importance of considering how inter-psychological processes can be internalized by individual learners. Thus, much like the social epistemology in the philosophy of science (Fuller 1988; Longino 2002; Toulmin 1972), the individual has agency and plays a key role in the development of knowledge but does so within the social languages of a relevant community. This suggests that instructional design for inquiry should consider how social practices are established and used to communicate ways of inquiring into the natural world. Such communication occurs across events leading to the development of knowledge, including the problem-posing phase of inquiry, the sensemaking talk around investigations, deliberation around meaning of results, and evaluation of the epistemic criteria for assessing proposed ideas, models, and theories.

42.6 Conclusion: Philosophical Considerations for Inquiry Teaching and Learning

Science education has considered inquiry as a goal for reform a number of times across decades – for examples, see Dewey (1929), Schwab (1960), Rutherford (1964), and NRC (1996). Whether or not inquiry was in the foreground, we have seen proposed educational change in the form of goals, standards, and frameworks. Reforms come and go and sometimes come back (Cuban 1990), yet careful consideration of aims should always be present in the conversation about education. This chapter examined philosophical considerations of inquiry, yet science education reform in any form or name can be informed by philosophy of science. Reform in education should not be aimed to reach final resolution of the issues around curriculum, instruction, and assessment once and for all. Rather, reform is a process that can include participants as part of a vibrant democracy where agency and identity are formed through active engagement in educational decision-making (Strike 1998).

This chapter argued for a view of philosophy informed by the empirical study of everyday practice (Fuller 1988; Kelly and Chen 1999; Lynch 1993). I conclude by first considering ways that this view of philosophy can inform science education. I then offer some research directions for the field of history, philosophy, and sociology of science and science teaching.

Philosophy has the potential to inform educational practice and ways of thinking about reform in educational policy. First, philosophy offers ways of posing questions. Posing questions and examining implications represent a contribution of such philosophical considerations. A number of central questions continue to be posed: What counts as understanding? What does it mean to learn? What is knowledge?

How can disciplinary knowledge and practice be assessed? Posing questions and examining in detail any proposed reform offer a contribution to the overall debate in educational reform. Second, philosophy can contribute through conceptual sorting. Through philosophical analysis of the conceptual content of educational texts (policy, curriculum, frameworks, standards) and of education events (research, teaching), philosophy can bring clarity or identify areas of ambiguity. Developing understandings about the nature of knowing, inquiry, and meaning is central to reform that progresses and advances thinking about education. While such meanings can be informed by empirical study, understanding the meaning of inquiry requires careful thought and analysis. The study of everyday practice in science and education settings (Kelly et al. 2012; Lynch 1993) can inform our views about the nature of science, inquiry, and meaning; nevertheless, there is considerable theoretical work needed to render empirical results informative. Thus, normative decisions about directions for science education cannot be answered by empirical study alone, or even more empirical studies – a balance must be struck between careful, descriptive studies and philosophical considerations of meaning. Third, philosophy of science can inform our field by scrutinizing the nature of education research, including the important work of understanding ways to develop productive conversations across theoretical traditions (Kelly 2006). Science and education are human endeavors that require ideas to be generated and assessed through dialectic processes. The field of educational research should consider ways to enhance discourse around educational practice.

With these philosophical considerations in mind, I now consider some plausible research directions for science education regarding inquiry. Inquiry in science education has taken many forms and served different goals (Abd-El-Khalick et al. 2004). In this chapter I identified a number of problematic aspects to thinking about learning science as inquiry. By drawing from a social epistemology in the philosophy of science, I have examined reasons why inquiry as an instructional approach has both potential and drawbacks. The efficacy of this approach depends crucially on how it is implemented, for whom, under what conditions, and for what purposes. I propose four areas for research regarding inquiry in science education.

First, we learned much as a field from the detailed, analytical work of the anthropology and sociology of science (e.g., Knorr-Cetina 1999). The study of everyday practice makes clear the social processes by which *what counts* as science is discussed, debated, and determined. Inquiry contexts, such as the model-based inquiry approach of Windschitl and colleagues (2008), provide a context to examine empirically the value of such approaches for science education. While science studies have their drawbacks, they offer insights into the inner workings of the various sciences. The methodological orientation to examine inquiry as it is interactionally accomplished in everyday life suggests that a similar approach in science education can be fruitful. Close, careful studies of the discourse events around inquiry can illustrate how inquiry is enacted. Contexts such as design challenges, investigations, and studies of socioscientific issues provide potentially inventive pedagogies that can be investigated empirically.

Second, there is a persistent lack of interest among students in pursuing science (Sjøberg and Schreiner 2010). Inquiry models for science instruction have been proposed as a means to address such concerns, beginning with Schwab (1960) and continuing thereafter. Yet, it is not clear that engaging students in inquiry, either into the natural world through investigations or into the socioscientific world through debate, will necessarily increase student interest in science. Research derived from philosophy of science may make science more real, authentic, or consistent with professional practice, but this may not take into account students' views and interests. Furthermore, studies examining the referent for science beyond that of professional science may point to directions that are better at engaging students – for example, ways that citizens use science to address everyday environmental concerns. Such studies would pose a new set of questions about what counts as science for the field.

Third, striving to meet the conceptual, epistemic, and social goals of science education (Duschl 2008) requires a critical analysis and discussions about the nature of inquiry. Such research would need to be reflexive about inquiry into inquiry. Work in science studies and the philosophy of education may be helpful for understanding how inquiry can be conceptualized in science education. I have argued both for the descriptive, empirical studies of science and science education and for the importance of the normative or moral arguments for reason, science, and education. The field of science education can be informed by both perspectives.

Fourth, inquiry most broadly construed entails learning and self-actualization. The educational goal of inquiry should not only be to meet specific standards, concepts, or procedures, but rather to develop the capacity for further learning. Through engagement in the sociocultural resources of other people and through interaction with the natural, designed, or social world, learners can develop an enhanced capacity to learn and develop new ideas. Education from inquiry should develop the ability to engage in more inquiry.

Acknowledgments I would like to thank William Carlsen, Christine Cunningham, Richard Duschl, and Beth Hufnagel for their helpful comments on an earlier draft of this chapter.

Chapter 43
Research on Student Learning in Science: A Wittgensteinian Perspective

Wendy Sherman Heckler

> *[W]e cannot avoid thinking about [Wittgenstein's] methods and their rationale if we are to find his philosophy intelligible.*
>
> (Minar 1995, p. 416)

43.1 Introduction

In the science education research literature, there is an overwhelming tendency among those who reference Wittgenstein's work to do so in ordinary ways. In other words, Wittgenstein is cited as if he has offered up a corrective theory that we can and should apply to our studies of the human condition; "meaning-in-context," "family resemblance," or "language games" come first to mind. But this chapter will suggest that such a tendency misses the central point of Wittgenstein's work: to model an alternative orientation for the philosophical project.

Wittgenstein warned against our becoming "bewitched" by natural language. He felt that many of the time-honored problems of philosophy were not problems at all, but only puzzles that result from a lack of clarity about how our language works. For example, we tend to see an expression such as "My back hurts!" solely as a report of a private experience. This is due to our picture of language as serving primarily or even exclusively to name things and, in particular, to name states of mind. Because of this representational notion of language, we tend to think of such expressions as reports of prior introspections or private experiences. As with "pain," so too with perceptions and thoughts: each person has access to an "inner world"

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_43,

of phenomena that no one else can breach. This raises difficult philosophical questions about how one's inner world coordinates with an outer world of external experiences; how we communicate with others, for instance, or how we "internalize" what we learn about the world. It underwrites venerable programs of skepticism, asking what we can know of other lives and worlds.

Wittgenstein thought that talk of private inner worlds was misguided and that philosophical misconceptions like this one arise from the grammar of our common expressions in tandem with this wrong-headed view of language. Pronouncements of being in pain are not reports of a check conducted over an internal state of affairs. Rather, Wittgenstein encourages us to think of such pronouncements as they are typically used: as a type of pain behavior, simply a way of acting when one is in pain. Describing one's pain is an alternative to crying out, not the result of an inward examination and processing of phenomena known only to oneself (cf., Hacker 1999).

Wittgenstein described the proper role of philosophy as akin to therapy. He thought the philosopher's task was to clear up conceptual confusions at play in our language or to "show the fly the way out of the bottle." Rather than affirming one side or another of well-known philosophical debates, Wittgenstein questioned the assumptions on which the debates took place and attempted to dissolve puzzles by revealing them as artifacts of unexamined grammars.

It is understandably tempting for science education researchers to dismiss Wittgenstein's advice. After all, research in science education isn't doing philosophy; rather, we attempt to solve actual, empirical problems by conducting studies about teaching and learning and developing theoretical explanations of the results. But what if the assumptions underlying our empirical work suffer from conceptual confusion? For instance, if private worlds are suspect, what can be said of studies of how learners construct personal meaning of scientific concepts? Or, to suggest a more appropriately Wittgensteinian manner of stating the issue: what if the question of "how learners construct personal meaning of scientific concepts" is examined not as an empirical question at all but for its merits as a sensible conceptual one? This chapter takes interest in questions such as these in an effort to encourage better understanding of Wittgenstein's unique contributions to philosophy and by extension, to the social sciences.

43.2 Wittgenstein's Life and Philosophical Contribution

Ludwig Wittgenstein's (1889–1951) life was extraordinary in its range of experiences; in contrast, his philosophical work remains notable for its single-minded focus on the implications of his alternative view of the project of philosophy (Monk 1990, 2011). Born in Vienna to an aristocratic family, Wittgenstein regularly interacted with musicians, artists, and intellectuals. While he is known for his career as a Professor of Philosophy at the University of Cambridge, Wittgenstein also sought fulfillment in various other vocations throughout his lifetime. He served in the

Austrian Army during World War I, including some time on the front lines in Russia and Italy and nearly a year spent as a prisoner of war. After the war, Wittgenstein took up elementary school teaching for a time in rural, largely impoverished Austrian villages in an attempt to restore his humanity and improve his soul. During World War II, and although it meant abandoning his professorship at Cambridge, he took a job at Guy's Hospital (in London) where he prepared pharmaceutical ointments and delivered medicine to patients. Wittgenstein was naturally inclined toward technical-mechanical expertise, having originally aimed to study aeronautical engineering as a young university student. While working for a time as an architect, he designed elements such as windows, doors, and radiators for his sister Gretl's home in Vienna. Wittgenstein's emotional life mirrored this vacillating search for vocational contentment: he was sensitive, temperamental, and by turns suicidal. He was also driven to perfection in each task and relationship he undertook and therefore routinely profoundly disappointed with the inability to achieve it (Monk 1990).

Wittgenstein's introduction to philosophical study resulted from his focus on mathematics. After beginning an education in engineering at the University of Manchester, he took interest in mathematics and its philosophical foundations. This interest led to a correspondence with Gottlob Frege, and most biographers credit Frege with encouraging Wittgenstein to work with Bertrand Russell at Cambridge (Monk 1990; Richter 2004; alternatively see Anscombe 1995). His studies eventually led to the ideas published in the *Tractatus Logico-Philosophicus,* a work Anscombe locates "halfway between Frege and Russell – at least in some ways" (1995, p. 396). In the *Tractatus* Wittgenstein is credited with advancing a "picture theory of meaning," in which the sense of a proposition is founded on its accurate portrayal of empirical matters (Richter 2004). According to common interpretation, Wittgenstein's *Tractatus* argues that logic can be shown through language but at the same time, logical propositions themselves are nonsensical (since logical propositions do not reflect actual worldly objects). The *Tractatus* was highly influential on members of the Vienna Circle, so that these logical empiricists were inspired to dismiss the philosophical ambition to find metaphysical truths and to equate philosophy with understanding "the logic of scientific language" (Hacker 2007a). Further, based on ideas from the *Tractatus* the Vienna Circle "proposed the principle of verification as the key to the notion of linguistic meaning and invoked verifiability as a criterion of meaningfulness" (Hacker 2007a, p. 2).

After the publication of the *Tractatus*, Wittgenstein gave up philosophy for a time but was eventually lured back to Cambridge and to revisiting his ideas based on conversations he had with members of the Vienna Circle and with Frank Ramsey (Monk 1990). As he lectured and worked with colleagues at Cambridge from the 1930s on, his thinking began to depart significantly from his earlier work.[1] In particular,

---

[1] But see Crary and Read (2000) for an exploration of the continuity in Wittgenstein's early and later philosophy.

Wittgenstein developed a wide-ranging and forceful rebuttal of the representationalist view of language. His conception of the nature of philosophy itself also matured, leading him to argue that the discipline is not characterized by foundational problems that need universal solutions, but rather consists in various and persistent missteps in the use of language which muddle our perspective. Although he prepared numerous manuscript versions of these ideas and came close to publishing them on several occasions, he instead left instructions with a cadre of trusted students for posthumous publication of his later writings (Monk 1990). The *Philosophical Investigations* and other subsequent publications drawn from his *Nachlass* express Wittgenstein's later philosophy, which argued essentially that, properly conceived, philosophy was a methodology for clearing conceptual confusions rather than a search for theoretical or generalized truths. Through philosophical analysis, we seek to understand how language contributes to – in fact, engenders – supposed philosophical puzzles such as the "mysteries" of consciousness, or introspective, private access to inner states of being. Philosophy's task was ideally to dissolve puzzles and not to write alternate theories that might account for them (Monk 2011).

Wittgenstein's later works[2] are often cited for their insights into a wide variety of philosophical topics, including meaning and understanding, rule following, the "inner" and "outer" realms of human activity, and the grounds of "certainty" (see Kenny 2006). In contrast to the representationalist view of language expressed in his earlier work, these writings identify the meaning of an expression as its rule-governed use in language, inextricably tied to its use in our lives (Diamond 1989). As Hacker summarizes,

> The meaning of an expression, with marginal qualifications, is its use. It is also what is understood by anyone who understands or knows what an expression means. And it is what is given by an explanation of meaning. An explanation of meaning, even a humdrum explanation given by means of a series of examples, is a rule – a standard of correctness – for the use of the explanandum. (2007b, p. 4)

Language does work other than representing; most simply, language expresses (Hacker 1999). This focus on the nature of language becomes the basis for Wittgenstein's therapeutic philosophical method: under careful scrutiny of their roles in language, ordinary concepts "dressed up" as theoretical ones lose their beguiling nature.

This chapter will focus primarily on Wittgenstein's later writings, for how they have obtained relevance in the science education research literature, and in particular as related to students' learning of science. Central to the treatment – and the idea will be revisited – is Wittgenstein's aversion to the "craving for generality" that marks normative academic discourses. The concepts emanating from his philosophy should not be read as pronouncements or contributions to a general theory. Rather, Wittgenstein's writings serve as exemplars in their own contexts and as lessons on how to "do philosophy" as a conceptual interrogation on any next relevant occasion (Hacker 1999, 2007b; Monk 1990).

---

[2] See, e.g., Wittgenstein (1958, 1960, 1967, 1969, 1980).

43.3 The Place of Wittgenstein's Writings in Science Education

Wittgenstein remains a relatively marginal figure in science education research. However, his work has been invoked with increasing regularity, especially since what might be termed the "social turn" in research on learning in (science) education (see Gergen 1985 for a formulation of this movement in psychology more generally). As Vygotsky's theories of learning became more prominent in educational studies, researchers sought to understand the social aspects of human development, especially through discursive interaction. Wittgenstein's writings on "private language" and the character of language more generally are a natural resource for consultation in this line of inquiry. Another source of Wittgenstein's influence has been through the social studies of science movement. Wittgenstein's corpus has been a central resource to sociological studies of science for the last two decades.[3] In turn, these studies have influenced science educators and the study of classroom science.

43.3.1 Wittgenstein as a Corrective to Conceptual Change Theory's Appeal to Rationality

Early mention of Wittgenstein in science education was in the context of the debate over the newly posited theory of conceptual change. "Conceptual change" theory was introduced as a disciplinary-specific alternative to Piaget's developmental theory of learning, where accommodation (or how perturbations could leverage significant revision of learners' conceptual knowledge schema) was hypothesized to mirror the process of theory change in professional science (Posner et al. 1982). According to Posner and colleagues' foundational formulation, scientific conceptions can only be integrated by a learner when there is dissatisfaction with existing (prescientific) conceptions and when the scientific concept in question is intelligible, plausible, and carries the potential for further productive use.

Critics of the conceptual change theory of learning invoked Wittgenstein in different ways in order to question Posner, Strike, Hewson, and Gertzog's characterization of learning as "a rational activity" that involves "a kind of inquiry" resulting in a learner "accept[ing] ideas because they are seen as intelligible and rational" (1982, p. 212). West and Pines (1983) argued for considering nonrational elements of students' ideas and learning and specifically suggested that learning involves "feelings of power, simplicity in complexity, aesthetics, and personal integrity" (p. 38). They cited the collection of Wittgenstein's writings published as *On Certainty* in their claim that even such rational-sounding notions as "doubt" and "certainty" are imbued with both rational and nonrational elements.

Garrison and Bentley (1990) provided a similar critique of the place of rationality in conceptual change, noting that Wittgenstein's discussion of language learning

[3] See (Bloor 1983, 1992; Lynch 1992a, b, 1993).

allows for the existence of "preconceptual" learning. Preconceptual learning includes children's use of primitive forms of language (taught by imitation and training) when learning to talk. They argued that, in contrast, *rational* learning should be considered "learning-by-explanation" and that it would come later, with conceptual understanding. The distinction is important, according to Garrison and Bentley, because they contend that leaning science is similar to a child's first learning a language. In their view, the concepts of science are so unlike the concepts of everyday life that the "language games" taking place in each context are vastly different, even incommensurable. For this reason, Garrison and Bentley speculated that learning science may consist of initial-language-type, preconceptual learning relying on processes *other than* rational choice between competing conceptions. Prior to conceptual learning, individuals learn to participate in language games via imitation and drill, and they acquire a "world picture" (or rule-like system of enabling beliefs) through exemplars and persuasion.[4]

Cobern (1995) adopted Garrison and Bentley's starting point that science and everyday life are premised on very different world pictures, or as Cobern saw it, different cultural worldviews. According to Cobern, "science…is fundamentally an issue of culture" that "requires learning to see the world in a new and very different way" (1995, p. 292). Along with Garrison and Bentley, Cobern accepted Wittgenstein's assessment that "the acquisition of a fundamental viewpoint is an issue of persuasion and internalization, rather than instruction and learning" and that this was "due to the lack of sufficient common ground" (Cobern 1995, p. 293).

As a sociocultural perspective on learning gained prominence in science education, more researchers began turning from a view of rationality as the evidence of a universal logic of science to a view of rationality as an expression of various local, collective rationalities – including those of groups of scientists and ultimately individual classrooms. The Wittgensteinian-instructed philosopher Stephen Toulmin was quite influential in this development, a point that was outlined clearly in the work of Kelly and his colleagues:

> Analysis of Toulmin also showed that his view of conceptual change is based on a theory of rationality of science in which science is viewed, not as a universal set of inference rules or commitments to central theories, but as a collective set of commonly held concepts, practices, and actions of members of a group called "scientists." Thus, conceptual change can be viewed as a theory of rationality in that it makes visible what counts as reasons for changes in knowledge within a group. (Kelly and Green 1998, pp. 148–149)

Furthermore, by the late 1990s, the focus on rationality in conceptual change underscored some trends seen in the science education research literature on student learning more generally:

> Rationality does not mean that scientists nor students follow stepwise inferences from data to ontological truths. History, philosophy, and sociology of science all suggest that scientific theory choice is problematic, contextual, ill-structured (Barnes and Edge 1982; Collins and Pinch 1993; Kuhn 1970). We should not assume that the actions of individual

---

[4] See Wagner (1983, pp. 610–611) for an earlier but similar argument based on Kuhn's philosophy.

> scientists are necessarily rational. Likewise, the possibility that rationality is local is accorded; that is, choices governing what counts as rational action are subject to the conventionalized practices of particular social groups (Rorty 1989; Strike 1984; Wittgenstein 1958). Nevertheless, incorporating rationality into educational theory allows for a way of talking about learning that appeals to the social nature of knowledge and the normative ideals for theory choice. (Kelly 1997, p. 365)

As will be discussed below, the impact of the field of science studies on views of students' science learning came into play more extensively during this time. In addition, science educators shifted from being concerned about learners as individual rational actors to focusing on rationality as a social practice and therefore on social aspects of learning science.

43.3.2 Wittgenstein's Philosophy as Supporting Views of Learning as a Sociolinguistic Process

In science education, Wittgenstein's work is often used to lend support to the notion that "learning is social" or some similar formulation that draws a contrast between the picture of learning as an individual comprehending and "internalizing" knowledge of the world and a picture of learning as something more like "the ability to participate in group life in a meaningful way." Wittgenstein's writings about the nature of language have been particularly influential in this regard, since talk can be indicative of either successful or marginal participation in group life. Notably too, Wittgenstein argued against the possibility of a private language known only to an introspecting subject (see, e.g., Hacker 1999). Initial interest in Wittgenstein's notion of "language games" was a precursor to these developments.

Using Wittgenstein's corpus, Stenhouse (1986) also critiqued the conceptual change literature in science education. He was concerned first with the nature of concepts, and second, with the nature of conceptual change. Citing Wittgenstein, Stenhouse introduced science educators to the idea that the acquisition of concepts is not to be thought of as the establishment of mental representations in the minds of individual learners. Rather, concept mastery is performative and linguistic: to understand a concept is to be able to use it correctly in context. In other words, "using a concept correctly" implies that one is able to follow the rules for the language game in play, e.g., science. For instance, a student who spoke earnestly of "the force on an object resulting from its acceleration" rather than the other way around would be judged to not yet understand the concept of "force." Stenhouse argued that this sense of concept attainment should already be familiar to teachers, who use schoolwork and test performance to assess students' conceptual understanding; teachers don't look at brains to assess understanding. He noted, "insofar as they are inter-personal and 'public,' all educational transactions must take place though language-games" (p. 417).

The language games Stenhouse (1986) envisioned for science and everyday life were varied and yet continuous with one another. He argued that what counts as using a concept correctly can be different in different language games, so that, for example, a child would not talk about “water” in the same way as a chemist would. In fact, Stenhouse suggested that language games were developmental, in the sense that the “language-games of ‘ordinary life’ are needed not only for initiating students into specialist language-games, but also in the setting up of these language games de novo by those who invented them” (p. 417). His recommendation for teachers was to take great care in understanding a child’s language game, so as to initiate conceptual change from within it.[5]

The notion of conceptual attainment as successful participation in language games has developed in the research literature since Stenhouse’s initial arguments. Kelly and Chen (1999) studied high school science classroom work from the perspective that “the meaning of a word, symbol, or construct is situationally defined by its use in a particular discourse practice (language game)” (p. 909). For high school students learning to construct evidence-based arguments in science, Kelly and Chen argued “that practice using terms in multiple contexts is central to understanding” (1999, p. 909). Relatedly, in advocating that classroom discourse structures change from the familiar initiation-response-evaluation (or I-R-E; see Mehan 1979) format to one of “transformative communication,” Polman and Pea (2001) characterized both types of discourse as Wittgensteinian language games. In the first case, students and teachers orient to IRE structures as the familiar – and allegedly problematic – language game of modern institutionalized schooling. On the other hand, using the transformative communication practices espoused by the authors is said to allow teachers’ work to instead focus on “transforming students’ actions into more successful ‘moves’ in the ‘language game’ of science” (Polman and Pea 2001, p. 227). Thus, some language games are scientific, and some not, and in this way the formulation of “language games” preserves our normative dispositions.

Although their focus was on the “complex of representations, tools, and activities of a discipline” that they label “disciplinary discourse,” Airey and Linder (2009) used the concept of language game to develop their treatment of how students learn (or attain fluency in) this disciplinary discourse. They argued that a “mutually accepted system” like a language game “can only occur if both student and lecturer have experienced the ways of knowing of some part of the discipline” and that “such ways of knowing may perhaps only be holistically experienced through certain types of disciplinary discourse” (p. 40). They differentiated between students’ imitation of discourse and their holistic understanding of it, saying that successful teachers notice when students are not playing a language game correctly and seek to remedy this in order for students to achieve fluent disciplinary understanding. Thus, the game formulation is tied to levels or stages of learning.

Gyllenpalm and Wickman (2011) employed a sociocultural perspective of analysis to study what they name the “inquiry emphasis conflation” in science education: Teachers in classrooms tend to mistakenly equate “experiment” with any pedagogical

---

[5] In contrast, as noted earlier, Garrison and Bentley (1990) used Wittgenstein’s notion of language games to argue that learning science was a fundamentally different process than learning in everyday life. They promoted the necessity of a “break” with everyday experience for learning science.

"laboratory task" and "hypothesis" with "prediction about the outcome of a laboratory task." From their analytic perspective, a focus on language games highlights the ways in which individual actions are tied to cultural institutions; by looking at "pivot terms" that tie to "central aspect[s] of two or more cultural institutions and their associated activities" (p. 910), they can better understand the ways in which different meanings may impact educational goals.

While for some researchers the notion of "language game" in science education is used largely to underscore the idea of conceptual understanding as linguistic performance, for others, this participation in language necessarily shifts our focus on learning itself from an "individual process" to a "social" one. In characterizing the philosophical commitments of conceptual change theory in science education, Kelly (1997) argued that "learning science is an acculturation, an initiation into a set of language games" (p. 367). Through Toulmin's philosophy, Kelly also emphasized the public nature of language games and (per Wittgenstein) rejected the notion of individualized, "private" language games. He contrasted the radical constructivist attempt to map "social" processes onto presumed private language games with conceptual change theory's commitment to public, shared concepts "because of the socialization that learners experience in the process of learning science" (1997, p. 369). At the same time, students "may need to *internalize* these [acculturated, scientific] conceptions and language games" (p. 370, emphasis added), a notion which he differentiates from the radical constructivist claim that students must originally create or construct this knowledge on their own.[6]

Kelly and Crawford (1997) directly addressed the "socio-cognitive discontinuity" in educational theories about cognition and indeed argued for "resisting any association of cognition as separate from social" (p. 555). Ivarsson et al. (2002) continued in this direction. They integrated some of Wittgenstein's views with Vygotsky's learning theories in order to illustrate how some conceptual change research may be advancing misguided conclusions, due to a focus on individual cognition. In particular, Ivarsson and colleagues looked at students' understanding of the earth's shape and gravity when they were given maps to use as part of an interview protocol. They argued for rejecting the notion that inner processes underlie external (discursive and nondiscursive) action:

> There is no sense, following [Vygotskian and Wittgensteinian] perspectives, in assuming that there is a level of thinking that is "pure" and that underlies reasoning in human practices. We cannot separate thought processes, say in the context of doing geometry or playing chess, from the conceptual tools that are applicable to such activities. Thinking is the use of tools. Or, as Wittgenstein so suggestively put it in the context of the use of language: "When I think in language, there aren't 'meanings' going through my mind in addition to the verbal expressions: the language is itself the vehicle of thought" (Wittgenstein 1953, §329). (Ivarsson et al. 2002, p. 78)

---

[6] However, even before Kelly's attempts at sorting out philosophical differences between these views, some radical constructivists hinted at a willingness to concede the sociality of language; Wheatley approvingly cited Bloor's pronouncement in his "commentary on Wittgenstein, 'The real source of 'life' in a word is provided not by the individual but by the society'" (Wheatley 1991, p. 11).

Students who were shown maps in Ivarsson, Schoultz, and Säljö's study had no difficulty identifying the shape of the earth as round, even though previous research indicated that a significant number of students have difficulty thinking of the earth in this way. In drawing attention to the interactional nature of their interviews, these researchers maintained that an attempt to study "mental processes" apart from cultural tools used in discourse is worthless: "There is nothing to be gained by positing such a level of inquiry as the one implied by a notion of pure cognition underpinning our thinking" (Ivarsson et al. 2002, p. 97).

In sum, as views about the social nature of cognitive processes became more commonplace in science education research, references to Wittgenstein were used to support those general arguments. The study of social aspects of learning science necessitated examination of real-world interactions between students and teachers. For many researchers, participation in "language games" became a way to conceive of learning that provided a welcome alternative to a view of learning science as acquiring suitable mental representations of scientific concepts. "Language games" have thus been used to reference the discourse structure in classrooms as well as to emphasize the location of conceptual understanding. Many studies of science learning that focus on classroom discourse theorize that learning involves a combination of social and individual elements; e.g., meaning is constructed through discourse and interaction but must be internalized by the individual. However, a few researchers have used Wittgenstein to support an argument for abandoning the individual-social dichotomy altogether.

43.3.3 Wittgenstein's Alignment with Science Studies and Its Influence in Science Education

In the late twentieth century, sociology of science gained prominence with science educators as a model of how to conceptualize and study science and thus study science learning in the classroom. This seemed a natural extension of the project that began with the conceptual change theory of learning; after all, students' attempts at scientific meaning making were seen to parallel those of scientists. Furthermore, as noted above, changing views about rationality – from one, universally correct version to many local kinds – were seen to necessitate close examination of knowledge production and use in an assortment of contexts, including science classrooms (cf., Kelly 1997).

Two sociologists studying scientific practice and noted in the science education literature are especially relevant in assessing Wittgenstein's influence on this research genre. Perhaps the most obvious connection between science studies and Wittgenstein occurs through the writings of David Bloor on the Strong Programme in the Sociology of Scientific Knowledge (SSK). Bloor relied on Wittgenstein to justify his SSK project because Wittgenstein's later writings discuss and acknowledge the rule-governed nature of human forms of life (specifically, of language use and mathematics). Bloor (1983) interpreted Wittgenstein as positing that social consensus determines the correct interpretation of a rule; if this is so, then sociology would naturally be in a position to explain the genesis of this consensus and thus to explain human knowledge (including knowledge of logic, mathematics, and science). Another frequently cited, Wittgensteinian-inspired sociologist who studied scientists at work is Michael Lynch. Interestingly, Lynch critiqued Bloor's interpretation of Wittgenstein's writings on rule following and their implications for science study. Lynch argued for understanding Wittgenstein not as having "made science and mathematics safe for sociology" but instead as having "made things entirely unsafe for the analytic social sciences" (1992a, p. 232). According to Lynch, Wittgenstein does not license sociology to be the final arbiter of explanations of knowledge construction. On this account, Wittgenstein's relevance for science education may be not only about our conceptualizations but our conceptualizations of social scientific analysis.

With his colleagues, Kelly integrated Wittgenstein's perspectives into sociocultural views of learning in studies conducted over the late 1990s and early 2000s. In addition to arguing for a social conception of learning, many of these studies drew a direct parallel between studies of classroom science learning and studies of science as conducted in professional laboratory settings. Kelly and Crawford (1997) described an approach to studying science classrooms that emulated the success of sociological studies of professional science:

> A common thread among at least two of these research traditions, the empirical program of relativism (Collins, 1981), and the Strong program (Bloor, 1976), is that they are empirical; that is, they explore the scientific enterprise as it unfolds through investigations of the actors and actions (for review, see Kelly, Carlsen, & Cunningham, 1993). We take a similar research methodological stance in this study: We explore school science through an ethnographic approach, studying the actions and actors that comprise the culture of a conceptual physics classroom. Through detailed, over-time analysis of the social and discursive practices of the members of one high school physics class, we seek to document the actual practice of school science as it is constructed, signaled, and acknowledged. (Kelly and Crawford 1997, p. 534)

Kelly and Crawford cited the Garfinkel et al. (1981) study of Cocke and Disney's discovery of the optical pulsar as exemplary of an approach for describing how a cultural object of science took shape from a series of inscriptions, over the course of data runs. Their own study of data runs in a conceptual physics classroom described students' ways of determining "what counted as the acceleration of carts rolling down an inclined ramp" (p. 545). Kelly, Brown and Crawford (2000) used a study of university chemistry laboratory work by Lynch et al. (1983) for inspiration in analyzing the ways in which "science" was "situationally defined" in a third grade classroom during an experiment on algae growth. In both the university chemistry lab and the elementary school algae experiment, "Written instructions and the suggested experimental design underspecified the actions required to make sense of and accomplish the task of a science experiment," so that "something more" was needed to complete the practical inquiry (p. 650). Kelly, Chen and Prothero (2000) noted that their perspective was informed by ethnomethodology (Lynch's analytic orientation) and that their empirical study of writing in a university oceanography course "provide[d] a specification of the epistemic activities" (p. 702) at play in the setting, a reference to Lynch's (1992a) discussion of the ways in which ethnomethodological studies of work provide an empirical extension of Wittgenstein's philosophy. Lynch (1992a) himself argued that this extension is "not a move into empirical sociology so much as an attempt to rediscover the sense of epistemology's central concepts and themes" (pp. 257–258) through their description as practical activities.

Lynch's (1992a) discussion of ethnomethodology as an extension of Wittgenstein's work was developed into his conception of "epistopics" (Lynch 1993). His intent in suggesting investigations of "observation, description, replication, testing, measurements, explanation, proof, and so on" was to "divorce [these terms] from a 'metatheoretical' aura and to attend to the manifest fact that they are *words*" (1993, p. 280, emphasis in original). In science education, Tapper (1999) used Lynch's epistopics as an organizing theme in his analysis of students' talk during laboratory practical work. Tapper noted that Wittgenstein's notions of language game and family resemblance are foundational to the concept of "epistopics," which Lynch talks about as practices that look different across different settings but share a family resemblance across a set of similar language games (Tapper 1999, p. 449).

Studies in the sociology of science used Wittgenstein's writings to authorize their project of careful examination of scientific practice, albeit in different ways. Science studies have served as exemplars and sources of analytic insight for researchers studying the "social construction of science" in classrooms. Although science educators have acknowledged the link between science studies and Wittgenstein's philosophy, it is not clear that the differences in interpretations of Wittgenstein's program by sociologists of science have been fully appreciated.[7]

43.3.4 Wittgenstein's Philosophy as the Basis for Analytic Approaches to the Study of Learning

A final theme to be examined is the use of Wittgenstein's writing in developing specific analytic programs or tools in science education. Aside from offering concepts that change our theoretical views of what is happening during science learning, Wittgenstein's philosophy has been taken as offering up imperatives for how to study the world around us. For example, Kelly (2005) focused on Wittgenstein's advice to "don't think, look!" as confirming the importance of empirical study of "*what* people come to know" and "*how* people come to know in various settings" (p. 86, emphasis added). Through empirical exemplars, he argued that descriptive studies of learning in science classrooms serve three purposes: to "illustrate how situated practices define meanings" (p. 88), to "make visible the practices involved in constructing and learning scientific knowledge" (p. 91) in order for science educators to direct interest in them, and to "focus on the everyday social practices of actual people" (p. 93), perhaps ultimately in order to "develo[p]

---

[7] Papayannakos (2008) is an exception.

ways of understanding and empathizing, and thus improving human conditions" (p. 99). Notably, however, Kelly's (2005) focus on "don't think, look!" presented description as an alternative to nonempirical studies but did not specifically point to the divergence of a program of analytic *description* from the "craving for generality" (often via theoretical *explanations*) that typically marks all scholarly investigation, whether empirical or not (see *Zettel*, §314, and Wittgenstein 1960, p. 17).

On the other hand, Macbeth's (2000) study of an interview between a student and conceptual change researcher (a scene from the professional development materials developed as part of the Harvard-Smithsonian Private Universe Project) is descriptive and, although not explicitly Wittgensteinian, shows an attempt to "bring into view, and even clarify, the conceptualizations of a research literature" (p. 236). The study described a scene in which a researcher constructed a "completely dark room" in order to challenge a student's conception that she will be able (eventually) to see there. Macbeth invoked Wittgenstein throughout the study, not to identify particular constructs as objects of analysis, but rather to compare the scene at hand with various exemplars given by Wittgenstein in his later writings.[8] Notably, and in a manner quite different from most studies of students' conceptions, the diagnostic interview examined in the study is not described as being about the meanings of terms, e.g., "light" and "dark" and "vision." Rather, the interview discourse is considered for what work it is doing: the work of a diagnostic interview and simultaneously the work of producing a professional development exhibit for teachers. Descriptions are given of how questions are asked and heard differently by the student subject and teacher audience, but the analysis is not used to promote a new theoretical understanding of meaning or discourse. In taking science education research itself as the topic of interest, and showing how researchers attach "beliefs" and "understandings" to students through diagnostic interviews, Macbeth attempted to provide clarity about our professional analytic concepts.

The most sustained use of Wittgenstein's work as basis for an analytic program in science education originated with Wickman and Östman (e.g., 2002a, b), who introduced Wittgenstein's writings to science educators as the foundation for a "tools taken from Wittgenstein to analyze discourse change" (2002b, p. 603). Their acknowledged frustration was with a sociocultural view of learning, which addressed the connection between people's actions and the sociohistorical contexts of which they are a part, but did not specifically posit a process for changes in learning to occur. Since they accepted that meaning is given through discourse processes, Wickman and Östman proposed looking closely at discourse in order to pinpoint the circumstances of discourse change. They examined transcripts of (classroom-based) interaction in order to determine how meanings change for students in the course of a classroom activity.

---

[8] For example, Macbeth describes how the student hears her interviewer's question "Have you ever been in a completely dark room?" as a reasonable query rather than as a professional science educator's attempt to ascertain whether she harbors a misconception about light and vision. He references Wittgenstein's comment "on how asking an Englishman if he has ever been to Budapest is quite different than asking if he has ever been to the moon" and notes that the student "hears the question about a "completely dark room" as of the former kind" (p. 242).

The methodology developed by Wickman and Östman involves analyzing student talk in order to determine which meanings appear to be "standing fast" for students and conversely where students apparently perceive gaps in understanding. They suggested that these gaps are filled when "participants establish new relations in terms of similarities and differences to what is standing fast" (2002b, p. 605). Finally, the analysis considers and sorts the gaps which are filled from those which continue to linger after the educational encounter. The authors cite their significant debt to Wittgenstein as follows:

> Wittgenstein explored the idea that it is relations that make the immediate intelligible. He noticed that "What stands fast does so, not because it is intrinsically obvious or convincing; it is rather held fast by what lies around it" (Wittgenstein 1969, p. 144). He elaborates this idea by referring to "family resemblances" when explaining the meaning of language-games (Wittgenstein 1953/1967, pp. 66–67): There is no single similarity that is common to all "games." Instead there is "a complicated network of similarities overlapping and criss-crossing: sometimes overall similarities, sometimes similarities of detail." These similarities connect everything we call games in the same way as "the various resemblances between members of a family." However, relations are not just similarities. Wittgenstein also refers to differences in his description of language-games.
>
> Hence, both similarities and differences beget "what is standing fast." However, Wittgenstein shows that an exhaustive description of all these relations for all possible contexts is not possible. Neither is there a single definition that is meaningful in all contexts. An explanation can only make sense if it relates to similarities and differences to what is already standing fast in a specific context. Meaning is tied to the context of a language-game. *Knowledge* could thus be understood as *relations of similarities and differences in what is immediately intelligible* and *learning* as *constructing new relations to what is immediately intelligible*. (Wickman and Östman 2002b, p. 605, emphasis added)

In other words, "language game" was conceived as a theoretical object employing the Wittgensteinian constructs of "standing fast" and "family resemblance" in order to provide alternative formulations of knowing and learning in science. But importantly, these constructs were used to determine the procedure for analysis of transcribed discourse occurring during science learning scenarios. Lines of transcript were scrutinized for terms that appeared to be understood by students (i.e., those that stand fast) and terms that appeared to need clarification (i.e., demonstrating a gap in understanding). Documentation of the ways in which students closed the gaps (by constructing relations to what is known) provided the authors with ways to describe science learning that could focus on issues related to specific science content lessons (e.g., chemical reactions or biological structures) or that could be used to answer larger questions about science education (e.g., the nature of student-teacher interaction or in situ misconceptions).

Originally, this method was used to study the ways in which students produce generalizations during laboratory work (Wickman and Östman 2002a) and to determine what students were able to learn about insect morphology in a university-level lab practical (Wickman and Östman 2002b). Over the next decade, other studies borrowed and refined the methodological approach. Wickman (2004) reframed the methodology as "practical epistemology analysis" and with it studied university students' learning during a chemistry laboratory activity in which unknowns were to be identified through (qualitative) analysis of reaction properties. Lidar et al. (2006) employed practical epistemology analysis to study the ways in which teachers' actions and students' apparent views of school science knowledge interacted in a seventh grade class engaged in chemistry activities.

Jakobson and Wickman (2007) studied children's spontaneous use of metaphors in learning science and determined that metaphors were used to construe relations between familiar and unfamiliar terms, to make aesthetic descriptions and evaluate classroom norms. In a related study, Jakobson and Wickman (2008) used practical epistemology analysis to further develop the connection between aesthetic judgment and normative participation in elementary school science. Hamza and Wickman (2008) asked whether the assumption in science education that misconceptions impact learning is true during real-time practical lab work and found through practical epistemology analysis that "misconceptions in electrochemistry did not constrain the ways students established relations to fill gaps noticed during the practical" (p. 160). Finally, Lidar et al. (2010) also used practical epistemology analysis to revisit the misconceptions literature in science education. Specifically they sought to illuminate a way in which individual experiences in learning might be synthesized with social and institutional ones, especially though examining the role of context and the use of artifacts in learning processes (see p. 693). Lidar and colleagues (2010) focused on children's conceptions of the earth and gravity and identified points at which different student groups 'take the learning path in different directions' perhaps "due to previous experiences or interaction with the teacher, peers, books, artifacts, or nature" (p. 706).

Combining practical epistemology analysis with analysis of teachers' epistemological moves (cf., Lidar et al. 2006) and with the analysis of companion meanings (or what might be otherwise known as the "hidden curriculum"), Lundqvist et al. (2009) developed an analytic program they labeled "communication analyses of companion meanings, or CACM" (p. 860). Again, Wittgenstein was cited for the insight that "people act without hesitation or doubt" such that most meanings can be seen to "stand fast" in talk (p. 863). As assumed in other practical epistemology analysis studies, Lundqvist and colleagues argued that "To learn something new, people have to create *relations* between the new and what already stands fast for them" (p. 864, emphasis in original). However, for students, teachers have a role in the learning process, and Lundqvist, Almqvist, and Östman noted that teachers' turns in discourse may serve to direct students and result in "changes in the students' practical epistemologies" in what can be seen as "confirming, instructional, reorienting, reconstructing, and generating moves" (p. 864, cf. Lidar et al. 2006). However, Lundqvist and colleagues emphasized the importance of analyzing epistemological moves in situ, since per Wittgenstein, the meaning of such moves is contextual:

> In a different situation, the same kind of epistemological move might have a completely different meaning. This design accords with Wittgenstein's methodological advice, which is to *look* at the circumstances in which words and sentences are used (e.g., Wittgenstein, 1953/2001: §66, 1969: §501). (Lundqvist et al. 2009, p. 864, emphasis in original)

With an understanding of students' practical epistemologies and teachers' epistemological moves in hand, CACM was used to uncover the local norms at play in the science classroom and then "to identify and problematize norms as resources in the practice studied, as well as constituting specific worldviews and being potential consequences of students' socialization" (Lundqvist et al. p. 865). Through actual analysis of empirical materials, Lundqvist and colleagues showed how naïve empiricist and naïve rationalist views of science may be at play in classroom science lessons, a result that "could attract considerable criticism" for the way in which it contradicts "many countries' policy documents with regard to how to portray science and its activities" (p. 870).

In these many ways, Wittgenstein's corpus has thus served as an inspiration to science educators seeking new ways of researching learning in science, not just in the theoretical assumptions made about learning, but in actual analytic practices. Wittgenstein has been read as telling us to focus our efforts on describing language use in practice. He has also been interpreted as authorizing an analysis of meanings that stand fast versus those which must be resolved through building relations. In this way, educators have used Wittgenstein's philosophy to first describe classroom life on a micro-interactional scale and in some cases to use these descriptions to answer larger questions about science education or learning.

43.3.5 Summary

The discussion above is not exhaustive with respect to Wittgenstein's influence in science education research; others have considered the implications of the *Tractatus* in science education (e.g., Besson 2010; Rowlands et al. 2007) or the import of Wittgenstein's concepts for NOS pedagogy (e.g., Irzik and Nola 2011). But this chapter's focus is on the ways in which Wittgenstein's later writings have informed our conceptions of and research on students' science learning. The impact of Wittgenstein's philosophy in science education, while certainly not ubiquitous, can be seen in substantial strands of argument across the literature of the last 20 years. First, Wittgenstein was influential in a shift among science educators away from a singular definition of rationality as it relates to knowledge, learning, and particularly scientific rationality. Second, Wittgenstein is often invoked by researchers who aim to study learning from a sociocultural and discursive perspective. His notion of "language games" helped researchers transition from thinking of conceptual understanding as "the acquisition of mental schema" to conceiving of it as "the ability to use language correctly in various contexts." Wittgenstein was tangentially influential in the movement that sought to build studies of science classroom learning in the model of sociological studies of professional laboratory science, since his philosophy was central to the science studies movement itself. Finally, researchers have used Wittgenstein's philosophy to argue for a different model of analysis, for example, studies that focus on description and studies that focus on the ways in which words do or do not "stand fast" in actual instances of talk.

43.4 A Critical Assessment of Wittgenstein's Role (So Far) in Science Education

The discussion so far suggests that many of the arguments or lines of inquiry introduced above tend to make use of Wittgenstein in "ordinary" ways, that is, as a source of analytic conceptual innovation for science education research investigations. Most of these projects use Wittgenstein in ways that are familiar in our pursuit of new topics or distinctions. But when we read Wittgenstein as yet another resource or authority for speaking differently, we may risk missing what he has to say, as a program aimed at rewriting the very terms of doing philosophy. In this way, straying from Wittgenstein's disciplined form of analysis is not difficult to do. Indeed, whether one has or not is a central contest in the commentaries on his corpus.[9] In this light, it is a virtual certainty that inconsistencies can be found in treatments of Wittgenstein's work in science education. Often we see them within paragraphs, or even sentences, of suggestions for following Wittgenstein's insights as questionable formulations of the implications of these insights. This is not necessarily because specific passages or citations are misunderstood. To the contrary, Wittgenstein *does* talk about the meaning of a word being its use in a language game or the impossibility of a private language, for example.

However, a major source of incongruity is the difference between Wittgenstein's project – his method of doing philosophy "as therapy" – and the project that drives most work in science education. For Wittgenstein, the goal of philosophy is to untangle conceptual confusions. His writings critique the very enterprise of philosophy as we know it, a reading that is very difficult to find in science education. In education research, the identifying task is to build a scientific account of various aspects of the educational experience, e.g., a theory of learning that can explain and predict human action or at least the acquisition of scientific understanding. Yet it is just this kind of theory building that was a target of Wittgenstein's efforts at conceptual clarification; it was precisely these "totalizing" accounts and ambitions that he was dissolving. What Wittgenstein pointed to over and over again in his work was our tendency to theorize the world and to inflate otherwise ordinary words so as to appear extraordinary and foundational. It was the pursuit of such foundations that he was inveighing against; he was writing a critique of the very possibility:

> When philosophers use a word – "knowledge," "being," "object," "I," "proposition," "name" – and try to grasp the *essence* of the thing, one must always ask oneself: is the word ever actually used in this way in the language-game which is its original home? –
>
> What *we* do is to bring words back from their metaphysical to their everyday use. (Wittgenstein 1958, §116, emphasis in original)[10]

---

[9] For instance, see Malcolm (1989) and Baker and Hacker (1990); or see Sharrock and Button (1999) on the Lynch-Bloor exchange cited earlier.

[10] Note also the use of "language game" in this passage: not as a theoretical imperative but something mundane and ordinarily recognizable.

Wittgenstein's recommendation for science education researchers, then, would undoubtedly have been to step back and "battle against the bewitchment of our intelligence by means of language" (Wittgenstein 1958, §109). The "bewitchment" will not be broken by the introduction of new topics, but rather by an examination of old habits, and especially those deeply taken for granted in grammatical confusions.

43.4.1 "Meaning" as a Source of Conceptual Confusion

Although there are many candidate terms in this battle, "meaning" seems to cast a particularly charming spell on contemporary theories of learning. This handbook chapter has focused on the ways in which Wittgenstein's writings have been used in research on learning in science; all of it are in some way connected to accounts of meaning. Meaning is subject to local forms of rationality, which must be investigated empirically, uncovered, and articulated. The concept of "language game" serves as an alternative to "mental images," as a vehicle through which meaning is constructed or conveyed. "Meaning-in-use" usually refers to the performative and public nature of meaning; however, the contextual and temporary nature of meaning is also often linked to this phrase as well. Meanings that "stand fast," according to the use of this expression in science education, are those that are not questioned during talk.

In science education research, each of the above concepts or phrases associated with Wittgenstein's philosophy has been pressed into service on behalf of a driving interest in students' meaning making. "Meaning making" typically refers to a notion that the meanings of words or expressions are constructed or created via a process involving an interaction between prior understanding and engagement with new phenomena, whether those phenomena are physical or discursive. The picture is something like this: meanings result from engaging in practices; or, people assign meanings (typically, to words or perhaps gestures in discourse) as an outcome of interacting with others and/or the physical world. Alternatively, one might say that for science education researchers, meaning making involves a process of verifying and then attaching or assigning an ostensive definition to a "concept," whether this concept is said to be located in discourse or in mental schema.

To wit, Kelly and Green (1998) write, "Members of a group ascribe meaning to the processes, artifacts, practices, and signs and symbols that they construct in and through everyday activity" (p. 147). And Wickman (2004) notes of his "practical epistemology analysis" methodology that "The focus here is…to use a formal theory of meaning-making in illuminating the *connection* between *how* people produce meaning and *what* meaning is produced in a specific practice" (p. 327, emphasis in original). Lidar et al. (2010) outline the basic analytic practice:

> An encounter is where meaning making happens…The meaning-making process is thus analyzed by studying encounters where gaps could occur, and how people to fill the gaps, establish relations between the new in an encounter, and what stands fast. Biesta and Burbules (2003, p. 36) describe meaning making as "the way in which the organism responds to the environment." In practical epistemology terminology, this could be expressed: Meaning making is to create relations between the new in an encounter and what is standing fast. (p. 694–695)

In this way, Wittgenstein's philosophy has been tied to a generally "constructivist" logic of meaning making in science education, where uncertainty is continuously resolved by individuals linking their objects of inquiry to known meanings and/or objects in the environment. And the study of meaning, on this view, is rightfully an empirical investigation of "how" people make meaning and "what" meanings they make.[11]

However, from a Wittgensteinian viewpoint, this picture of meaning making in science education is entirely misleading. Again, recall that Wittgenstein championed seeking conceptual clarity about the terms which scholars were routinely tempted to use in a theoretical way. Thus, as an alternative to taking an unquestioned empirical interest in "meaning," we may first want to grasp – conceptually – the way in which we might think of the term. Recall Hacker's summary of Wittgenstein's philosophy in this regard:

> The meaning of an expression, with marginal qualifications, is its use. It is also what is understood by anyone who understands or knows what an expression means. And it is what is given by an explanation of meaning. An explanation of meaning, even a humdrum explanation given by means of a series of examples, is a rule – a standard of correctness – for the use of the explanandum. (Hacker 2007b, p. 4)

Wittgenstein's philosophy implies that "meaning" is something we should think of as *conventional* and in that sense *stable*, not arbitrarily "made" (or constructed) on the spot, as a result of some kind of process. What is meant by "meaning" in our ordinary, everyday discourse is not mysterious or in need of scientific explanation. When we are uncertain of the meaning of an expression, we find recourse in exemplars that illustrate its use; in other words, the meaning of an expression can be sought in imagining its typical use in language.

Now, of course, an expression can be misunderstood by or unfamiliar to persons or groups of persons. The meaning of an expression can change, or new expressions with new meanings can be created for specific purposes. These can, over time, become convention. And certainly, one can use double entendres, puns, or other wordplay to joke about meanings – but again, these too are orthodox. "Being ironic" on the one hand, or "getting the joke" on the other, in fact depends on the conventional nature of meaning. But these examples license neither the picture of a general, pervasive process of "meaning making" nor a science which seeks to explain individual (or community) engagement in a constant skeptical inquiry

---

[11] Does conceptualizing meaning making as being "social" change its nature for the purposes of empirical investigation? Kelly and Crawford (1997) state: "We view meaning as of a group, not an individual, and therefore view the substance of cognition as social (Wittgenstein 1958)" (p. 536). Social constructivism is often based on the view – said to be taken from Wittgenstein – that groups "make meaning" by creating rules for using expressions (and this is the process to be empirically investigated; cf. Bloor 1983). On this point, Sharrock and Button's (1999) and Francis's (2005) critiques of Bloor's program are instructive. Briefly, constructivism treats consensus as a precondition of rule following (and thus in need of explanation) rather than seeing the regular agreement about meaning as part of the use of language in our lives (see also Richter 2004; similarly Diamond 1989; Lynch 1992a). In this way, social constructivism shares with "individual" constructivism the same wrong-headed view of meaning as resulting from a process that requires theoretical explanation.

with the world, pursuing a means of anchoring words with meanings in order to proceed with learning (or even with basic communication).[12]

In other words, a first distinction to be drawn here is between "meaning" as an object of empirical analysis and "meaning" as we might *ordinarily* think of it: We ask the meaning of an unfamiliar word or expression we encounter in everyday life, and it is explained to us via examples or definition. Ryle similarly deflates the meaning of "meaning": "To know what an expression means involves knowing what can (logically) be said with it and what cannot (logically) be said with it. It involves knowing a set of bans, fiats and obligations, or, in a word, it is to know the rules of the employment of that expression" (1971, p. 363).

And there is a second sense in which to think of "meaning" as knowing how to use an expression. It is helpful to understand the context of Wittgenstein's words and that they took place in a larger discussion about other notions of what "meaning" might be. In part, what Wittgenstein was doing in emphasizing meaning-in-use was contrasting this with a notion that the meaning of a word or expression is identical with the object denoted by it (cf., Ryle 1971). Richter (2004) notes that "the main rival views" to be contrasted with Wittgenstein's notion of meaning-in-use were "that the meaning of a word is some object that it names" or "that the meaning of a word is some psychological feeling" (no page number). In other words, Wittgenstein was drawing a distinction between meaning as *doing* and meaning as *representing*. He was critiquing representational notions of language. Yet analytic orientations in science education that theorize meanings as being "assigned to processes, artifacts, practices, and signs and symbols" or meaning making as consisting in construing relations between concepts return us to a picture of "meanings" as representational "links" – between the world and talk and between known and new. Of course, explaining the meaning of a word *can* consist in giving an ostensive definition. But Hacker reminds us of the proper way to think about an ostensive definition, which is "*not [as] a link* between word and object, or language and reality, but a rule for the use of a word" (Hacker 2007b, p. 4, emphasis added). Again, Ryle is useful here: "the meanings or significations of many kinds of expressions are matters not of *naming* things but of *saying* things" (1971, p. 362, emphasis in original).

---

[12] Here it is instructive to consider how the science studies literature has been looked to as exemplary of studying new meaning creation. Specifically, Garfinkel et al. (1981) study of the discovery of an optical pulsar has been recommended as a model for the study of "the processes by which scientific objects are discursively created" (Kelly and Crawford 1997, p. 535) and thus for how the "school science knowledge creation" of classroom cohorts may be similarly examined. This tendency to link science studies and research in science education perhaps stems from our history of connecting our understanding of how scientists create knowledge to how people create meaning (e.g., a la conceptual change and various constructivist theories of science learning). But Garfinkel, Lynch, and Livingston's examination of talk recorded during the optical pulsar discovery occurred *after* the event had been taken up and affirmed within the relevant science community. With hindsight the "night's work" can get flagged as the "origin" (or part of the origin) of a new conventional understanding about pulsars, but we shouldn't then imagine that new meanings are created this way in *every* lab encounter. Neither should we focus on students' ordinary science classroom interaction as an incessant creation of new meanings. See Greiffenhagen and Sherman (2008) on the problem with conceiving of students' knowledge of the natural world as having "the form of a systematic, causal (proto-scientific) theory" (p. 16).

The upshot of these considerations is that science educators' efforts to explain "meaning making" appear misguided, especially among those who find instruction in Wittgenstein's later works. The nature of "meaning" is not mysterious when we consider its ordinary use. Meanings are not connections, associations, names, or links between language and the world. In contrast to the prevailing *theoretical* orientation, when we *ordinarily* focus on meanings, we focus on their conventional nature; we focus on the typical rules for using an expression, and not on how meanings might be idiosyncratically "made" by individuals or groups. In short, there is no empirical imperative for the study of meaning making because there is no general, overarching *process* at play in need of explanation.

43.4.2 Meanings "Standing Fast"

Yet, the impulse to explain in matters of meaning persists, perhaps most vividly among the advocates of practical epistemology analysis. Practical epistemology analysis theorizes just such a process and turns on Wittgenstein's notion of "standing fast" to anchor it. Wickman (2004) proposes that when "a word is 'clearly understood' in a specific language-game [it] can be operationalized as 'standing fast,' which means that it can be seen to be used without hesitation or questioning" (p. 328). Words that do stand fast act as anchors to those that do not; and by establishing these different standings, we can examine how new meanings can be created. In other words, "standing fast" is the marker of certain knowledge, and sequences in which students speak without running into apparent difficulty are taken as evidence for words – and therefore meanings – "standing fast."

But, in what context was Wittgenstein using the phrase "standing fast"? The passage from *On Certainty* cited by Wickman and Östman (2002b) reads:

> The child learns to believe a host of things. I.e. it learns to act according to these beliefs. Bit by bit there forms a system of what is believed, and in that system some things stand unshakeably fast and some are more or less liable to shift. What stands fast does so, not because it is intrinsically obvious or convincing; it is rather held fast by what lies around it. (Wittgenstein 1969, §144)

On the surface, it seems reasonable that these remarks could leverage the kind of methodology developed as "practical epistemology analysis": find out what students seem to know and not know as evidenced in their ways of speaking, and investigate what lies around it to make this knowledge certain (or not).

But importantly, this passage is actually part of a larger argument that Wittgenstein is making about the nature of certainty and doubt. He was drawing a contrast between words that *stand fast* and ones that are *known* or *learned*. Quoting at length from *On Certainty* illustrates more of this context:

> How does someone judge which is his right and which is his left hand? How do I know that my judgment will agree with someone else's? How do I know that this color is blue? If I don't trust myself here, why should I trust anyone else's judgment? Is there a why? Must I not begin to trust somewhere? That is to say: somewhere I must begin with not-doubting; and that is not, so to speak, hasty but excusable: it is part of judging.

> I should like to say: Moore does not *know* what he asserts he knows, but it stands fast for him, as also for me; regarding it as absolutely solid is part of our *method* of doubt and enquiry.
>
> I do not explicitly learn the propositions that stand fast for me. I can discover them subsequently like the axis around which a body rotates. The axis is not fixed in the sense that anything holds it fast, but the movement around it determines its immobility.
>
> No one ever taught me that my hands don't disappear when I am not paying attention to them. Nor can I be said to presuppose the truth of this proposition in my assertions etc., (as if they rested on it) while it only gets sense from the rest of our procedure of asserting. (1969, §150–153, emphasis in original)

Wittgenstein is calling attention to the skepticist's quest for a formal grounding of our knowledge. How do we know we have a body? How do we know that my "blue" is your "blue"? and so on. Wittgenstein's Cambridge colleague G. E. Moore addressed philosophical skepticism by famously declaring that his hands exist because he knows they exist. But in the passage above (and throughout *On Certainty*), Wittgenstein questions the grammar of this assertion. He argues that "knowing" is sensible only when "not knowing" is possible; "Doubting and non-doubting behavior. There is the first only if there is the second" (Wittgenstein 1969, §354).

In the specific case of knowing one's hands exist, "If Moore were to pronounce the opposite of those propositions which he declares certain, we should not just not share his opinion: we should regard him as demented" (1969, §155). This is not to claim that it is impossible to imagine a context in which such a statement is coherent (e.g., as a joke or, more seriously, as being said by someone just awakening from a procedure where extremities had been amputated). Wittgenstein's point is that one does not generally consider possession of body parts to be in question. So, "standing fast" for Wittgenstein was an alternative way to describe what Moore said that he *knows* and an attempt to dispel the skepticist orientation altogether by illustrating that such a statement is not in need of any kind of grounding. Moore was looking for assurances that no actual language game needs.

With this very specific purpose for the use of the phrase "standing fast" in mind, it is difficult to support the interpretation of it being advanced in science education research. Since at least the work of Ausubel, educational theorists have been arguing that learning is a process of linking new knowledge to existing knowledge. "Practical epistemology analysis" represents a contemporary interpretation of this theory, more invested in language and social interaction than its predecessors, but still focused on the idea that knowledge must be secured in order for learning, or even communication itself, to take place. Wittgenstein on the other hand explicitly rejected a foundational view of knowledge in general:

> But since a language-game is something that consists in the recurrent procedures of the game in time, it seems impossible to say in any individual case that such-and-such must be beyond doubt if there is to be a language-game—*though it is right enough to say that as a rule some empirical judgment or other must be beyond doubt*. (1969, §519, emphasis added)

> A doubt without an end is not even a doubt. (1969, §625)

> For why should the language game rest on some kind of knowledge? (1969, §477)

Of course, there are often times in conversation when meanings are unclear, and it is sensible to suggest that students who encounter unfamiliar words or usages during a classroom task may infer meanings from more familiar terms. What Wittgenstein cautions against, as he is wont to do, is the idea that something like a linguistic gap-closing exercise is constitutive of *all* meaning and thus learning, let alone all use of language.

43.4.3 Meaning, Interpreting, and Understanding

The discussion above suggests that any program that aims to formally explain students' meaning making is ill advised. This seems to be Wittgenstein's counsel, though it may be a decidedly unsatisfactory conclusion for science education researchers. It is tempting to think that the matter has been oversimplified in this discussion by focusing on the ordinary and conventional notion of "meaning." After all, Wittgenstein also emphasized meaning-in-context, presumably pointing to the sometimes unexpected and unique use of words. Furthermore, science educators' interests in this regard are understandable, as students in the science classroom do not yet know the conventions of science or even school science. It could be argued that what we are really after in science education is how students *interpret* meanings in various contexts, and particularly in the classroom setting, e.g., how they interpret "gene" or "heredity." Certainly, we "interpret" the meaning of talk in interaction. This may be particularly true in instances when one encounters an unfamiliar expression, a likely occurrence in the science classroom. If our interest is not in meanings, do we instead need a series of empirical investigations and ultimately a theory to explain *interpretations*? In other words, perhaps the question is what *interpretations* are made by science students, and how are they made?

The Lidar et al. (2010) study of students' discussions about the earth's shape and gravity provides delightful examples of what could be construed as novices' interpretive work. When asked "If you were to walk for many days in a straight line, where would you end up?" some second, fourth, and fifth grade students were able to produce the sought-after answer; one would end up back where he or she started. But other students mention running into a house or the ocean. And one group of students finds a "straight" road outward from their town on a map and "walks" along it with their fingers for "20 steps" to arrive at an answer to the question. The latter group's answer to the question is unique and unexpected – but is being able to explain and predict an occurrence like this the goal of our empirical investigation of science learning? Is explaining and predicting such interpretations even possible?

Again, we can examine Wittgenstein's writings for some guidance. In the case of learning a new meaning, he discusses how ostensive teaching can be variously interpreted:

> Let us then explain the word 'tove' by pointing to a pencil and saying 'this is tove'…Now the ostensive definition 'this is tove' can be interpreted all sorts of ways…The definition can then be interpreted to mean:
>
> "This is a pencil",
> "This is round",
> "This is wood",
> "This is one",
> "This is hard," etc., etc. (Wittgenstein 1960, p. 2)

In other words, it is entirely possible that even in the most basic of interactions – pointing and naming – interpretations of what is meant can be diverse. Nevertheless, none of these interpretations is unreasonable, and all point to a sensible conclusion reached from witnessing the pointing and talking described. The meanings of various interpretations of "tove" are *still* conventional. Likewise, the interpretations of some students in Lidar and colleagues' (2010) study may be unexpected, and while it is instructive for teachers to be aware of a range of possible student interpretations of questions asked in a classroom activity, it is difficult to know what about them is in need of explanation or what explanations set them apart.

The temptation of Wittgenstein's vignette about "tove," or a focus on it as a play on interpretation – and it is a dangerously compelling one – is to assume that *every* interaction in language consists in making an interpretation. Words or expressions *can* be interpreted, *but they don't have to be*. Here again is where we want to be reminded of Wittgenstein's philosophical project to "bring words back from their metaphysical to their everyday use" (Wittgenstein 1958, §116). Wittgenstein cautions against the tendency to assume that an interpretation always lies behind sense and meaning. He uses the example of the command "fetch me a red flower from the meadow" and asks, must one conjure up an image of a red patch and compare it to the flowers before him in order to comply with the order? In other words: must we interpret, e.g., "red" in order to obey the command? His clever response: "consider the order '*imagine* a red patch'" (Wittgenstein 1960, p. 3). What process is to be imagined here? Wittgenstein continues, "Now you might ask: do we interpret the words before we obey the order? And in some cases you will find that you do something which might be called interpreting before obeying, in some cases not" (1960, p. 3).

As with "meaning," it would appear that there is nothing foundational or extraordinary about "interpretation" that calls for empirical investigation and theory building. The astute reader will surmise that any next candidate term, once considered in the context of its typical use in the language, will be "deflated" in a similar way, e.g., understanding[13]:

> 'What happens when a man suddenly understands?' – The question is badly framed. If it is a question about the meaning of the expression 'sudden understanding,' *the answer is not to point to a process that we give this name to*. – The question might mean: what are the tokens of sudden understanding; what are its psychical accompaniments?…The question what the expression means is not answered by such a description; and this misleads us into concluding that understanding is a specific indefinable experience. (Wittgenstein 1958, §321–322, emphasis added)

> Trying to understand may involve (polymorphous) processes, but actually understanding is neither an act nor a process of any kind. We distinguish between thinking that one has understood and actually having understood: thus, understanding carries *no subjective sovereignty* for its claimant. Since understanding in these cases (we exempt the notion of 'empathy' here) does not designate *any* process, the notion that understanding speech is a matter of 'processing' it (the concept favored by cognitivists infatuated with computational jargon) cannot pass muster. (Coulter 2008, p. 28, emphasis in original)

---

[13] Or, "learning" (Macbeth et al. 2011).

In light of these discussions, a conceptual analysis of "meaning" would seem to recommend that we not think of meanings as individually or situationally "constructed" as the product of some internal or social process or any combination of the two. The meaning of an expression can be interpreted, and people can understand or misunderstand an utterance. A particular expression can have different uses and thus different meanings. But meanings themselves are not "negotiated" or "assigned" in interaction, in the sense of having been created from an internal or external process that must then be explained. What we *can* do in conversation is to ascertain whether or not someone understands how to use an expression and whether someone (even ourselves) misunderstood what was expressed. But in ordinary life we don't make these assessments by looking "behind" or "underneath" talk for the meanings assigned to an expression, as if these were separate from the talk itself. Per Wittgenstein, "When I think in language, there aren't 'meanings' going through my mind in addition to the verbal expressions: the language is itself the vehicle of thought" (1958, §329). Or, as Coulter reminds us, "it is the scenic performance (or its possibility) which comprises the criterion for having understood something, not any phenomena postulated as 'internal' to the person" (2008, p. 28). In other words, we judge understanding or misunderstanding by linguistic performance, by whether or not someone has followed the correct rule for using an expression.

43.5 Conclusion

Wittgenstein's later philosophy has served to inspire new interest in language and thinking across the social sciences, and science education is no exception. Specifically in science education, Wittgenstein's writings have been used to argue for an alternate conception of rationality, to support theories examining the discursive and social nature of learning, to advocate for investigations of science classrooms that parallel ethnographic and sociological investigations of professional science labs, and to develop alternative research methodologies. And yet, this chapter has argued that efforts to merge concepts from Wittgenstein's philosophy into the typical project of science education research often can be misguided. Rather than understand Wittgenstein's writings as a penetrating critique of our familiar ways of doing "analysis," science education researchers have routinely attempted to recruit selected arguments and formulations for use in familiar programs of research. But this habit likely results in perpetuating conceptual confusions, if not introducing new candidates. Minar argues that "we cannot avoid thinking about [Wittgenstein's] methods and their rationale if we are to find his philosophy intelligible" (1995, p. 416). In the observation is a recommendation for how the science education literature might proceed differently with Wittgenstein's insights.

The "ordinary ways of researching" in science education are tied to a historical sense of the project of education research more broadly, which is to "scientize" teaching: education researchers essentially do what teachers do, but with the power of "theory" behind their judgments (cf. Sherman 2005). This urge to theorize was an anathema to Wittgenstein. In an extensive passage early in *The Blue and Brown Books*, he laments what he calls the "craving for generality" in academic endeavors[14]:

> Now what makes it difficult for us to take this line of investigation [i.e., Wittgenstein's philosophical method] is our craving for generality.
>
> This craving for generality is the resultant of a number of tendencies connected with particular philosophical confusions. There is—
>
> (a) The tendency to look for something in common to all the entities which we commonly subsume under a general term….The idea of a general concept being a common property of its particular instances connects up with other primitive, too simple, ideas of the structure of language. It is comparable to the idea that *properties* are *ingredients* of the things which have the properties; e.g., that beauty is an ingredient of all beautiful things as alcohol is of beer and wine, and that we therefore could have pure beauty, unadulterated by anything that is beautiful.
>
> (b) There is a tendency rooted in our usual forms of expression, to think that the man who has learnt to understand a general term, say, the term "leaf", has thereby come to possess a kind of general picture of a leaf, as opposed to pictures of particular leaves…. We say that he sees what is common to all these leaves; and this is true if we mean that he can on being asked tell us certain features or properties which they have in common. But we are inclined to think that the general idea of a leaf is something like a visual image, but one which only contains what is common to all leaves….This again is connected with the idea that the meaning of a word is an image, or a thing correlated to the word….
>
> (c) Again, the idea we have of what happens when we get hold of the general idea 'leaf,' 'plant,' etc. etc., is connected with the confusion between a mental state, meaning a state of a hypothetical mental mechanism, and a mental state meaning a state of consciousness (toothache, etc.).
>
> (d) Our craving for generality has another main source: our preoccupation with the method of science….Philosophers constantly see the method of science before their eyes, and are irresistibly tempted to ask and answer questions in the way science does.…I want to say here that it can never be our job to reduce anything to anything, or to explain anything. Philosophy really *is* 'purely descriptive'….
>
> Instead of 'craving for generality' I could also have said "the contemptuous attitude toward the particular case." (1960, pp. 17–18)

Taking up Wittgenstein's writings means seeing them in light of *his* project: to "bring words back from their metaphysical to their everyday use" (Wittgenstein 1958, §116). In science education, we see the tendencies toward generality described above in studies which aim to formally explain students' "meaning making," even in studies which purport to be informed by Wittgenstein's writings. An alternative program of analysis resting on "therapeutic" descriptions of the ordinary use of concepts has been suggested in the critiques advanced in this chapter.

Citing Norman Malcolm, Richter (2004) identifies four primary ways in which Wittgenstein's therapeutic method of philosophy could be employed: "describing circumstances in which a seemingly problematic expression might actually be used in everyday life, comparing our use of words with imaginary language games, imagining fictitious natural history, and explaining psychologically the temptation

to use a certain expression inappropriately" (no page number). In the discussions above, an attempt has been made to contrast the use of "meaning" and related terms in science education research with their ordinary, mundane use in order to reconsider not only the topics of our research but the research program itself. Wittgenstein advocated a very different kind of descriptive enterprise.

It is important to clarify that in taking this position, Wittgenstein should not be seen as "antiscience" or "'anti-philosophy."[15] Scientific practice is completely appropriate for making sense of the natural world. What Wittgenstein is arguing is that the assumptions we make about the natural world in studying it the way we do are not assumptions we can make about the way language works; thus, the study of people is necessarily different from the study of the natural world (cf. Hutchinson et al. 2008; Winch 1958). Rather than aim for producing general theoretical explanations of human language-based action, we should aim for careful, patient examination and description of the use of concepts in our lives (cf., Diamond 1989).

> Here we come up against a remarkable and characteristic phenomenon in philosophical investigation: the difficulty—I might say—is not of finding the solution but rather that of recognizing as the solution something that looks as if it were only a preliminary to it….This is connected, I believe, with our wrongly expecting an explanation, whereas the solution to our difficulty is a description, if we give it the right place in our considerations. If we dwell upon it, and do not try to get beyond it.
>
> The difficulty here is: to stop. (Wittgenstein 1967, §314)

Wendy Sherman Heckler is Associate Vice President for Academic Affairs and Dean of University Programs at Otterbein University in Westerville, Ohio, USA. Her M.A. and Ph.D. in science education are from the Ohio State University and her classroom teaching experience is in physics, chemistry, and mathematics. Her research explores issues of conceptual clarity in education research design and empirical claims, through an integration of the perspectives of analytic philosophy and ethnomethodological sociology. At Otterbein, she has taught courses in research methods and design and the philosophy of research, as well as courses in science education pedagogy, physics, and integrative studies.

Chapter 44
Science Textbooks: The Role of History and Philosophy of Science

Mansoor Niaz

44.1 Introduction

Gerald Holton's (1952) *Introduction to Concepts and Theories in Physical Science* provided a glimpse for students and teachers as to how science evolves through the interactions of theories, experiments, and the work of actual scientists within a history and philosophy of science (HPS) perspective. This textbook has been a source of inspiration for many students of HPS. Looking back after almost 50 years, Holton (2003) considered that the textbook facilitated understanding of science as a coherent story based on the thoughts and work of living scientists. More recently, a new edition of this textbook has presented science as a human adventure, from Copernicus to Einstein and beyond (Holton and Brush 2001).

Writing in a special issue dedicated to *Students' Models and Epistemologies of Science,* Linn et al. (1991) pointed out: "Gerald Holton infused Harvard Project Physics with marvelous historical examples of scientific investigation. These were heralded as ground breaking, but were rarely imitated. Instead, if they discuss process at all, *science textbooks describe an outmoded and incorrect view of scientific knowledge acquisition*" (p. 729, italics added). The importance of history and philosophy of science was generally recognized by science educators in the 1960s (Klopfer 1969; Robinson 1969), and in the last 20 years, there has been a worldwide sustained effort to provide a rationale for its inclusion in the science curriculum (Matthews 1990, 1994/2014; Scheffler 1992).

Many researchers and teachers have endorsed the inclusion of history and philosophy of science (HPS) in the science curriculum, textbooks, and classroom

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_44,

practice (Hodson 1985, 1988, 2008, 2009; Matthews 1994/2014, 1998; Niaz 2008, 2009a, b, 2011). Interestingly, however, Bevilacqua and Bordoni (1998) have stated: “We are not interested in adding the history of physics to teaching physics, as an optional subject: the history of physics is ‘inside’ physics” (p. 451). Guisasola et al. (2005) have endorsed a similar thesis. This is an important argument, which has generally been ignored in the science education literature and especially that related to textbooks. In other words, we do not have to justify or request for the inclusion of HPS in the science curriculum and textbooks. Teaching science without the historical context in which ideas and theories develop comes quite close to what Schwab (1962, 1974) has referred to as “rhetoric of conclusions.” Matthews (1998) has argued that philosophy is not far below the surface in any science classroom, as most textbooks and classroom discussions deal among others, with concepts, such as law, theory, model, explanation, cause, hypothesis, confirmation, observation, evidence, and idealization (p. 168). Similarly, Niaz and Rodríguez (2001) based on a historical framework have shown that HPS is already “inside” chemistry, and we do not need separate courses for its introduction.

At this stage it is important to clarify that the approach (HPS being inside the science curriculum) suggested here does not rule out the possibility of designing separate courses dealing with various aspects of the history of science both at the undergraduate and graduate level. It is worthwhile to provide here some examples of such an approach. Abd-El-Khalick (2005) explored the views of preservice science teachers by including a discussion of historical episodes such as dinosaur extinction controversy, Copernican revolution, Michelson-Morley experiment, cold fusion, and verification of the relativity theory. Pocoví (2007) studied the effect of history-based instructional material (Faraday’s writings) to facilitate freshman students’ understanding of field lines. Hosson and Kaminski (2007) developed a teaching strategy based on the history of the optical mechanism of vision (Alhazen’s writings) for facilitating high schools students’ reasoning about vision. Niaz (2009b) developed a course for facilitating in-service chemistry teachers’ understanding of nature of science by including historical controversies related to atomic models and the oil drop experiment. This clearly shows that the two approaches can be used to facilitate an understanding based on HPS.

Abd-El-Khalick (2005) has expressed the relationship between nature of science (NOS) and history and philosophy of science (HPS), in cogent terms:

> … if we want teachers to address NOS instructionally, our efforts to help them develop the necessary understandings need to go beyond a few hours of NOS-related instruction in a science- methods course. Naturally, history and philosophy of science, which are the ‘stuff’ of NOS, are primary candidates for enriching the development of science teachers in the area of NOS. (p. 38)

The role of history of science in science education and especially the textbooks has been the source of considerable discussion in the literature.[1] At this stage it is

---

[1] For example, see Brush (2000), Bensaude-Vincent (2006), Chiappetta and colleagues (2006), Gooday and colleagues (2008), Kindi (2005), Niaz (2010a), Siegel (1978), and Zemplén (2007).

important to differentiate between two types of studies related to science textbooks that can be classified as:

(a) Domain specific: These studies are based on a historical reconstruction of a given topic of the science curriculum. The following are some examples of such studies presented in this chapter: quantum hypothesis (Brush 2000), photoelectric effect (Niaz et al. 2010a), periodic table (Brito et al. 2005), and atomic structure (Niaz 1998, 2000a; Justi and Gilbert 2000; Padilla and Furio-Mas 2008).
(b) Domain general: These studies are based on a series of nature of science (NOS) dimensions, which are in turn derived from the history and philosophy of science. Such dimensions consider NOS to be empirical, tentative, inferential, creative, theory driven, social, and culturally embedded. The following examples of this research are presented in this chapter: Abd-El-Khalick et al. (2008) and Leite (2002).

Although there is an overlap between these two types of studies, the distinction between the domain specific and domain general is important. Domain-general dimensions can be used to evaluate various parts of the textbooks, irrespective of the science content selected. In contrast, domain-specific studies are based on a historical reconstruction of a topic, and, for example, criteria developed for atomic structure cannot be used for evaluating the photoelectric effect.

Purpose of this chapter is to review research based on analyses of science textbooks that explicitly use a history and philosophy of science framework. This review has focused on studies published in the 15-year period (1996–2010) and has drawn on the following major science education journals: *International Journal of Science Education, Journal of Research in Science Teaching, Science Education,* and *Science & Education.* In order to select a study for review, I used the following list of criteria: title of the article, abstract, keywords, theoretical rationale, method, conclusion, and references. Furthermore, it was not just one criterion or certain terms but rather the overall contribution of the study towards facilitating an understanding of the science topic, within an HPS perspective that determined its selection. It is important to note that there are some issues such as science literacy, science-technology-society (STS), conceptual change, pedagogical content knowledge, analogies, and constructivism which are important within an HPS perspective. However, articles related to such issues were included only if they had an explicit bearing on some aspect of HPS and thus facilitated greater understanding. Based on these criteria 52 articles were selected for review, and Table 44.1 provides a distribution of the articles based on the year of publication and the journal. Table 44.2 provides a distribution of the selected articles according to the following subjects: biology, chemistry, physics, and school science. It can be observed that over half the studies(28 out of 52) were published in *Science & Education*, which clearly shows the importance of HPS for this journal. In the following sections discussion of each of these studies is presented. Table 44.2 shows that 19 studies dealt with school science (primary, secondary, and high school). However, 15 of these studies explicitly dealt with biology, chemistry, and physics textbooks at the high school level and hence were discussed along with other studies in these subjects.

Notes

1. Textbooks included in the subjects of biology, chemistry, and physics are based on university freshman or higher levels
2. Textbooks included in the subject of school science are based on primary, secondary, or high school textbooks in biology, chemistry, and physics

44.2 University and High School Biology Textbooks

According to Chiappetta and Fillman (2007): "For over half a century, high school biology textbooks have played a critical role in science education because most students enroll in this course and use the adopted textbook that is a central component of the curriculum" (p. 1848). Similarly, Bybee (1989) has emphasized the role of textbooks in reforming biology education.

Chiappetta and Fillman (2007) analyzed five best-selling high school biology textbooks published in the USA (2002–2004), in order to study the inclusion of the following four NOS aspects: (a) science as a body of knowledge, (b) science as a way of investigating, (c) science as a way of thinking, and (d) science and its interactions with technology and society. These authors discuss the issue of inter-coder agreements and analyzed a much larger sample (than the 5 % in previous studies) of the textbooks from the following major topics: methods of science, ecology, cells, heredity, DNA, and evolution. It is concluded that these textbooks have a better balance of presenting the four NOS aspects as recommended by the reform documents (AAAS 1989; NRC 1996) than a previous study conducted 15 years ago, especially with regard to devoting more text to engaging students in finding out answers and learning how scientists do science.

Nature of science as depicted in five Turkish secondary school biology textbooks was studied by Irez (2009). These textbooks were widely used and published in the period 2006–2007. The following 11 themes regarding NOS were identified: description of science, characteristics of scientists, scientific method, empirical NOS, tentative NOS, nature of scientific theories and laws, inference and theoretical entities in science, subjective and theory-laden NOS, social and cultural embeddedness of science, and imagination and creativity in science. Based on these themes, the author also generated cognitive maps regarding NOS that provided an overall picture of how science was described in each textbook. Results obtained revealed that discussions regarding NOS represented a very small part of the textbooks and science was generally portrayed as a collection of facts and not as a dynamic process of generating and testing alternative explanations about nature. Of the 11 NOS themes studied, the author considered the following to be particularly misrepresented: scientific method and the tentative nature of scientific knowledge.

Coverage of human evolution in high school biology textbooks published in the USA (1900–2000) has been studied by Skoog (2005). Despite the sequencing of the human genome (Roberts 2001), human evolution continues to be a controversial topic in most parts of the world. Mayr (1997) has expressed this dilemma within a historical perspective: "No Darwinian idea was less acceptable to the Victorians than the derivation of man from a primate ancestor" (p. 25). Taking a longitudinal approach, Skoog has analyzed 113 high school textbooks in the following time periods: (a) 1900–1919 (n = 8): Only two textbooks stressed the validity of evolution. However, none of the textbooks contained material on human evolution or human fossil record. (b) 1920–1929 (n = 14): Five of the textbooks included some material concerned with human evolution and the human fossil record. The uniqueness of humans was noted in 11 of the 14 textbooks. This period was also characterized by widespread attempts to ban the teaching of evolution or its inclusion in textbooks. (c) 1930–1939 (n = 15): Four textbooks provided brief passages regarding human evolution. Discussions of the human fossil record were found in six textbooks. (d) 1940–1949 (n = 15): As compared to the previous time periods, these textbooks emphasized evolution to a greater extent. However, five textbooks failed to include any material on human evolution. (e) 1950–1959 (n = 15): Overall, eight textbooks lacked a discussion on both human evolution and the fossil record. According to Skoog (2005) this lack could be attributed to the following: "The 1950s were characterized by growing social unrest and insecurity as the Cold War and anti-communist fervor were building. Communism was associated with godlessness as was evolution by some" (p. 404). (f) 1960–1969 (n = 17): This period saw the publication of three textbooks and their revised editions, funded by the National Science Foundation under the auspices of the *Biological Science Curriculum Study* (BSCS). These textbooks gave unprecedented emphasis to human evolution, and this led the competing publishers to follow suit. (g) 1970–1989 (n = 17): Due to legislative attempts in various states to gain equal time for creationism, the unprecedented emphasis given to evolution did not continue in this period. Even the new versions of BSCS textbooks were characterized by less directness and certainty with respect to human evolution. (h) 1990–2000 (n = 12): Overall, the textbooks representing this period emphasized human evolution in a very comprehensive manner. Following N. Bohr, who considered science to be "the gradual removal of prejudice," Skoog (2005) concluded: "It is imperative that policy-makers, administrators, teachers, authors, and publishers work together to provide biology textbooks … [an opportunity] … to pursue the 'removal of prejudices' in the future citizens of America" (p. 419).

The study by Hofmann and Weber (2003) was included as it critiques Wells (2000), which is often cited by creationists who object to evolution in the science curriculum. Furthermore, Wells evaluated 10 science textbooks with respect to the notion of "universal common ancestry," and all textbooks that considered common descent as a "fact" were poorly graded. Hofmann and Weber (2003) have argued that fossil and molecular evidence is more than sufficient to warrant science educators to consider common descent as a well-established scientific fact.

According to Moody (1996) exposition of evolutionary theory in secondary school biology textbooks published in the USA has been adversely affected due to the influence of some nonscientific beliefs in the general public. Reviewing previous research on this topic, the author points out that it has been primarily concerned with measuring the quantity of space devoted to evolution in such textbooks during several decades. In contrast, the present study devised procedures to assess the overall role of evolution in the structure of the textbook. Results obtained revealed that the role of evolution in textbooks published in the 1990s increased considerably. This coincides with the results of Skoog (2005) who also reported a similar comprehensive increase in the coverage of evolution. Skoog, however, does not cite the work of Moody (1996).

German et al. (1996) analyzed nine high school biology laboratory manuals, published in the USA, during the period 1986–1993, to assess the promotion of scientific inquiry. It was hypothesized that open-ended laboratory activities (including pre-laboratory) which stress process skills reflect the nature of science more accurately. Inventory used for evaluating laboratory manuals was based on the following topics of the biology curriculum: cell structure, diffusion/osmosis, fermentation/cell respiration, leaves, tropisms, circulation, respiration, learning/behavior, hormones, and field studies. Authors used inter-rater agreements to establish the reliability of the inventory. Results of this study indicated that in general, high school biology laboratory manuals are highly structured in that they provide step-by-step detailed instructions. These manuals seldom provided opportunities for students to pose a question to be investigated, formulate a hypothesis to be tested, predict experimental results, work according to their design, or formulate a new question based on their own investigation.

Barberá and colleagues (1999) have traced the developments in the Spanish biology curriculum in the twentieth century (period of 100 years) based on the official publications of the nine national curricula and main textbooks used in this period. The main objective of the study was to focus on the relationship between socially controversial biological issues and the decision making procedures used by the different Spanish governments. Special attention was given to one of the most sensitive issue in biology education, namely, teaching of evolution. Authors found the political, social, and religious beliefs held by powerful and influential social groups to be particularly important in the elaboration of curriculum guidelines for socially controversial issues. It was concluded that such studies provide the necessary background for understanding biology education and its future development.

It seems that evolution is one of the most difficult and controversial topic of biology textbooks. Interestingly, its coverage in textbooks varies according to the prevailing sociopolitical environment. For example, during the cold war (1950s), the coverage of evolution decreased in textbooks published in the USA. Similarly, in Spain the coverage of evolution seems to depend on the political, social, and religious beliefs of influential social groups. A recent review has endorsed similar difficulties in teaching evolution (Smith 2010).

Flodin (2009) has studied different meanings of the gene concept within different subdisciplines in one biology textbook (Campbell and Reece 2005). This textbook is considered to be the most widely used English language science textbook in the world. According to the publisher it has reached two-thirds of all biology students in the USA. The author found the following interpretations of the gene concept in the textbook, depending on the subdiscipline: a trait (transmission genetics), an information structure (molecular biology), an actor (genomics), a regulator (developmental biology), and a marker (population genetics). These different functions of the gene concept are intermingled in the textbook, and the differences are not dealt with explicitly. The author concluded that such presentations in biology textbooks can become an obstacle to understanding for students and teachers. Findings of this study clearly show the importance of alternative interpretations of the gene concept and the need for a better explanation. Furthermore, it appears that textbook analyses are important and can improve even “the most widely used English language science textbook in the world.”

Conceptual variation in the depiction of gene function in upper secondary school biology and chemistry textbooks was studied by Gericke and Hagberg (2010). The study is based on 20 textbooks published in different countries (Sweden = 13, Australia = 2, Canada = 2, the UK = 2, the USA = 1). Of the 13 textbooks from Sweden, five were chemistry textbooks, as genetics forms part of the chemistry syllabus. The phenomenon of gene function can be described with multiple models, such as Mendelian, classical, biochemical classical, neoclassical, and the modern. Each of these models can be characterized by various epistemological features. Authors used content analysis (including inter-coder agreements) to determine the degree to which the epistemological features are represented in the subject matter and the five historical models. Results obtained revealed that most textbooks adopted a holistic approach that integrated various scientific frameworks, while ignoring conceptual variation and incommensurability between multiple models. It is concluded that such presentations can lead to cognitive conflicts for both the students and teachers, especially if they lack adequate knowledge of history and philosophy of science.

44.3 University and High School Chemistry Textbooks

Van Berkel and colleagues (2000) have explored the *hidden structure* of school chemistry based on the following research questions: (a) Why school chemistry textbooks from different countries look so remarkably similar? (b) What does the school chemistry curriculum look like? (c) Why is school chemistry so resistant to reforms? On the basis of content analysis of school chemistry textbooks (published in the Netherlands and UK) and syllabi, these authors have identified school chemistry as a form of normal science education (NSE), which is in turn based on Kuhn’s “normal science.” NSE is considered to be “dangerous” in that it isolates the learner from the history and philosophy of science and, as such, is narrow and rigid and tends to instill a dogmatic attitude towards science. The role of Kuhn’s normal science has been the subject of considerable research in science education and the analyses of science textbooks (Niaz 2011; Siegel 1978). Interestingly, Kuhn himself was somewhat ambiguous with respect to the relationship between NSE and science textbooks. Nevertheless the following statement from Kuhn (1977) is quite illustrative of the dilemma involved:

> The objective of a textbook is to provide the reader, in the most economical and easily assimilable form, with a statement of what the contemporary scientific community believes it knows and of the principal uses to which that knowledge can be put. *Information about how that knowledge was acquired (discovery) and about why it was accepted by the profession (confirmation) would at best be excess baggage. Though including that information would almost certainly increase the ‘humanistic’ values of the text and might conceivably breed more flexible and creative scientists*, it would inevitably detract from the ease of learning the contemporary scientific language. (p. 186, italics added)

This clearly shows that despite Kuhn's extraordinary contribution to HPS, he was perhaps not in tune with respect to how inclusion of HPS in science textbooks could invigorate students' and teachers' understanding of science.

Abd-El-Khalick and colleagues (2008) have drawn attention to the importance of including nature of science (NOS) in high school chemistry textbooks. These authors analyzed 14 textbooks (published in the USA, 1966–2005) including five "series" spanning one to four decades, with respect to the following NOS aspects: empirical, tentative, inferential, creative, theory driven, myth of the scientific method, nature of scientific theories and laws, and the social and cultural embeddedness of science. Based on the scoring rubric designed for this study, all three authors analyzed all textbooks independently and attained an inter-rater agreement of 86 %. Results from this study revealed that high school chemistry textbooks fared poorly in their representation of NOS, which led the authors to conclude: "These trends are incommensurate with the discourse in national and international science education reform documents (AAAS 1989; NRC 1996) …" (p. 835). Authors considered the following finding to be the most disturbing: All textbooks (except Toon et al. 1968) espoused the diehard myth of the "scientific method" (p. 848). Interestingly, Niaz and Maza (2011) in a study designed for evaluating nature of science found that Toon and Ellis (1978) had the highest score in a sample of 75 general chemistry textbooks. Abd-El-Khalick and colleagues (2008) refer to this as an "author effect" as compared to a "publisher effect." In other words science educators could approach textbook authors with well-formulated and documented arguments so as to facilitate the inclusion of such facets of NOS and HPS in their textbooks.

Justi and Gilbert (2000) analyzed high school chemistry textbooks (nine from Brazil and three from the UK, published 1993–1997) to study the presentation of atomic models. These authors report the use of hybrid models in textbooks based on various historical developments, such as Ancient Greek, Dalton, Thomson, Rutherford, Bohr, and quantum mechanics (Schrödinger's equation). Hybrid models do not provide students an opportunity to understand the dynamical nature of science, in which different approaches to understand phenomena are contrasted and critiqued. The authors concluded: "Hybrid models, by their nature as composites drawn from several distinct historical models, do not allow the history and philosophy of science to make a full contribution to science education" (p. 993).

Based on a historical reconstruction of the atomic models of Thomson, Rutherford, and Bohr, Niaz (1998) has analyzed 23 general chemistry textbooks published in the USA (1971–1992). All textbooks were evaluated on eight criteria which were validated by inter-rater agreements. Results obtained revealed that most textbooks emphasize experimental details based on observations, leading to the presentation of scientific progress as a *rhetoric of conclusions* (Schwab 1962), based on irrevocable truths. Such presentations in textbooks lack the conceptualizations of *heuristic principles* that led the scientists to design and interpret their experiments. For example, one of the criteria dealt with the Thomson-Rutherford controversy with respect to the single/compound scattering of alpha particles. Both Rutherford (1911) and Thomson performed similar experiments on the scattering of alpha particles, but their interpretations were entirely different. Thomson propounded the hypothesis of *compound scattering*, according to which a large angle deflection of an alpha particle resulted from successive collisions between the alpha particles and the positive charges distributed throughout the atom. Rutherford, in contrast, propounded the hypothesis of *single scattering*, according to which a large angle deflection resulted from a single collision between the alpha particle and the massive positive charge in the nucleus. This rivalry led to a bitter dispute between the two proponents (Wilson 1983). Rutherford's dilemma was that, on the one hand, he was entirely convinced and optimistic that his model of the atom provided a better explanation of experimental findings, and yet it seems that the prestige, authority, and even perhaps some reverence for his teacher (Thomson) made him waver in his conviction. A science student may wonder why Thomson and Rutherford did not meet over dinner (they were well know to each other) and decide in favor of one or the other model. These issues, if discussed in class and textbooks, could make the presentation of science much more human and motivating. Interestingly, none of the general chemistry textbooks (Niaz 1998) presented this historical episode, and two general physics textbooks (Rodríguez and Niaz 2004a) made a satisfactory presentation. One of these textbooks was by Cooper (1970), a Nobel Laureate in physics, who has endorsed a history and philosophy of science perspective in science textbooks (cf. Niaz et al. 2010b, for Cooper's perspective). In our efforts to study textbooks published in different cultures, next we analyzed 21 general chemistry textbooks published in Turkey and found that none of the textbooks referred to the Thomson-Rutherford controversy (cf. Niaz and Coştu 2009).

In a subsequent study, Rodríguez and Niaz (2002) reported that the importance of history of chemistry was recognized in the literature as early as the 1920s. O. Reinmuth (1932), editor of the *Journal of Chemical Education*, recognized the importance of the historical approach to teaching chemistry:

> It is much more important that he be shown how conclusions are reached on the basis of experimental evidence than that he memorize the conclusions. Too many students acquire the idea that scientific laws, theories and hypotheses spring full-armed from the brains of geniuses as the result of some occult phenomenon which the average man never experiences. (p. 1140)

Interestingly, this comes quite close and antecedes by about 30 years Schwab's (1962) advice that science cannot be taught as "rhetoric of conclusions." Indeed, Brush (1989) has cautioned that the historical approach does not consist in merely "assertion of the conclusions" that scientists have reached in the past, but rather "… to show how they were reached and what alternatives were plausibly advocated …." In order to pursue further the results reported by Niaz (1998) with respect to atomic models in general chemistry textbooks, Rodríguez and Niaz (2002) evaluated 30 textbooks published in the USA, in the period 1929–1967. Once again, results obtained revealed that most of the textbooks published in this period ignored the history and philosophy of science and lacked an understanding of the fact that students do not need to memorize experimental details but rather understand what the scientist was trying to do. It seems that despite the rhetoric with respect to the importance of history of chemistry, general chemistry textbooks have not changed much with respect to atomic models over 60 years (1929–1992).

A historical reconstruction of the determination of the elementary electrical charge and the ensuing controversy between R. Millikan and F. Ehrenhaft has been reported by Niaz (2000a). Both Millikan and Ehrenhaft had very similar experimental data, and still Millikan postulated the existence of a universal charged particle (electron) and Ehrenhaft postulated fractional charges (sub-electrons). Holton (1978) has provided the following insight on the impasse:

> It appeared that the same observational record could be used to demonstrate the *plausibility of two diametrically opposite theories*, held with great conviction by two well-equipped proponents and their respective collaborators. Initially, there was not even the convincing testimony of independent researchers. (pp. 199–200, emphasis added)

Niaz (2000a) has reported that of the 31 general chemistry textbooks analyzed (published in the USA, 1968–1999), none mentioned the Millikan-Ehrenhaft controversy. Similarly, none of the 43 general physics textbooks (published in the USA, 1970–2001) analyzed by Rodríguez and Niaz (2004b) mentioned the controversy. At this stage it could be argued that only advanced textbooks can be expected to include controversial aspects of scientific progress. To follow up on this, Niaz and Rodríguez (2005) analyzed 28 physical chemistry textbooks (published 1951–2002) and once again found that none mentioned the controversy. Interestingly, all these textbooks not only ignore the controversy but also consider the experiment to be characterized by its simplicity and precise results. For students, who still perform this experiment in their labs, such textbook presentations are quite perplexing (cf. Klassen 2009). Some textbooks even state that Millikan found no fractional charges and that the oil drop experiment was characterized by its simplicity and precise results. This in our opinion comes quite close to "distortion" of the historical events. Indeed, according to Kragh (1992) textbooks, "… not only distort historical reality, but they do so in a systematic way" (p. 359). Holton (2000) has endorsed the inclusion of such controversies in introductory science courses: "… introduction of the history and methodology of physics into the physics classroom, not least in terms of important controversies – is completely congenial to me … I agree one should teach research methodology in introductory physics and Millikan's case is certainly a well documented case that would lend itself to this purpose" (p. 1).

Padilla and Furio-Mas (2008) based on a historical reconstruction have traced the origin of concepts such as "chemical equivalent," "mole," and the "amount of substance." During the nineteenth century there was a widespread tendency (led by W. Ostwald) to replace the theoretical concept of "atom" with measurable notions of "volume" and "chemical equivalents," which led to considerable controversy. The progressive acceptance of the atomic-molecular theory was the origin of the magnitude, "amount of substance," and its unit, the "mole." These authors analyzed 30 general chemistry textbooks (published in the USA, 1980–2004) and found that a majority of the textbooks present the following: (a) amount of substance and mole within an ahistoric and unproblematic perspective and (b) misconceptions with respect to the mole concept, which is confused with number of elementary entities. It is concluded that lack of a historical perspective leads to distorted views of science, which does not facilitate meaningful learning. In an earlier study, Furió et al. (2000) analyzed 87 high school chemistry textbooks (published in Spain, 1976–1996), in order to determine the difficulties in teaching the concepts of “amount of substance” and “mole.” It was observed that a majority of the textbooks do not introduce these concepts in a meaningful way within a historical perspective.

The degree to which high school and university level general chemistry textbooks distort the image of science, while presenting acid–base reactions, is the subject of a study by Furió-Más et al. (2005). In order to understand acids and bases, these authors identified three historical models: macroscopic, Arrhenius, and Brönsted-Lowry. Authors have argued cogently with respect to understanding the macroscopic model based on early empirical knowledge of electrical conductivity of ionic solutions, before the later models. The study is based on 19 high school textbooks published (1975–2001) in Spain and 18 general chemistry textbooks published (1968–2000) in the USA. Results based on inter-rater agreements revealed the following: (a) Arrhenius and Brönsted-Lowry theories are described in all textbooks; however only 60 % justify the change from one theory to another; (b) 66 % of the textbooks ignored that the concept of hydrolysis helps to understand the conjugate acid–base pair in the Brönsted-Lowry theory; and (c) most textbooks presented a socially “neutral” description based on inductive generalizations that lead to a linear accumulative perspective of progress in science. It is plausible to suggest that the inclusion of the concept of acids and bases by G. N. Lewis would have provided a better historical perspective.

In the late nineteenth century, there was a dispute as to whether a mathematical description of osmotic pressure could contribute any chemical information with respect to what was happening at the molecular level during osmosis. This was particularly significant as the van’t Hoff osmotic pressure law, $\pi V = nRT$, was mathematically analogous to the ideal gas law, $PV = nRT$. By the middle of the twentieth century, based on thermodynamic concepts of osmosis, mathematical models provided greater chemical understanding of osmosis. However, by the end of the twentieth century, some chemists preferred a kinetic-molecular approach to osmosis rather than the thermodynamic approach. In order to understand these historical disputes, de Berg (2006) has analyzed 11 physical chemistry textbooks published in the period 1963–2002 (the USA = 7, UK = 4). Results obtained revealed the following: (a) A majority of the textbooks referred to and discussed the analogy between the van’t Hoff law and the ideal gas law; (b) except one, all textbooks provided a mathematical derivation of the van’t Hoff law; and (c) none of the textbooks referred to kinetic-molecular ideas. The author concluded that the kinetic-molecular approach is more accessible to students than the mathematical thermodynamic approach and thus deserves more attention in chemistry education, in order to facilitate greater understanding. Furthermore, thermodynamics should not just be a matter of manipulating symbols, but rather it is important to provide students with a qualitative sense of the problem.

Heat (an extensive property) and temperature (an intensive property) are an important part of the science curriculum at both the high school and university freshman level, and most students have considerable difficulty in differentiating between the two. An underlying issue that makes understanding difficult is the conceptual rivalry in the history of science between the caloric (heat as a substance) and the kinetic theories. According to Brush (1976), “The kinetic theory could not flourish until heat as a substance had been replaced by heat as atomic motion” (p. 8). De Berg (2008a) has analyzed the concepts of heat and temperature in 10 general chemistry textbooks published (1993–2006) in the USA. Results obtained revealed that heat is considered to be as follows: (a) *energy that flows* from an object at the higher temperature to one at the lower temperature; (b) *energy that is transferred* from an object at the higher temperature to one at a lower temperature; (c) process of energy transfer from a higher temperature object to a lower temperature object; (d) only three textbooks illustrated the difference between heat and temperature; and (e) no uniform picture of “heat” is presented and almost no exposure is given to the caloric theory. The author concluded that terms such as *heat flow* or *energy flow* are remnants of the caloric theory of heat and the language used: “…even in current textbooks is reminiscent of the old caloric theory…” (p. 86).

Chemistry students are generally not exposed to different ways of understanding a chemical reaction. De Berg (2008b) has analyzed eight chemistry textbooks published between 1758 and 1891 in order to understand the chemistry of the oxides of tin. This period is significant in chemical history as it covers the two chemical revolutions, associated with A. Lavoisier (1770–1790) and J. Dalton (1855–1875). Selected textbooks were from the UK, European continent, and the USA. Unlike the textbooks of today, these fulfilled multiple functions such as the teaching of chemistry to secondary, college, medicine, and pharmacy students. Results obtained provided insight into the foundation of a number of chemical ideas such as nomenclature and composition used in modern chemistry. Furthermore, four major preparation techniques for the production of tin oxides emerged: the heating of tin in air, the addition of nitric acid to tin, the alkaline hydrolysis of tin (II) and tin (IV) salts, and the hydrolysis of alkaline stannate salts. Early textbooks of the period give lengthy descriptions and explanations for these reaction schemes. It would be interesting to study this and similar topics in current textbooks.

In the early nineteenth century, Dalton’s research program in order to be operationalized required the following items as part of the positive heuristic (cf. Lakatos 1970): (a) chemical formulae, (b) atomic weights (masses), and (c) composition by weight of the compound. Early in Dalton’s career, only the third item was known and hence the inductivist approach concluded that only combining “equivalents” or “measures based on volumes” were important. The law of definite proportions in chemistry is basically an elaboration of the third item of Dalton’s positive heuristic. In contrast, Gay-Lussac’s law of combining volumes provided the antiatomists a rationale for accepting the laws of definite and multiple proportions without the “superfluous” atomic theory of Dalton. Niaz (2001a) analyzed 27 general chemistry textbooks (published in the USA, 1969–1999) to determine if they followed one of the following interpretations: (a) *Inductivist*: Gay-Lussac’s law of combining volumes provided a rationale for accepting the laws of definite and multiple proportions. (b) *Lakatosian*: Dalton’s atomic theory predicted and explained Gay-Lussac’s law of combining volumes. Results obtained (based on inter-rater agreements) revealed that only two textbooks followed the inductivist interpretation and the remaining 25 textbooks simply ignored the historical perspective.

The periodic table of chemical elements is considered to be a conceptual tool that helps to organize a great deal of information, leading to a better understanding of chemistry. Despite this overall positive picture, most chemistry teachers and textbooks give the impression that for almost 100 years (1820–1920), scientists had no idea or never asked the question as to whether there could be an underlying pattern to explain periodic properties of the elements. Brito et al. (2005) have presented a historical reconstruction of the development of the periodic table. The basic idea behind this study was the hypothesis that even before the electronic structure of the atom (Thomson, Lewis, Bohr, Moseley, and others) was discovered, different explanations were offered for periodicity. It is important to note that when D. Mendeleev (and others) started working on the periodic table, he had the following sources of information: Dalton's atomic theory, law of multiple proportions, Cannizaro's Karlsruhe lecture, fairly reliable atomic weights, atomicity (valence), and various physical and chemical properties of chemical elements. In his famous Faraday lecture, Mendeleev (1889) explained his hypothesis cogently: "… the veil which conceals the true conception of mass, it nevertheless indicated that the explanation of that conception must be searched for in the masses of atoms; the more so, *as all masses are nothing but aggregations, or additions, of chemical atoms …*" (p. 640, emphasis added). This clearly shows that among other factors, Mendeleev considered the atomic theory to be an important cause of periodicity of chemical elements. Based on inter-rater agreements, Brito and colleagues (2005) analyzed 57 general chemistry textbooks published (1968–2002) in the USA and found that a majority of the textbooks ignored the role played by the atomic theory in the development of the periodic table. It is concluded that it is more fruitful to present a more balanced picture to the students by highlighting how Mendeleev solved the dilemma by looking for underlying patterns to explain and understand periodicity.

The role of authors and publishers as agents of change in Spanish science pedagogical reform and textbooks has been explored by De Posada (1999). Fifty-eight high school chemistry textbooks published (1974–1998) in Spain were analyzed to understand the topic of metallic bonding. Results obtained revealed the following: (a) Almost half the textbooks simply define the metallic bond and thus obscure the relationship between models and experimental data; (b) theoretical models employed by textbooks are metaphorical in nature (similar to analogies) and are thus open to misinterpretations; (c) drawings used in textbooks need to be more explicit with respect to nature of metallic bonding; (d) the topic of metallic bonding needs to be integrated with other topics, in order to provide students meaningful learning; and (e) based on the General Act for the Educational System of 1990 (Spain), some textbooks had improved by including constructivist guidelines. This study could be extended by including the presentation of metallic bonding in university general chemistry textbooks.

In the early twentieth century, all chemical bonds were considered to be ionic (transfer of electrons), and even bonds in compounds such as methane and hydrogen were believed to be polar, despite their lack of polar properties. Lewis's (1916) theory of sharing electrons (covalent bond) when first proposed was completely out of tune with established belief. In order to understand the sharing of electrons, Lewis postulated the cubic atom (a theoretical device) that provided the rationale for the octet rule. For some chemists the idea of two sharing negative electrons was simply absurd and bizarre. Based on a historical reconstruction of the origin of the covalent bond, Niaz (2001b) has analyzed 27 general chemistry textbooks published (1968–1999) in the USA. Results obtained revealed (based on inter-rater agreements) that most textbooks did not deal adequately with the following aspects: (a) Postulation of the covalent bond by Lewis in 1916 posed considerable conceptual difficulties; (b) Lewis used the cubical atom in order to understand the sharing of electrons (octet rule); (c) sharing of electrons had to compete with the transfer of electrons (ionic bond), considered to be the dominant paradigm until about 1920; and (d) Pauli's exclusion principle (1925 and after) provides a theoretical explanation of the sharing of electrons, just as the cubical atom did previously. It is concluded that the transition from Lewis's cubic atom → Pauli's exclusion principle → what next provides an illustration of how scientific knowledge is tentative.

Shiland (1997) has analyzed eight high school chemistry textbooks published (1964–1994) in the USA, to evaluate the degree to which introduction of the quantum mechanical model of the atom complies with a conceptual change model (Posner et al. 1982). Four aspects of the model were operationalized by the following guidelines: (a) *Dissatisfaction* was measured by examining how the Bohr model was shown to be unsatisfactory and what specific evidence was provided; (b) *intelligibility*, which is the learner's ability to represent an idea, was measured by determining the number of pages required to present the theory; (c) *plausibility* was measured by examining whether the inadequacies of the Bohr model were addressed by the quantum model; and (d) *fruitfulness* was measured by listing problems or questions which required quantum theory to explain or predict an observable phenomena. Results obtained revealed that most textbooks did not fulfill the conditions required for conceptual change. It is concluded that high school chemistry teachers cannot rely on their textbooks to create the conditions necessary for conceptual change while introducing quantum mechanics.

Most students face considerable difficulty in understanding quantum mechanics and as a consequence use quantum numbers and electron configurations as algorithms that provide little insight in understanding progress in science. Cushing (1991) has referred to this as the level of empirical adequacy, namely, having a formula or algorithm that is capable of reproducing experimental data. Similarly, Posner and colleagues (1982) have outlined a series of criteria for promoting conceptual change that were used by Shiland (1997) to understand quantum mechanics in high school chemistry textbooks. Based on this conceptual framework, Niaz and Fernández (2008) have analyzed 55 general chemistry textbooks published (1968–2002) in the USA. Criteria based on the following aspects were elaborated to evaluate the textbooks: (a) origin of the quantum hypothesis, (b) alternative interpretations of quantum mechanics, (c) differentiation between an orbital and electron density, (d) differentiation and comparison between classical and quantum mechanics, and (e) introduction of quantum numbers based on electron density. Results obtained (based on inter-rater agreements) showed the following: (i) Most textbooks provide low dissatisfaction, intelligibility, plausibility, and fruitfulness on criteria a, b, and c;

(ii) on criterion d, some textbooks were partially intelligible (providing analogies) and partially plausible (providing thought-provoking ideas); and (iii) on criterion e, some textbooks were partially plausible (providing experimental data of ionization energies), and only one textbook fulfilled the conditions for fruitfulness by showing how heights of the peaks from photoelectron spectroscopy correspond to the number of electrons.

Teaching of chemistry at the college and university level in most parts of the world is oriented towards the preparation of chemists and other science-based professionals. *Chemistry in Context: Applying Chemistry to* Society, a textbook for non-science majors, has been developed by Schwartz and colleagues (1997) under the sponsorship of the *American Chemical Society*. Schwartz (1999) summarizes the origin, development, content, pedagogy, evaluation, and influence of this textbook and considers its potential implications for other disciplines and the instruction of science majors. The book introduces the principles of chemistry within the context of socially significant issues, such as global warming, ozone depletion, alternate energy sources, nutrition, and genetic engineering. The chemistry is included as needed to inform an understanding of chemical principles, and an additional feature is the inclusion of student-centered activities designed to promote critical thinking.

44.4 University and High School Physics Textbooks

According to Gardner (1999), although as science teachers we are generally not trained in history and philosophy of science, still “our implicit theories about the nature of science and technology influence the stories we tell our students” (p. 330). This clearly shows the need to take into consideration teachers’ prior epistemological beliefs. Indeed, this is an important guideline for both textbook authors and curriculum developers. This study discusses the meanings attached to the terms “science” and “technology” and outlines four views of the nature of their relationship: (a) *idealist view* (technology as applied science), (b) *demarcationist view* (separate fields), (c) *materialist view* (technology as a necessary precursor to science), and (d) *interactionist view* (scientists and technologists working together). Five high school physics textbooks published in Canada (1986–1992) were analyzed within this perspective. Results obtained revealed various positive features, such as recognition of the human face of science and technology, frequent reference to careers in which knowledge of physics might be useful, and many illustrations of interesting technological artifacts. However, some of the textbooks are dominated by an idealist storyline which represents a limited view.

Newtonian mechanics has been the subject of critical appraisal by E. Mach (1960/1883). Mach’s work was deeply rooted in his philosophy which assumed that only sensations can be known and are real, and he was particularly critical of Newtonian concepts of absolute time and space and inertial mass. Mach’s views with respect to matter and motion were later known as Mach’s principle, which was of heuristic value for Einstein’s development of his general theory of relativity.

Assis and Zylbersztajn (2001) have analyzed five general physics textbooks published (1963–1995) in the USA, in order to trace Mach's influence in the teaching of classical mechanics. Results obtained revealed that all five textbooks are influenced by Mach and especially with respect to the dynamical operational definition of inertial mass. Interestingly, however, none of the textbooks recognized that Mach was the originator of this definition of inertial mass.

Starting from Newton to Poincaré, the concept of force in physics has been the source of considerable discussion. At the International Congress for Philosophy in Paris in 1900, Poincaré asked if the fundamental equation of dynamics, $F = ma$, is verifiable experimentally. Later he himself responded by pointing that the problem was difficult as we do not even know what force and mass are. In order to scrutinize this difficulty, Coelho (2010) has analyzed about a hundred textbooks published in the twentieth and twenty-first centuries in different parts of the world. Knowing the difficulties involved some textbooks do not provide a definition of force. Most of the textbooks, however, define force to be the cause of acceleration. It is argued that as acceleration is observable, its cause must be something real. Thus, force is real. This interpretation has been questioned by some physicists and philosophers of science. According to Coelho (2010), "… the mere fact that these two kinds of theses coexist, shows the difficulty in 'seeing' force in phenomena" (p. 91).

Galili and Tseitlin (2003) have traced the historical origin of Newton's first law (NFL), which is the law of inertia, by consulting new translations of Newton's work in the twentieth century. This literature shows the richness of NFL in understanding the meaning of inertia. These authors analyzed 40 introductory physics textbook (high school, college, and university) published in Israel and the USA. Results obtained revealed that most textbooks (even those widely used) did not refer to NFL as it was considered to be a special case of Newton's second law. Finally, the authors concluded: "Newton's First Law is far from just a trivial special case of Newton's Second Law. As such, NFL can, and should, be carefully preserved and studied in the corpus of physics knowledge transmitted through the generations" (p. 68).

The presentation of the weight concept as a gravitational force has been questioned by Galili (2001). Even popular general physics textbooks (e.g., Sears & Zemansky) through many editions used worldwide have endorsed the following definition of weight as a gravitational force: "The weight of a body is the total gravitational force exerted on the body by all other bodies in the universe." According to Galili (2001), "This obscure definition, never introduced by Newton, can be neither empirically employed nor theoretically validated" (p. 1081). As an alternative based on a historical reconstruction, Galili has suggested an operational definition that distinguishes between weight and gravitational force in the following terms: "Weight of the body is the force, which acts downwards and causes spontaneous falling. Numerically, weight is given by the product mg^*, with g^* – the acceleration of a free fall, as it is measured in a particular frame of reference" (pp. 1082–1083). The study revealed that very few textbooks (e.g., Keller, Lerner) present this definition. Furthermore, given the complexity of the issues involved, some textbooks have simply excluded the definition of the weight concept.

The concept of electric field has been the subject of a study by Pocovi and Finley (2003), based on a historical reconstruction of the ideas of M. Faraday, J. C. Maxwell, and A. Einstein. Maxwell was able to give more impetus to Faraday's ideas of lines of force by expressing them mathematically. At this stage, for the action-at-a-distance theorists, forces were transmitted at a distance, whereas for the field theorists, the transmission took place through a medium. Einstein gave the field the status of a fundamental entity, so that any electromagnetic problem was completely described by the field equations. These authors analyzed two well-known and widely used general physics textbooks published (1978, 1991) in the USA. Results obtained revealed that both textbooks did not adequately explain the field concept in the description of electromagnetic phenomena. Furthermore, the equivalence of the action-at-a-distance and field views within electrostatics was generally ignored. According to the authors such presentations are problematic, as textbooks are assumed to be accurate, complete, coherent, and the primary source of information for students.

The development of the concept and theories of magnetic field within a historical perspective has been explored by Guisasola et al. (2005). These authors analyzed 30 introductory physics and electromagnetism textbooks published (1972–1999) in the USA. Results obtained (based on inter-rater agreements) revealed that a majority of the textbooks (a) present the introduction to the theory of magnetic field in a nonproblematic, nonhistorical, and linear accumulative manner. Development of the theory of the magnetic field had to overcome many difficulties, and various theories were proposed; (b) ignore the problems which occurred in identifying the sources of stationary magnetic field and the equivalence between charges in movement and magnets; (c) do not relate the theory of magnetic field to theories from other areas of physics, such as mechanics or optics; (d) do not discuss Maxwell's laws as an attempt to unify characteristics common to electricity and magnetism; and (e) possible limitations of the theory are not discussed.

Vaquero and Santos (2001) have analyzed 38 high school and general physics textbooks published (1844–1900) in Spain in order to explore the role played by heat and kinetic theory. Authors used the following questions for evaluating the textbooks: (1) use of imponderable fluids (18 textbooks were classified as affirmative), (2) use of the term caloric to refer to heat (14 textbooks were classified as affirmative), (3) use of the concept of energy in a general form (14 textbooks were classified as affirmative), (4) use of the mechanical theory of heat (21 textbooks were classified as affirmative), and (5) use of the kinetic theory of gases (5 textbooks were classified as affirmative). According to the authors affirmative responses to the first two questions would indicate traditionalism and to questions 3 and 4, modernity. If the kinetic theory of gases appeared, then the textbooks were considered as "quite complete." This state of the textbooks is attributed to the curricular plans of Spanish universities and the overall political climate in which physics was relegated to a minor faculty. It is interesting to note that even current chemistry textbooks published in the USA (as reported by De Berg 2008a, see previous section) and physics textbooks (cf. Cotignola et al. 2002) have difficulties in the presentation of heat. Similarly, the presentation of kinetic theory in current textbooks (published in the USA, cf. Niaz 2000b) lacks the historical context in which the kinetic theory developed. Further analyses of textbooks published in Spain after 1900 could provide evidence as to how kinetic theory was introduced progressively.

An analysis of thermodynamics in general physics textbooks has led Tarsitani and Vicentini (1996) to suggest that "… several mental representations of the same subject do exist, even in the case of a 'mature' science, and in fact are often found in scientific literature … different textbooks may expound the same subject agreeing on many phenomenological and theoretical aspects, yet disagreeing not only on the logical structure and definition of fundamental concepts, but also on the general view of the scope and object of the subject matter" (p. 51). Based on a historical reconstruction, these authors have found two approaches to presenting thermodynamics in textbooks: (a) statistical approach (following among sources, J. C. Maxwell's *theory of heat*) and (b) phenomenological approach (following primarily M. Planck's *Treatise on Thermodynamics*). Two examples of textbooks (published in the UK & USA) that follow the statistical approach are discussed. Three examples of textbooks (two published in the USA and one in Switzerland) that follow the phenomenological approach are presented. A comparison of the two types of textbooks shows that in the phenomenological approach, physical theory is nearest to experience and the kinetic theory does not play a central role. On the other hand, the statistical approach has its own problems, as it works with abstract models, which makes the explanation of the second law and entropy problematic.

Niss (2009) has emphasized the importance of metamodeling in statistical mechanics textbooks, as it facilitates a better understanding of the purpose of modeling and hence the nature of science. Textbooks were selected according to the following criteria: inclusion of a chapter on phase transitions, articulate modeling issues, represent a class of textbooks, and not too idiosyncratic in approach. Five textbooks were selected, considered to be classics in the field, and published (UK = 1; USA = 4), over a period of 70 years (1936–2001). Results obtained revealed the following: (a) Different messages are sent with respect to what constitutes a good model; (b) models are used to elaborate phenomenological theories of phase transitions; however these theories differ widely; (c) present different notions of what it means to understand a physical phenomenon; and (d) recent textbooks pay more attention to universality that is capturing different physical systems under the same umbrella. It was concluded that the five textbooks provide different metamodeling knowledge, which is not presented explicitly.

Cotignola et al. (2002) have analyzed thermodynamic concepts in seven general physics textbooks published in the USA (1991–1998). According to the authors, "Most books now use a definition of heat closer to the presently accepted one: a process of energy transfer associated with a temperature difference between the system under study and its surroundings. In spite of a correct initial definition, many authors (Resnick, Tipler, Giancoli, Serway and Hewitt) finally succumb to 'heat is a form of energy'" (p. 285). Joule's experiments referred to the different equivalent processes capable of producing the same increase in the system's temperature. Given the central role heat had in the beginnings of thermodynamics, five of the textbooks while describing Joule's experiments do not correctly differentiate between heat and energy. Only three of the textbooks correctly explain internal energy, namely, energy associated with the internal structure of the system under study.

It is well known that Thomas Kuhn directed the project "Sources for History of Quantum Physics," a valuable archive now available at various institutions around the world. Based on this experience, Kuhn raised a provocative question: Who first proposed the quantum hypothesis? Kuhn (1978) stated categorically:

> … the arguments in Planck's first quantum papers [Planck 1990] did not, as I now read them, seem to place any restrictions on the energy of the hypothetical resonators that their author had introduced to equilibrate the distribution of energy in the black-body radiation field. Planck's resonators, I concluded, absorbed and emitted energy continuously at a rate governed precisely by Maxwell's equations. His theory was still classical …. (p. viii)

Kuhn concluded that it was P. Ehrenfest and A. Einstein who first recognized that the blackbody law could not be derived without restricting resonator energy to integral multiples of hν. In other words, Planck in 1900 simply introduced an approximate mathematical quantization in doing the calculations. Kuhn's thesis has been endorsed by some historians (e.g., Brush 2000; Kragh 1999). However, physicists have in general resented the attempt to deprive Planck of credit for the quantum hypothesis. In order to evaluate the support for Kuhn's thesis, Brush (2000) has analyzed 28 general physics textbooks published in the USA (1990–1997). Results obtained showed that only six textbooks supported Kuhn's hypothesis with respect to the origin of the quantum hypothesis. In comparison, Niaz and Fernández (2008) found that of the 55 general chemistry textbooks published in the USA, only one reluctantly supported Kuhn's hypothesis.

Tampakis and Skordoulis (2007) have examined the reception of quantum mechanics in the Greek scientific community through nine physics textbooks published in Greece (1913–1963). Authors found that the quantum theory appeared first in a textbook in 1925, with a brief mention of Planck's hypothesis and the photoelectric effect. It was not until 1962 that quantum mechanics was finally established in Greek textbooks. Authors attribute this delayed appearance to three factors: scientific, social, and ideological. It is concluded that the debate between the political left and right and the church organizations led to an extremely idealistic misinterpretation of the theory, before a more technical interpretation appeared in the textbooks.

Thought experiments (TEs) have played an important role in the history of science and have also been recognized in science education (Gilbert and Reiner 2000). Velentzas et al. (2007) have investigated the role of thought experiments in the theory of relativity and quantum mechanics in general physics textbooks (ten published in the USA, 1961–1997, and one in Greece, 1999). In general, these textbooks considered TEs to be an important tool when presenting these topics, and the following were used quite frequently: Einstein's train and elevator and Heisenberg's microscope. Despite the use of TEs, some textbooks preferred real experiments, especially the Michelson-Morley (MM) experiment in the context of the theory of relativity. Indeed, the MM experiment shows how in the history of science experiments are difficult to understand and interpret. According to Lakatos (1970, p. 162), starting from 1905, it took almost 25 years for the MM to be understood and considered as the "greatest negative experiment in the history of science." Brush (2000) has analyzed 26 general physics textbooks published in the USA (1990–1997), with respect to the "genetic" relationship between MM and Einstein's special theory of relativity (STR). Results obtained revealed that nine textbooks still attributed Einstein's theory to the negative result of the MM. Nevertheless, it is a cause of concern that these nine textbooks included those widely used all over the world (e.g., Serway, Sears, Zemansky). More recently, Arriassecq and Greca (2007) have analyzed the MM experiment in high school physics textbooks published in Argentina (n = 9, 1980–2000) and general physics textbooks published in the USA (n = 6, 1971–2001). Most textbooks in their study suggested that the starting point for Einstein's STR was the MM experiment, which contributes to generate a distorted view of the dynamics of scientific research. Even textbooks written by famous physicists (e.g., *Feynman's Lectures on Physics*) contribute to this empiricist perspective of science. The genetic relationship between the Michelson-Morley experiment and Einstein's STR in physics textbooks published in three different countries (Argentina, Greece, USA) is a good example of what Holton (1969) has referred to as the myth of experimenticism. According to this myth, progress in science is presented as the inexorable result of logically sound conclusions derived from experimentally indubitable premises.

Treagust and Harrison (2000) have analyzed Feynman's (1994) Lecture 1 "atoms in motion" in his *Six Easy Pieces* and consider it to be "a classic example of expert pedagogical content knowing" (p. 1162). The *Lecture* was found to contain effective explanations based on science content, educational context, and teacher- and student-related factors. Furthermore, these authors differentiate between scientists' explanations and science teaching explanations. Science explanations are characterized as strictly theory and evidence driven. In contrast, the *Lecture* includes rich and creative metaphors, analogies, and models based on anthropomorphisms and teleological expressions.

Millikan's (1916) determination of Planck's constant h (photoelectric effect) has been the subject of a study by Niaz et al. (2010a). Of the 103 general physics textbooks (published in the USA, between 1950s and 2000s) analyzed, only five made a brief mention of Millikan's presupposition and belief in the classical wave theory of light. A historical reconstruction shows that Millikan recognized the validity of Einstein's photoelectric equation and at the same time questioned the underlying hypothesis of light quanta. Very few textbooks mentioned that Millikan's experimental data provided support for Einstein equation but not his theory. Again, none of the textbooks mentioned that scientific theories are underdetermined by experimental evidence. Only one of the textbooks came close to referring to the dilemma faced with respect to the lack of acceptance of Einstein's quantum hypothesis in the scientific community, precisely because of the rivalry with the classical wave theory of light.

44.5 School Science Textbooks

Leite (2002) has analyzed five high school physics textbooks published (1996–1998) in Portugal based on criteria, such as historical experiments, analyses of data from historical experiments, integration of historical references within the text, use of original historical sources, evolution of science, and sociopolitical context in scientific research, among others. Results obtained (based on inter-rater agreement) led the author to conclude that the historical content included in these textbooks hardly provided students with an adequate image of science and the work of the scientists.

Milne (1998) has emphasized the role of stories in science textbooks as presentation of science cannot be reduced to just including facts. Stories can take various forms: (a) Heroic: focus on a hero who single-handedly contributed to the development of science. (b) Discovery: scientific knowledge is presented as having occurred as the result of an accident. (c) Declarative: processes or scientific concepts as objects that are open to observation by anyone. (d) Politically correct: a critical examination of the interaction between science and society. Examples from high school textbooks are provided to illustrate heroic stories, such as Galileo as an individual who had the courage to stand against the dark forces of the inquisition. Milne (1998) concluded: "… if we wish to involve students more in thinking about the enterprise that we call science, we would do well to tell stories that emphasize the human aspects of the development of scientific knowledge" (p. 186). Milne also presented her own version of the life and work of Galileo. This version has been critiqued by Whitaker (1999), as it lacked some historical details and the necessary differentiation between "observations" and "experimentation." The role of experimentation in Galileo's work is the subject of considerable debate. Milne (1999) responded by pointing out that her story did not represent the truth and that there are various ways to elaborate stories in science.

The role of ideologies in Norwegian grade 8 science textbooks (n = 4, published in 1997) has been explored by Knain (2001). Ideologies are considered to be grounded in worldviews (Cobern 1996) which are culturally influenced and shared by people through social interaction. For each textbook, 30 pages were selected from the following topics: nature of science (introductory chapter), nature (astronomy), and society (fighting diseases). For example, portraying scientific development as dependent on the work of individual scientists doing crucial experiments is evident from the following historical note in one of the textbooks: "An Englishman, Alexander Fleming, discovered that a certain mould fungus with the name *Penicillin* precipitates a substance that kills bacteria" (p. 325). For most textbooks in this study, experiments and observations are what make science different from other ways of knowing. Furthermore, controversies constitute an important part of science as experimental results are difficult to interpret and their relevance in the sociopolitical context is not obvious.

Importance of biographies of scientists in science education has been explored by Dagher and Ford (2005). Authors analyzed the images of science and scientists in 12 biographies of historic and contemporary scientists written for primary and middle school children, published in the USA (1987–2003), and addressed the following research questions: (1) How is the scientist described in the biography? (2) What is the nature and process of scientific knowledge? (3) How are social processes related to science portrayed? Results obtained revealed a marked difference in how different authors portrayed their subject depending on the age of the target audience. Biographies for primary school (e.g., M. Curie & A. Einstein) emphasize personal characteristics and childhood of the scientists. Biographies for secondary school provide more details of nature of scientific work and processes of science. Authors concluded that biographies can be used: "… to provide useful springboards for arousing student curiosity and interest in exploring the historical record" (p. 391).

As a topic of the science curriculum, teaching of the pendulum incorporates conceptual, methodological, and cultural aspects (Matthews et al. 2005). Based on these aspects Koliopoulos and Constantino (2005) have analyzed school science textbooks (primary and secondary) published in Greece and Cyprus. Results obtained revealed that in both countries the pendulum is confined mainly to the study of the simple pendulum, which is incidental and limited and never introduced as a comprehensive unit. At the gymnasium level the textbooks espouse an empirical approach in which the dependence of the period on the length of the string of the simple pendulum and the acceleration of gravity emerge from a simple observation of the pendulum motion. At the lyceum level apart from the experimental activity, textbooks include the derivation of mathematical relations. Given the pendulum's historical connection with clock making, time measurement, the longitude problem, and navigation, it readily constitutes "…a window on the scientific revolution" (Matthews 2000, p. 293). Despite this rich cultural context, we found only one study dealing with the presentation of the pendulum in textbooks.

44.6 Educational Implications

Various topics of the science curriculum provide an opportunity to illustrate the tentative nature of scientific knowledge, and still very few textbooks referred to this important aspect of nature of science. American Association for the Advancement of Science has expressed this in cogent terms: "The notion that scientific knowledge is always subject to modification can be difficult for students to grasp. It seems to oppose the certainty and truth popularly accorded to science, and runs counter to the yearning for certainty that is characteristic of most cultures, perhaps especially so among youth" (AAAS 1993, p. 5). Indeed, divergent opinions that often lead to controversies are one of the most important aspects of scientific progress (Niaz 2009a). Modern philosophers of science have referred to this facet of nature of science in explicit terms:

> Many major steps in science, probably all dramatic changes, and most of the fundamental achievements of what we now take as the advancement or progress of scientific knowledge have been controversial and have involved some dispute or another. Scientific controversies are found throughout the history of science. This is so well known that it is trivial. What is not so obvious and deserves attention is a sort of paradoxical dissociation between science as actually practiced and science as perceived or depicted by both scientists and philosophers. While nobody would deny that science in the making has been replete with controversies, the same people often depict its essence or end product as free from disputes, as the uncontroversial rational human endeavor par excellence. (Machamer et al. 2000, p. 3)

Similarly, Dybowski (2001), a practicing teacher, has designed an innovative course in the history of physical chemistry that facilitates an appreciation of how scientific inquiry actually happens in research laboratories and recounted his experience: "… we sometimes find that we come away with two (or more) differing views of events that cannot be reconciled. At first, this failure to bring closure is disconcerting to some students, but one underlying theme of the course is the appreciation of the *possibility of divergent opinions on certain issues, even in a science like chemistry*" (p. 1623, emphasis added). Different approaches to teaching thermodynamics (cf. Tarsitani and Vicentini 1996, physics section) are illustrative of this dilemma.

Most textbooks in this review presented the experimental details, without the conceptualization that progress in science is based on competing frameworks of understanding that clash in the face of evidence. Writing in a special issue dedicated to *Nature of Science in Science Education*, Lederman et al. (1998) asked a very pertinent question, "*what seems to be the problem?"* and then responded:

> Most texts briefly, and inadequately, discuss the nature of science in the opening chapter, and then portray science in a distorted, positivistic, and 'final form' fashion throughout the rest of the book. (p. 507)

Despite some improvement, it seems that problems with respect to most textbooks seem to be the same. In this context, Kubli (2005) has emphasized the role of "real" experiments: "The element of uncertainty – the sure sign of a *real experiment* – is drastically reduced if we repeat an experiment whose result can be deduced from the textbook. But even in the classroom, we can regenerate something of the pioneering spirit if we show how difficult it originally was to arrive at a result, and if we can convey the fascination of breaking new ground" (pp. 515–516, italics added). Based on wave-particle duality, Niaz and Marcano (2012) have provided further evidence on this aspect.

Almost half a century ago, Polanyi (1964) had drawn our attention to an important facet of textbooks, by emphasizing the degree to which established knowledge in textbooks departs from the events associated with the original discovery:

> Yet as we pursue scientific discoveries through their consecutive publication on their way to the textbooks, which eventually assures their reception as part of established knowledge by successive generations of students, and through these by the general public, we observe that the intellectual passions aroused by them appear gradually toned down to a faint echo of their discoverer's first excitement at the moment of Illumination … A transition takes place here from a heuristic act to the routine teaching and learning of its results, and eventually to the mere holding of these as known and true, in the course of which the personal participation of the knower is altogether transformed. (pp. 171–172)

Drawing on the "events associated with the original discovery," "excitement at the moment of illumination," and teaching science as practiced by scientists can indeed be an important guideline for future science textbooks (Niaz 2010b).

44.7 Conclusion

This chapter analyzed 52 studies published over a period of 15 years (1969–2010) in four major science education journals, and the following are some of the important findings:

(a) Most biology, chemistry, physics, and school science textbooks lack a historical perspective required to facilitate a better understanding of the dynamics of scientific progress.

(b) Most of the textbooks analyzed were published in the USA and to a much lesser extent from the following countries: Argentina, Australia, Brazil, Canada, Cyprus, Greece, Israel, the Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, Turkey, and the UK.

(c) Few studies provided details of the procedure and reliability of the application of the criteria/rubric for analyzing textbooks. One study (Chiappetta and Fillman 2007) used Cohen's *kappa* statistic, and some studies provided details of inter-rater agreements.

(d) Studies analyzed in this chapter refer to a wide range of 21 subjects that form part of the science curriculum, such as the following: nature of science = 9, atomic structure = 8, Newtonian mechanics = 5, quantum mechanics = 4, special theory of relativity (Michelson-Morley experiment) = 4, evolution = 4, gene concept = 1, oil drop experiment = 2, heat and temperature = 2, chemical bonding = 2, electromagnetism = 2, thermodynamics = 2, science stories = 2, laboratory manuals (biology) = 1, acids and bases = 1, osmotic pressure = 1, periodic table = 1, kinetic theory = 1, statistical mechanics = 1, photoelectric effect = 1, and pendulum = 1 (note this gives a total of 56 instead of 52, as some studies dealt with more than one subject). In all these studies, a majority of the textbooks lacked a history and philosophy of science (HPS) perspective. However, it is important to note that a small number of textbooks did provide material based on HPS that can further students' understanding of science. This shows that HPS is already "inside" the science curriculum, provided textbook authors and teachers make an effort to scrutinize the historical record.

(e) Review of the literature in this chapter revealed that if a topic/concept was difficult/controversial, textbooks try to avoid presenting it, and the following are some of the examples: (i) concept of force (Coelho 2010), (ii) concept of weight (Galili 2001), (iii) Newton's first law (Galili and Tseitlin 2003), (iv) inclusion of evolution which can facilitate "removal of prejudices" (Barberá et al. 1999; Skoog 2005), (v) difference between heat and temperature (Cotignola et al. 2002; de Berg 2008a), (vi) different approaches to thermodynamics (Tarsitani and Vicentini 1996), (vii) role of atomic theory in the development of the periodic table (Brito et al. 2005), (viii) postulation of the sharing of electrons, covalent bond (Niaz 2001b), (ix) origin of the quantum hypothesis (Brush 2000; Niaz and Fernández 2008), (x) special theory of relativity and the Michelson-Morley experiment (Brush 2000; Arriassecq and Greca 2007), (xi) interpretation of alpha particle experiments by Thomson and Rutherford (Niaz 1998), (xii) interpretation of oil drop experiment by Millikan and Ehrenhaft (Holton 1978; Niaz 2000a), and (xiii) photoelectric effect. Millikan's data supported Einstein's equation but not his theory (Niaz et al. 2010a).

Mansoor Niaz received his B.Sc. (1966) and M.Sc. (1968) from Peshawar University, Pakistan, and then took graduate courses (1969–1971) in physical chemistry at Yale University. He worked as a Senior Fulbright Research Scholar at Purdue University (1988–1989). At present he is a Professor of Science Education at Universidad de Oriente, Venezuela. His research interests include the application of history, philosophy of science, and cognitive psychology to science education. He has served/been serving on the editorial boards of the following journals: *Science & Education, Journal of Research in Science Teaching, International Journal of Science Education, Journal of Science Education and Technology, Interchange, Chemistry Education Research and Practice, International Journal of Science and Mathematics Education, Educación Química, and Revista de Educación en Ciencias.* Niaz has published over 150 articles in international refereed journals. Three recent publications: (a) Niaz (2009). *Critical appraisal of physical science as a human enterprise: Dynamics of scientific progress*. Springer, Dordrecht; (b) Niaz (2011). *Innovating science teacher education: A history and philosophy of science perspective.* Routledge, New York; and (c) Niaz (2012). *From 'science in the making' to understanding the nature of science: An overview for science educators.* Routledge, New York.

Chapter 45
Revisiting School Scientific Argumentation from the Perspective of the History and Philosophy of Science

Agustín Adúriz-Bravo

45.1 Argumentation in Science and in Science Education

The purpose of this chapter is to examine the notion of scientific argumentation as it is applied in the realm of science education nowadays, but this examination is done – in accordance with the thematic thread of this handbook – shifting from the extensively used discursive perspective to one centred on *metatheoretical* issues. In order to set an initial consensus for the discussion that follows, it might be convenient to advance here a broad definition of argumentation, which will be eventually revisited to incorporate more theoretical elements. Using the phrasing on the back cover of Myint Swe Khine's (2012, n/p) compilation, scientific argumentation could be loosely identified with 'arriving at conclusions on a topic through a process of logical reasoning that includes debate and persuasion'. This definition points out that an argument typically involves (a) supporting an assertion on other elements, (b) a range of options when choosing such elements and (c) strategies to convince the argument's recipients that the favoured option is appropriate.

Literature reviews around argumentative practices in the science classroom rapidly conduct to acknowledging that argumentation is a central issue or focus – or more properly a 'line of research' (Jiménez-Aleixandre and Erduran 2008) or a 'strand' (Nielsen 2011) – within current didactics of science (i.e. science education as an academic discipline). However, such reviews show, at the same time, that 'argumentation in the field of science education has constituted itself into a multi-disciplinary topic, most profoundly approached from language sciences' (Archila 2012, p. 363;

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_45,

my translation). Hence, the interest of this chapter to recover an *epistemic* focus, which could be broadly defined, borrowing Greg Kelly and Charles Bazerman's words, as the recognition

> that writing and argument play important roles in scientists' and technologists' thinking and forming knowledge communities […]. The forms of expression, invention, and knowledge are responsive to the particular argumentative fields of the professions and disciplines. The epistemic activity of researchers is shaped by rhetorical concerns of who is to be convinced of what, how others respond to novel work, what the organization of their communicative activity is, and what the goals of community cooperation are […]. The representation and role of evidence in relation to generalizations and claims has been a particularly crucial matter in the development of scientific argument. (Kelly and Bazerman 2003, pp. 28–29)

Indeed, argumentation has been recognised by some traditions, authors and texts in the philosophy of science as a key epistemic feature of the scientific enterprise,[1] i.e. a feature constitutive of its very nature, which serves to *demarcate* science from other human activities. It could arguably be stated that

> the majority of philosophical conceptions on the structure of a scientific theory, as well as some of the most important models of [scientific] explanation, incorporate argumentation (understood as justifying inferences) as a central piece in the scientific machinery. (Asti Vera and Ambrosini 2010, p. 6; my translation)

This argumentation-based perspective on the nature of science is apparent in Stephen Toulmin's (1958) famous book, *The uses of argument*, especially in essay IV, where he examines 'substantial arguments' in the experimental sciences. But it should be noted that although argumentation-like processes have been consistently considered in the metatheoretical discussion of scientific processes and products by philosophers (e.g. Giere et al. 2005), the use of the expression 'scientific argumentation' is not as extended as it could be expected within the philosophy of science – at least until very recently. This may be partly due to the concealment of the more elaborate communicative aspects of science in the rather formalist, syntactic view 'received' from the Vienna Circle. In the philosophy of science, the idea of scientific argumentation has been very usually rephrased in terms of explanation, justification, debate, controversy, judgement, persuasion, rhetoric, etc.

Many portrayals of science-in-the-making have pointed to the existence of an extremely elaborate, social, use of *evidences* to give support to our complex, articulated understandings of the natural world (i.e. *scientific explanations*) and, at the same time, to *convince* other people that such understandings are plausible

---

[1] See the following 'focussed' philosophy of science textbooks for more or less extensive discussions around philosophers that inspect the centrality of argumentation in science: Asti Vera and Ambrosini (2010), Føllesdal and Walløe (1986), and Salmon (1995). Also of particular interest for this chapter are the portrayals of the 'combined' scientific practice of argumentation-explanation that revolve around the notion of *abductive* reasoning (cf., Adúriz-Bravo 2005; Aliseda 2006; Bex and Walton 2012; Giere 1988; Giere et al. 2005; Lawson 2009; Samaja 1999).

and fruitful.[2] Such accounts of the nature of science share four main characteristics:

1. They consider explanation – in argumentative contexts – as one of the core epistemic practices of science (cf., Bricker and Bell 2008; Jiménez-Aleixandre and Erduran 2008; Khine 2012, who all cite the *philosophical* origins of this idea that has been imported into didactics of science).
2. They revolve around the notion of evidence (or data, proof, reasons, supporting assertions, warrant and a host of other phrasings) as a key to understand scientific semiosis (i.e. meaning production).
3. They highlight the constituent intentions of the 'acts of speech' (*à la* John Searle) or 'language games' (*à la* Ludwig Wittgenstein)[3] included in the very fabric of the scientific activity (cf., Asti Vera and Ambrosini 2010).
4. They acknowledge the social and situated character of the aforementioned processes, which are developed at the interior of specific knowledge communities with their rules and values.

In accordance with this pre-eminent role given to argumentation in science, it has been repeatedly suggested from didactics of science that argumentation should be incorporated as a major component in a high-quality science education for all (cf., Erduran and Jiménez-Aleixandre 2008; Jiménez-Aleixandre 2010; Osborne 2005). The consideration of argumentation as a central process of 'scientists' science' has permitted didacticians of science (i.e. science educators as researchers) to advance at least three main reasons for the inclusion of argumentation in 'school science'[4] (cf., von Aufschnaiter et al. 2008, p. 102):

1. Meaningful and critical science learning requires argumentation. In this sense, 'learning to argue is seen as a core process […] in learning to think and to construct new understandings [, since] comprehending why ideas are wrong matters as much as understanding why other ideas might be right' (Osborne 2010, p. 464). Thus, mastering the argumentative aspects of science and examining actual pieces of scientific argumentation would help distinguish claims and statements that are supported from those that are not, and also to assess the

---

[2] Leema Kuhn Berland and Brian Reiser (2009) also present a three-element characterisation of argumentation, which is very similar to the one proposed here. They talk about: '(1) using evidence and general science concepts to *make sense of the specific phenomena being studied*; (2) *articulating these understandings*; and (3) *persuading others of these explanations* by using the ideas of science to explicitly connect the evidence to the knowledge claims' (p. 29; emphasis in the original).

[3] These two theoretical constructs refer to the communicative activity as a whole, with all its pragmatic constraints, where different types of texts – among them, arguments – are produced.

[4] The distinction here between 'scientists' science' and 'school science' (cf., Izquierdo-Aymerich and Adúriz-Bravo 2003) is based on the French tradition in *didactique des sciences*. In the theory of didactical transposition (Chevallard 1991), there is a 'savoir savant' constructed within the disciplines and a 'savoir enseigné', taught at school, which emerges from transposing (i.e. performing adaptive operations on) the former. Thus, science as done at school resembles in some aspects, and differs in some others from, science as performed by scientists.

quality and pertinence of the supports provided. It could be safely stated that this first reason is very general, goes beyond scientific argumentation and its epistemology and values arguing in all its cognitive, metacognitive and communicative dimensions,[5] linked to 'fostering the development of students' rationality' (Siegel 1995, p. 159).

2. Since scientists produce and evaluate arguments all the time in order to do science, a school science that is structured around argumentation would convey important messages about the nature of science, hence the need to inform argumentation-based instruction with findings from the philosophy and history of science. In coherence with this second reason, in science classes, a non-negligible part of students' activity would be to construct arguments around their understandings of the natural world, and to share, defend and criticise such arguments as it is done in actual scientific practice (cf., Driver et al. 2000, for school science, and Giere 1988, for scientists' science). Here we could use the distinction proposed by Marilar Jiménez-Aleixandre and colleagues (2000) between doing authentic school science and 'doing the lesson', the first one being characterised by 'the generation and justification of knowledge claims, beliefs, and actions taken to understand nature' (p. 758). It should be noted, of course, that the resulting nature of science that would circulate in the classroom *would heavily depend on the notion of argumentation that is being implemented*, be it more 'rationalist' or more 'constructivist' (see the 'tensions' defined in Sect. 45.2).
3. When considering science education as a tool for scientific literacy and citizen education, it is suggested that students need to engage in argumentation in order to tackle decision-making and to participate in socioscientific debates similar to those that they will encounter in their adult lives. As Jiménez-Aleixandre and colleagues (2000) point out: one of the most currently valued educational goals is 'equip[ping] students with capacities for reasoning about problems and issues, be they practical, pragmatic, moral and/or theoretical' (p. 757); it has been repeatedly proposed that argumentation would foster such capacities. Those capacities would involve evaluating different pieces of scientific evidence and judging their relative importance in making decisions around key issues of personal and social importance. Along this line, and closely following the French linguist Christian Plantin (2005, 2011), Pablo Archila states that

> argumentation has been positioning itself as a social imperative, if it is considered as a way to treat differences, eliminating them, or moving them forward towards collective welfare […]; [education for citizenship] can resort to argumentation to justify, on the basis of shared values, the existence of positions on debated issues that are socially sensitive, such as racism, abortion, the defence of the environment, war, women and children, animal rights, among others. (Archila 2012, p. 364; my translation)

Thus, there is strong consensus that 'student participation in argument develops communication skills, metacognitive awareness, critical thinking [reason 1 above],

---

[5] An anonymous reviewer of this chapter suggested the inclusion of this remark. Emphasis on this central 'learning to learn' aspect of argumentation is probably a cause for the blurring of its more specific epistemic aspects, linked to the nature of science.

an understanding of the culture and practice of science [reason 2], and scientific literacy [reason 3]' (Cavagnetto 2010, p. 336).

Due to this interest in the diverse contributions of argumentation to science education, in the last decade a vast and rapidly expanding corpus of literature has accumulated in didactics of science.[6] Several possible approaches to the study of argumentation in school science have been put forward, related to the theoretical conceptualisations utilised and to the practical aims sought.[7] In this sense, '[a]ccording to different conceptualizations in this domain [of argumentation studies] instructional accounts to promote argumentative abilities of students also differ considerably' (Böttcher and Meisert 2011, p. 104). It could be added that, in consistency with those different conceptualisations, the 'natures' of science propounded for instruction also differ.

Underneath the variety of approaches, different intellectual threads can be recognised. A number of disciplines, fields of study or theoretical frameworks have converged to help didacticians of science in the task of defining, fostering and assessing argumentation in science education.[8] Nevertheless, the epistemic perspective, where an HPS[9] background would be of use, has been somewhat obscured by active discussion from linguistic, cognitive, ethnographic or pedagogical perspectives. Indeed, as stated above, most research around the place of argumentation in science education has been developed within the area of 'research with a focus on classroom discourse during the teaching and learning of science' (von Aufschnaiter et al. 2008, p. 103), with some studies also focussing on written argumentative products (cf., Adúriz-Bravo et al. 2005; Bell and Linn 2000; Erduran et al. 2004). Thus, the interest has been mainly put in the strictly *linguistic* aspects.

---

[6] In Archila (2012), Buty and Plantin (2008a), Erduran and Jiménez-Aleixandre (2008), Jiménez-Aleixandre (2010), Jiménez-Aleixandre and Díaz de Bustamante (2003), Khine (2012), Nielsen (2011), Sampson and Clark (2006, 2008), and Sanmartí (2003), there are rather comprehensive literature reviews on the subject, with more than three hundred references in English, French and Spanish.

[7] For example: Abell and colleagues (2000), Adúriz-Bravo and colleagues (2005), Bell and Linn (2000), Driver and colleagues (2000), Duschl (1990), Duschl and Osborne (2002), Fagúndez Zambrano and Castells Llavanera (2009), García Romano and Valeiras (2010), Henao and Stipcich (2008), Islas and colleagues (2009), Konstantinidou and colleagues (2010), Lawson (2003), Linhares Queiroz and Passos Sá (2009), Newton and colleagues (1999), Osborne and colleagues (2001), Revel Chion and colleagues (2005), Ruiz and colleagues (2011), Sanmartí (2003), Sasseron and Carvalho (2011), and Schwarz and colleagues (2003).

[8] See, for instance, Cadermártori and Parra (2000), Candela (1999), Kuhn (1992), Martins (2009), Mason and Scirica (2006), and Pontecorvo and Girardet (1993), among a host of others, for theoretical foundations ranging from psychologist James F. Voss to semiotician Mikhail Bakhtin, going through argumentation theorist Frans van Eemeren and social anthropologist Jean Lave.

[9] I will here use the acronym HPS (history and philosophy of science in/for science education) to denote the area of research within didactics of science that strives to incorporate a metatheoretical perspective in science education (cf., Matthews 1994/2014, 2000). This area would mainly draw from the meta-sciences (philosophy, history and sociology of science), but it would also include elements from the science studies and from other 'less disciplined' metatheoretical endeavours, such as science-technology-society (STS), feminist epistemologies or public understanding of science.

In order to transcend this discursive approach, and to recover substantive links between scientific argumentation and metatheoretical reflection on the nature of science, the aim of this chapter is threefold:

1. Identifying and characterising a subset of literature on argumentation in science education where connections to HPS are apparent or can be unproblematically proposed.
2. Spotting there some of the 'bridges' that are explicitly announced or can be implicitly recognised between mainstream HPS and argumentation in the science classroom, such as evidence-based science education, inquiry, nature of science and scientific explanation and justification.
3. On the basis of the two previous points, 'revisiting' some defining aspects of school scientific argumentation with an epistemic perspective, using categories from HPS that may help in the re-conduction of this issue towards convergence with the area of research of this handbook.

As stated above, the current state of development of the emerging line of research around argumentation within didactics of science is impressive, with several hundreds of papers accumulated (cf., Osborne et al. 2012). Consequently, this chapter does not purport to be a comprehensive literature review in all aspects of argumentation,[10] but rather an account of some productions on school scientific argumentation selected due to their possibility to be 'tuned' to the discussions in our own field, HPS. At the same time, the chapter makes an effort to incorporate into the English-speaking discussion in science education some less visible contributions from the continental, 'Didaktik' tradition (cf., Westbury et al. 2000), to a great extent shared by Germanic, Scandinavian, Latin, Greek and Slavic countries.

45.2 The Notion of School Scientific Argumentation

In this chapter, I call 'school scientific argumentation' (cf., Adúriz-Bravo 2011) the argumentative *processes* (i.e. discursive practices) and *products* (i.e. texts in any semiotic register) that occur in the science classrooms of all educational levels – from Kindergarten to University. In this sense, 'argumentation' here refers both to argu*ment* and argu*ing*, i.e. 'the product, statement or piece or reasoned discourse […] and […] the social process or activity' (Jiménez-Aleixandre and Erduran 2008, p. 12).

---

[10] The tables of content of the three available *handbooks* on school scientific argumentation (i.e. Buty and Plantin 2008a; Erduran and Jiménez-Aleixandre 2008; Khine 2012) can give readers an idea of the current lines of research within the strand. These lines would be, once chunked and retitled, argumentation, learning and concept formation; argumentation, learning environments and communities of practice; argumentation, discourse and language games; argumentation, social interactions and meaning negotiation; argumentation and scientific reasoning; argumentation and socioscientific and moral issues; argumentation and science teacher education; argumentation-based instruction; argumentation quality and assessment; and argumentation and epistemic criteria and practices.

From now on, the chapter will be restricted to the argumentation intentionally generated so that students understand and use scientific theories and models for problem-solving within the boundaries of science. What we can call ‘socioscientific argumentation’ will thus be purposefully excluded, since such kind of argumentation has epistemological traits that cannot be totally captured with the elements discussed in this chapter.[11] Among those special traits of socioscientific argumentation, the following could be mentioned: (a) it is heavily context dependent; (b) it usually results from a co-construction by different utterers; (c) it draws upon moral reasoning; and (d) it does not have as main reference ‘the scholarly societies acknowledged to create and validate scientific knowledge’ (Tiberghien 2008, p. xi), but rather social representations and knowledge from different disciplined and undisciplined sources.

The installation of school scientific argumentation as a central issue of science education can be attributed to what may be seen as an ‘argumentative turn’. That is to say, in the last four decades or so, social sciences, and social interests and debates more generally, seem to be moving in the direction of recognising argument and arguing as key features of our post-modern culture in general and of science in particular. Within the argumentative turn, at least three fields that are important for the endeavours of our community of didacticians of science are shifting towards the consideration of the nature of science as strongly argumentative (cf., Adúriz-Bravo 2010):

1. Firstly, new school science curricula point at scientific argumentation as one of the central competencies to be achieved during compulsory education (cf., Buty and Plantin 2008b; Jiménez-Aleixandre and Federico-Agraso 2009). True citizenship is now being characterised by the ability to engage in (socio-)scientific argumentation and to make informed decisions in fields such as environment, climate, energy, sustainability, public and individual health, food and pollution. It could be argued that these curricula express the current social expectations (i.e. the ‘social imperative’ of which Archila [2012] talks) on the education of critical citizens.
2. Secondly, meta-sciences (philosophy, history and sociology of science) and other metatheoretical perspectives have turned towards the study of the scientific language and have directly challenged the received view that considers it an *ex post facto* labelling system that operates after clear and distinct ideas and concepts have been construed. The language of science is now ‘problematised’; it is seen as a rich and complex set of cultural tools that enable semiosis: giving meaning to the natural world and making sense to the users (cf., Sutton 1996, who speaks about language as an ‘interpretive system’). Within this context, where a ‘linguistics of science’ is emerging, argumentation is considered a paradigmatic genre in science.

---

[11] For authoritative works on argumentation in connection with socioscientific issues, see Zeidler (2003, especially Chaps. 3, 4, 5, and 7) and Sadler (2011, especially Chaps. 11 and 12).

3. And thirdly, with direct bearings to the corpus of knowledge examined in this chapter, didactics of science and other educational studies (learning psychology, classroom ethnography, etc.) have been paying increasing attention, at least in the last 15 years, to the so-called cognitive-linguistic ability (cf., Sanmartí 2003) of scientific argumentation, analysing ‘argumentation discourse in science learning contexts’ (Jiménez-Aleixandre and Erduran 2008, p. 4). The science classroom is now depicted as a cultural system where language has a structuring function and thus ‘talking science’ (cf., Lemke 1990) should be turned into content to be explicitly and specifically taught.

It could be contended that the first of these three fields – new curricula that express new social mandates – has installed argumentation as a central issue for science education; the second field – metatheoretical studies on the language of science – has enriched our image of the nature of science by acknowledging the existence of argumentative games; and the third field – educational studies on argumentation – has equipped didactics of science with theories and methods, and it has at the same time promoted the over-emphasis on the discursive aspects.

Consistent with this prior analysis, it is the contention here that the notion of school scientific argumentation can be broadly characterised through resorting to the idea of evidence; it can then be more concretely defined using a distinct linguistic stance, and, afterwards, it can be inspected from a metatheoretical perspective, ascertaining its participation in the construction of science.

For a broad definition, this chapter resorts to Jiménez-Aleixandre and Díaz de Bustamante (2003), who see scientific argumentation as ‘the ability to relate data and conclusions, to evaluate theoretical propositions in the light of empirical data or data from other sources’ (p. 361, my translation).

The term ‘evidence’ will be used here to designate not only empirical data arising from observation and experimentation but also theoretical reasons, authoritative claims, elements from worldviews, ethical considerations, stakeholders’ interests and other kinds of ‘supporting assertions’.[12] Thus, evidence collectively denotes the *grounds* provided to justify the assertion or claim that is being argued for:

> Evidences are the observations, facts, experiments, signs, samples, or reasons with which we intend to show that a statement is true or false. (Jiménez-Aleixandre 2010, p. 20; my translation)

This initial, general, characterisation identifies scientific argumentation as one of the basic processes of knowledge construction, a process that

> recasts the role of evidence and data in scientific classrooms: rather than being used to demonstrate the scientific canon or even to guide students to construct correct scientific principles, it is the grounds on which claims – generated by students in the process of argumentation – are warranted. (Atkins 2008, p. 63)

---

[12] A conception of evidence that is broader than ‘experimental data’ on the one hand better captures the history of scientific activity and on the other hand is essential in order to account for argumentation in socioscientific contexts.

This approach to argumentation represents a sophistication of the definition presented in Sect. 45.1, at least in the line of its first highlighted element – ‘arriving at conclusions […] through a process of logical reasoning’ – as it underlines the *functional* role played by evidence in the derivation of such conclusions.

For a more specific definition, it is useful to adhere to the one presented by the research group LIEC (*Lectura i Ensenyament de les Ciències*, ‘Reading and Science Teaching’) from the Universitat Autònoma de Barcelona in Spain:

> Argumentation is a social, intellectual, and verbal activity that allows justifying or rebutting a claim; it consists of making statements taking into account the recipient and the aim with which they are transmitted. In order to argue, one must choose between different options or explanations and reason the criteria that permit evaluating the chosen option as the most adequate. (Sanmartí 2003, p. 123; my translation)

According to this strongly linguistic approach, arguing would then be elaborating a text (be it oral, written or multi-semiotic) with the aim of changing the epistemic value of the ideas sustained by an audience (or a single recipient) on an issue or matter. Such a change is sought through providing meaningful reasons so that the audience or recipient see that a new set of ideas is ‘justified’ by evidence in its most general sense, introduced above. The weight attributed here to justifying and convincing to some extent mirrors the other two highlighted elements of the definition in Sect. 45.1: ‘a process […] that includes debate and persuasion’.

This theoretical conceptualisation on scientific argumentation, and a host of others to which didactics of science has resorted, stem from ‘a range of relevant disciplines’ (Bricker and Bell 2008, p. 474). According to Bricker and Bell’s (2008) classic article, the most relevant of such disciplines are formal logic, argumentation theory, science studies (and here the philosophy of science would be included) and the ‘learning sciences’. The next paragraphs draw on the contributions of the first three, which are more pertinent for an HPS approach.

In order to characterise scientific argumentation from a didactical point of view, some ‘tensions’ (cf., Adúriz-Bravo 2010) that underlie the notion of argumentation – within and outside the science classroom – need to be discussed; such tensions are unveiled when analytical tools from the aforementioned disciplines are employed. It could be safely said that these tensions have many times been dismissed or underrepresented in the literature of didactics of science, partly perhaps as a result of the hegemony of the so-called Toulmin’s argumentation pattern (or ‘TAP’) as the preferred theoretical and methodological framework (see Sect. 45.2.1). The generalised use of TAP has fixed the discussion around semiformal reconstructions of arguments akin to those propounded by the theory of argumentation of mid-twentieth century or, rather, around a highly stylised didactical version of such reconstructions.

The four tensions that are developed in the following subsections are:

1. The opposition between two intellectual traditions to study argumentation, namely, the *Anglo-Saxon* (e.g. Stephen Toulmin, Henry W. Johnstone Jr., Ralph H. Johnson, Douglas Walton, G. Thomas Goodnight) and the *continental* (e.g. Arne Naess, Chaïm Perelman, Oswald Ducrot, Frans van Eemeren & Rob

Grootendorst, Christian Plantin).[13] These two traditions would represent complementary ways of going beyond the classical, neo-Aristotelian, approach to the study of arguments: in the first case, by 'softening' the requirements of syllogistic logic, and in the second, by opening the floor to pragmatic and rhetorical constraints.

2. *Logic* versus *dialogic* argumentation. The opposition between two extreme forms of argumentation – argumentation as explanation and argumentation as debate – is traditionally presented as the existence of 'analytical' and 'dialectical' arguments.[14] Such opposition is usually conflated with the distinction between the use of formal and informal logic in order to analyse such arguments, revised in the fourth tension.
3. Arguing as *explaining* versus arguing as *justifying*, partially connected to the former, and pointing at Jiménez-Aleixandre and Erduran's (2008, p. 9) distinction between producing scientific knowledge about the world and giving 'rhetorical significance' to that knowledge. The 'explanatory' part of argumentation, in this context, would entail making sense of a phenomenon on the basis of data, while the 'justification' part would mean supporting the claim that the data are consistent with the proposed explanation and therefore convincing an audience of its validity (cf., Osborne and Patterson 2011, p. 629, who use similar phrasings, but sharply separate these two operations).
4. Arguments as texts of *'harder'* versus *'softer' syntax*. This refers to the clash between the existence of sanctioned patterns with an a priori rationality dictated by formal logic, leading to heavily 'idealised notions of arguments' (Jiménez-Aleixandre and Erduran 2008, p. 15), and the pragmatic use of what we can call *para-logical* (i.e. ampliative) techniques to capture argumentation 'as it is practiced in the natural languages' (Jiménez-Aleixandre and Erduran 2008, p. 14). Among these 'real' argumentative practices, scientists', teachers' and students' discourse would be included.

45.2.1 Anglo-Saxon Versus Continental Approach to Argumentation

Since the three traditions that follow this first one can be said to hinge to some extent on an *ab initio* divergence between theoretical approaches to argumentation, this subsection is longer and more detailed than the rest; in those, cross-references to the ideas exposed here are made.

---

[13] For other authors not mentioned in this list, see Reygadas and Haidar (2001), Santibáñez (2012).

[14] This opposition is in turn based on Aristotle's division of 'perspectives' on argumentation that has been thoroughly used in continental studies and retrieved by the Anglo-Saxon tradition: logical, dialectical and rhetorical (cf., Harpine 1985; van Eemeren and Houtlosser 2003). The chapter concentrates only in the first two classes of arguments.

The Anglo-Saxon tradition in argumentation studies was long based on the assumption that arguments are more or less ‘syllogistic’ (i.e. deductive-like) in nature (this restrictive requirement of ‘deductivity’ is still retained in the general definition of argumentation presented in Sect. 45.1). Arguments were usually portrayed as a tight structure in which a key assertion is logically inferred from a set of supporting assertions (Asti Vera and Ambrosini 2010). As Stephen Toulmin critically remarks,

> [T]he assumption […] made by most Anglo-American academic philosophers [was] that any significant argument can be put in formal terms: not just as a syllogism, since for Aristotle himself any inference can be called a ‘syllogism’ or ‘linking of statements’, but a rigidly *demonstrative deduction* of the kind to be found in Euclidean geometry. Thus was created the Platonic tradition that, some two millennia later, was revived by René Descartes. (Toulmin 2003, p. vii; my emphasis)

Accordingly, classical argumentation theory among Anglo-Saxon authors more or less overlapped in scope and methods with the discipline of logic – the main aim being to ascertain the *validity* of arguments using formal techniques.

In the Anglo-Saxon tradition, the main connecting threads would be the attention paid to the *syntactic* aspects of the language used to argue and the aim of analysing individual propositions and their structural relations in order to justify and assess theoretical arguments, dialogic exchanges and informed judgements set against the backdrop of their social contexts. The evolution of this tradition could be seen as an expansion of the traditional apparatus to study argumentation – which strictly resorted to formal logic – towards the use of ‘para-logical’ tools, moving then onto ‘informal logic’. The focus is thus to capture ‘natural’ arguments, to formulate

> [the] statements [referred to in those arguments] in a ‘normal’ (philosophical, universal) language in some canonical form [, since a]fter 2,300 years of formal logic, [argumentation theory is] still infinitely remote from having a clear idea of what such a language should look like. (Bar-Hillel 1970, p. 204)

This Anglo-Saxon approach to argumentation will be here characterised through rapidly examining the work of the British-born philosopher of science Stephen Toulmin, with a peripheral mention to the Canadian argumentation theorist Douglas Walton and the American educational psychologist Deanna Kuhn.

Toulmin’s (1958) framework hinges upon a naturalistic approach to the rationality of practical arguments (which he calls ‘substantial’ arguments). Substantial arguments are opposed to ‘theoretical’ arguments, which are analytic and necessary. This means that, in the latter, the argued assertions are the conclusions of *sensu stricto* inferences; such assertions are deductively connected to a set of premises providing the evidence for it (hard data or other grounds, but always satisfying the relationship of logical necessity with the conclusion). Thus, what is being sustained is already ‘contained’ in what we know.

Substantial arguments, on the contrary, seek to offer ‘justification’ for an assertion that is deemed to be of interest, in a specified and recognisable context. Thus, Toulmin suggests going beyond formal logic when modelling arguments and proposes an ‘argumentation pattern’ with tightly interrelated components:

the *claim* (which is the statement in need of justification), *data* to support such claim and a *warrant* that allows the 'legitimate' transition from data to claim. Even more 'real' arguments in the natural language are heavily modalised and include qualifiers, rebuttals and backing to the warrant.

It could be stated that, in Toulmin's framework, the claim – 'conclusion' *sensu lato* – has more content than that of the evidences provided, and thus it is only partially sustained by them. Accordingly, it is convenient to portray the 'movement' from the premises containing the evidence to the conclusion as an ampliative inference, which should be captured with inductive, analogical, abductive, etc. reasoning patterns (cf., Stadler 2004; Diéguez Lucena 2005).

In turn, the goal of Walton's (1996) framework is more related to understanding persuasive arguments, for example, in legal contexts. Walton is thus more interested in *dialogic*, conversational argumentation (see next subsection), where 'actors exchange replies and counter-replies' (Asti Vera and Ambrosini 2010, p. 133; my translation). Walton's *schemes* for 'presumptive reasoning' refer to strategies used in hypothetic, non-demonstrative, argumentation. To capture those schemes, he enumerates a variety of categories; for instance, he talks about 'arguments based on experts' opinions', which might be instrumental both for scientists' science and school science. *Pertinence* of the utterances – and of the reasons given therein – is a key theoretical element of his framework.

As a complement to the general Anglo-Saxon perspective, D. Kuhn (1993, 2010), moving markedly away from philosophical and linguistic considerations, proposes a conceptualisation of science and of science education as argumentative endeavours that resorts to psychological and cognitive foundations. In this sense, she is a good example of contributions to argumentation from the 'learning sciences'.

Opposing the Anglo-Saxon tradition, we can talk of a 're-emergence' of a continental approach to argumentation studies, which occurs after World War II and is of course favoured by external, socio-cultural, factors (cf., Jiménez-Aleixandre and Erduran 2008). Chaïm Perelman's life story – he was a Polish Jew who immigrated to Brussels – is a good example of this. The continental tradition will here be represented in the works of the expert in rhetoric Perelman, the Dutch scholars in 'speech communication' Frans van Eemeren and Rob Grootendorst and Christian Plantin. The connecting threads of this tradition would be the introduction of the audience as a key element and the attention to pragmatic and rhetorical aspects.

Perelman publishes, together with Lucie Olbrechts-Tyteca, his *Traité de l'argumentation* in 1958 (the same year of Toulmin's *The uses of argument*). In this book, the authors propose a 'new rhetoric', understood as an art of persuading and convincing; with this, they also intend to abandon formal logic in the evaluation of argument validity. But, differing from the Anglo-Saxon perspective, persuasion is highlighted; in order to characterise arguments, Perelman constructs new concepts around this idea, such as argumentative force and relevance or the 'intensity of adherence of an audience'. The introduction of the audience as 'a genuine actor in the argumentative phenomenon' (Asti Vera and Ambrosini 2010, p. 110; my translation) is generally considered to be Perelman's main contribution.

Van Eemeren and Grootendorst, at the Universiteit van Amsterdam, develop what they call a *pragma-dialectical theory* of argumentation; like Perelman, they seek to analyse and assess argumentation as a natural practice of language. Pragma-dialectics takes into account the fact that arguments are usually presented within interactive, dialogic discussion. These authors also confront the use of syllogistic structures to study argumentation, since formal logic would be opaque to the subtleties of the social practice of arguing. Scientific argumentation would also need this approach, since scientists direct their arguments to convince peers (or other audiences) so that they accept the point of view that is being offered. Carlos Asti Vera and Cristina Ambrosini (2010) recognise a very 'fecund' starting point in pragma-dialectics, since 'it proposes not abstracting arguments of any of their dimensions, in order to analyse and evaluate them as they are presented in the social theatre, in their empirical, dialogic and contextual determinations' (p. 133).

Plantin is also interested in a rhetorical study of dialogic argumentation (he calls it 'dialogale' in French: cf., Plantin 2011) and again focuses on persuasion as one of its central characteristics. He interprets argumentation as a way of producing speech in situations where doubt, debate and confrontation predominate. It is interesting to remark that Plantin wants to redeem rhetoric from its reputation as a 'sorceress' (Buty and Plantin 2008b, p. 21); according to him, rhetoric has been stereotypically discredited, being repeatedly associated with manipulation, void words and politicians' clichés (for these he uses the very graphic French expression of 'langue de bois').

45.2.2 Logic Versus Dialogic Argumentation

What I call 'logic argumentation' – where arguments are practically confounded with explanations or inferences – can be described, using Richard Duschl's terminological choices (cf., Duschl et al. 1999; Duschl 2008), as the production of analytical arguments. These arguments are grounded in (formal) logic, and they constitute a movement from a set of premises to a conclusion (cf., Asti Vera and Ambrosini 2010). What I call 'dialogic argumentation' – where arguing is seen as exchange of ideas or confrontation – fits with the idea of dialectical arguments, which are 'those that occur during discussion or debate and involve reasoning with premises that are not evidently true' (Duschl 2008, p. 163). It could arguably been said that it was in order to understand this latter kind of arguments that the field of (new) argumentation theory emerged in the 1950s, somewhat vanishing its boundaries with informal logic.

This broad distinction made under this tension can be related to the two major scholarly approaches to argumentation in Sect. 45.2.1 as follows: the stereotypical Anglo-Saxon approach was almost restricted to analytical arguments and logic argumentation (as is apparent in Toulmin's critique), while the best-known continental frameworks over-emphasised dialectical arguments and dialogic argumentation. This simplified, one-to-one relationship tends to relax in more recent texts.

For didactical purposes, it seems convenient to blur this watertight distinction and consider that school scientific argumentation combines in itself the long-standing Greco-Latin traditions of arguing as producing ‘any piece of reasoned discourse’ (Jiménez-Aleixandre and Erduran 2008, p. 12) and arguing as ‘dispute or debate between people opposing each other with contrasting sides to an issue’ (Jiménez-Aleixandre and Erduran 2008, p. 12). Thus, on the logic side, argumentation evokes the etymological meaning of the Latin verb ‘arguere’: ‘make clear through discourse’; such meaning stems from the Indo-European root ‘arg-’, meaning ‘brilliant’ (conserved in modern terms such as the Italian ‘argento’, ‘silver’ or the French ‘argille’, ‘clay’). On the dialogic side, argumentation points at one of the standard meanings of the English verb ‘argue’: ‘discuss’, ‘dispute’ and ‘disagree’. But these two aims of clarifying and debating coexist – and are virtually impossible to divorce from each other – in the language game of argumentation in science.

45.2.3 Arguing as Explaining and Arguing as Justifying

When argumentation is seen as a vehicle for scientific explanation, the emphasis is put on the sharing of theoretical elements that permit us to understand the world. Arguments are seen as ‘solid’, i.e. with a claim well supported by foundations and backings (cf., Asti Vera and Ambrosini 2010), and such a view purports to be context and audience independent.[15] In this first perspective, Toulmin’s idea of warrant is paramount: warrants serve as the explanatory elements; their aim is to give testimony of the legitimacy of the transition from data to claim. Warrants provide general, abstract and *uniform* transitions, which are relatively autonomous of (i.e. not referring directly to) particular sets of data.

When argumentation is seen as an act of speech where justification is demanded and offered (cf., Tindale 1999, who examines this idea based on Michael Billig and Chaïm Perelman), the focus is moved to the recipient’s or audience’s adherence to the claim presented. In this second perspective, more akin to continental studies, ‘argumentation is a feature of social relations and shares in the complexity of those relations’ (Tindale 1999, p. 75).

In science education, the distinction between argumentation as explanation and argumentation as justification can be partially aligned with what Nussbaum and colleagues (2012) call the ‘two faces of [school] scientific argumentation’. According to these authors, argumentation is on the one hand *explanatory*, when it presents and debates scientists’ theories about reality. On the other hand, argumentation is *prescriptive*, when it informs scientific (and socioscientific) debates, where decision-making is often required. These authors distinguish between ‘theoretical discourse, pertaining to what theories of the world best fit the data and practical, deliberative discourse, regarding how to apply those theories to reach practical goals’ (Nussbaum

---

[15] This is what Constanza Padilla (2012) calls ‘demonstrative dimension’ of argumentation.

et al. 2012, p. 17). Accordingly, students and teachers together would use scientific arguments in the science classroom to explain theoretically *and* to circulate and share understandings and applications.

45.2.4 Hard and Soft Arguments

This last tension, as advanced above, has to do with the capacity attributed to formal, abstract structures to capture real discourse. The classical, positivistic approach of categorical rationalism 'supposes enthroning formal logic as the *exclusive* model of rationality' (Asti Vera and Ambrosini 2010, p. 110; my translation, emphasis in the original). Through the lens of formal logic, only what we might call 'hard arguments' survive: those that are 'fully explicit [and] neatly packaged into premises and conclusions' (Smith 2003, p. 34).

If one adheres to this restriction, real argumentation practices are almost always subsumed into the realm of material (or informal) fallacies. There is an *ab initio* 'half-empty glass' metaphor operating here, since – from the point of view of hard rationality – most arguments are considered to be logically non-pertinent, only psychologically persuasive, and often intended to deceive (cf. Asti Vera and Ambrosini 2010). Even in the case of (empirical) science, most relevant arguments do not measure up to the extremely restrictive standards of demonstrative argumentation, since they contain in their fabric elements that are not bound by the relationship of necessity, and therefore cannot be completely formalised without consideration of their empirical content.

Two options arise to oppose this 'hard' approach: in the first place, rationality can be resigned altogether, slipping down the irrational slopes of contextualism, relativism or constructivism. A 'third way', which seems more productive for science education, would be to broaden the scope of arguments that can be considered well supported. This third way would imply a 'temperate', non-aprioristic, rationality, which resorts to the use of 'para-logical' techniques, i.e. non-demonstrative patterns of inference such as induction or abduction. Softening the syntax admitted for arguments is, in all cases, allowing a richer study of argumentation as it occurs in the real world. This would constitute a *naturalisation* of argumentation theory.

For this last tension, the link to the Anglo-Saxon-continental dispute is not straightforward. One might be tempted to assume that the Anglo-Saxon approach closes up the number and variety of patterns of argumentation that are admissible and is therefore more identifiable with the idea of 'harder syntax'. This might be the case for the classical studies, those that fall under Toulmin's critique, but it is certainly not applicable to post-Toulminian accounts of scientific argumentation among English-speaking scholars. On the other hand, a pairing of what I have proposed to call 'softer syntax' to continental accounts would be too hasty, since the examination of the structure and components of an argument is seldom a concern among authors who zoom out to rhetorico-pragmatic considerations.

45.3 The Epistemics of School Scientific Argumentation

This section is devoted to dissecting some of the epistemic aspects of school scientific argumentation, aspects that can be theorised through the lens of HPS.[16] The section discusses different constituting elements of the *epistemics* (i.e. epistemology) of argumentation, identified on the basis of a review of the literature in didactics of science that is heavily theory driven. That is to say, the review is guided by an attention to metatheoretical perspectives and especially to the philosophy of science. As it was advanced in the introduction to the chapter, in order to organise such review, possible 'bridges' between argumentation and HPS are defined.

Under the five bridges enumerated here, studies on school scientific argumentation with an interest in one or more particular epistemic aspects are grouped. The studies may or may not present an explicit HPS background, and this will be indicated for each case. The five resulting groups are:

1. *Argumentation as an epistemic practice.* In this first approach, undoubtedly the most exploited one, the bridge consists in identifying argumentation as a paradigmatic example of epistemic practice, i.e. a practice of knowledge construction that gives its character to the scientific activity. Richard Duschl (1998, 2008), Marilar Jiménez-Aleixandre (Jiménez-Aleixandre and Federico-Agraso 2009; Bravo-Torija and Jiménez-Aleixandre 2011), Gregory Kelly (Kelly and Chen 1999; Kelly and Takao 2002), Victor Sampson and Douglas Clark (2006, 2008), and William Sandoval (Sandoval 2003; Sandoval and Reiser 2004; Sandoval and Millwood 2005, 2008), among many others, have advocated for a conceptualisation of argumentation along this line.
2. *Argumentation as a feature of the nature of science.* In this second, more encompassing approach, the bridge consists in describing the 'non-natural' nature of science,[17] at least partially, through inspecting the role that argumentation (both in the senses of explaining and of justifying) plays in doing, thinking and talking about the natural world. Authors who can be located within this perspective[18] identify science not with the 'discovered' facts of the world, but rather with an extremely elaborate inferential and discursive construction regarding the ways in which scientists appropriate and transform those facts.
3. *Argumentation in scientific inquiry.* In this third approach, school science is designed as an inquiry-based endeavour aiming at genuine scientific literacy (see public policy documents such as AAAS 1993; NRC 1995). The bridge here

---

[16] The name of this section is a paraphrasis of an expression by Sandoval and Millwood (2008, p. 72).

[17] Both Lewis Wolpert (1992) and Lydia Galagovsky (2008) refer to this 'non-naturality' of science in the titles of their books. Nevertheless, the meanings of the expressions that they use are quite distinct from each other. Wolpert's thesis, positivistic in its foundations, is that science is a way of thinking far away from common sense. Galagovsky's compilation of chapters aims at showing how science is a very elaborate human construction and not a mere expression of the way the world is.

[18] For example, Allchin (2011), Duschl (1990, 1998), Hodson (2009), Lawson (2003, 2005, 2009), and McDonald (2010)

is the attention to the inclusion of argumentative skills in such an endeavour. A grasp of the nature of science in science education

> involves understanding *how knowledge is generated, justified, and evaluated* by scientists and *how to use such knowledge to engage in inquiry* in ways that reflect the practices of the scientific community. (Clark et al. 2010, p. 1; emphasis in the original)

The two elements of the nature of science italicised in this quote could be somehow referred to the two poles of tension 3: on the one hand, students need to comprehend the epistemic practice of knowledge generation (explanation); on the other hand, students need to apply that knowledge in school scientific inquiry (justification). Proposals along this line[19] strive to meaningfully connect argumentation and inquiry through the introduction of evidence- and argument-based practices in the science classroom.

4. *Model-based argumentation.* In this fourth approach,

> the general model-based perspective in […] the philosophy of science [is used in order to] understand arguments as reasons for the appropriateness of a theoretical model which explains a certain phenomenon. (Böttcher and Meisert 2011, p. 103)

The bridge here is that argumentation is regarded as a tool to assess and apply the models that constitute the content of school science. Authors who use this perspective (Adúriz-Bravo (2011), Böttcher and Meisert (2011) and much less directly Lehrer and Schauble (2006), who talk about 'model-based reasoning' and Windschitl et al. (2008), who talk about 'model-based inquiry') conceptualise models using *semantic* tools from the philosophy of science of the last three decades.

5. *Argument-based school science.* This fifth approach is rather unspecific; it suggests that argumentation should be a substantive part of the (social) activity in the science classroom (and in science teacher education). Authors adhering to this perspective talk about 'argumentation-based' teaching or instruction.[20] The bridge here are the reasons provided in favour of this position, drawn mainly from the sociology of science (with references to Helen Longino or Bruno Latour, for instance) and to a lesser extent from other metatheoretical perspectives.

A proviso should be made here: in the very biased selection of literature in which the bridges between argumentation and HPS have been identified, papers that use HPS elements for the design of instructional units and materials, but then fail to use those elements to characterise or justify the presence of argumentation in those units and materials, were purposefully excluded. For instance, Bell and Linn (2000), Monk and Osborne (1997) and Revel Chion and colleagues (2009) use the history and philosophy of science to lay the foundations for the teaching of different

---

[19] For example, Clark and colleagues (2010), Duschl and Grandy (2008), Sampson and Clark (2007), Sandoval and Reiser (2004), and Windschitl and colleagues (2008).

[20] Cf., Driver and colleagues (2000), Izquierdo-Aymerich (2005), Newton and colleagues (1999), Ogunniyi (2007), and Ogunniyi and Hewson (2008).

scientific topics (Darwin's ideas, light, the bubonic plague, etc.), and then – more or less independently of those foundations – they propose to implement argumentation as a teaching strategy.

In the subsections that follow, the five aforementioned bridges are explicated through one or two epitomic examples of each of them.

45.3.1 Argumentation as an Epistemic Practice

Richard Duschl's work locates explanation at the vertex of the pyramid of the activities in science (cf., Duschl 1990), identifying it as a privileged aim of the scientific enterprise. In his framework, and following Gregory Kelly and Deanna Kuhn, argumentation would constitute one of the most favoured epistemic (i.e. knowledge-producing) practices. Consistent with this conceptualisation of scientists' science, Duschl proposes, for school science,

> [s]hifting the dominant focus of teaching from what we know (e.g., terms and concepts) to a foc[us] that emphasizes how we know what we know and why we believe what we know (e.g., using criteria to evaluate claims). (Duschl 2008, p. 159)

School science would then require 'epistemic apprenticeship' (Jiménez-Aleixandre and Erduran 2008, p. 9): students should appropriate criteria to evaluate arguments in the light of evidence. Accordingly, science in the classroom could be structured as a set of 'epistemological and social processes in which knowledge claims can be shaped, modified, restructured and, at times, abandoned' (Duschl 2008, p. 159). Duschl talks about 'knowledge-building rules' that represent or embody the epistemic practices of the community formed by students and teacher(s).

Thus, the core of this conceptualisation of argumentation as an exemplar of educationally valuable epistemic practice would be captured in questions such as

> What counts as a claim? What counts as evidence? How do you decide what sort of evidence supports, or refutes, a particular claim? How are individual claims organized to produce a coherent argument? What kinds of coordination of claims and evidence make an argument persuasive? (Sandoval and Millwood 2008, p. 72)

One of the most favoured strategies in the studies allocated in this first group has been to recognise epistemic *statuses*, *criteria* or *levels* in students' argumentative practice, with the aim of 'assessing the nature or quality of arguments in the context of science education' (Sampson and Clark 2008, p. 449). Such assessment is done, for instance, in terms of their complexity, robustness, validity, etc.

For this first bridge, explicit recurrence to authors from the area of HPS has been somewhat low. In Sandoval and Millwood (2008), for instance, of almost 30 cited references, only three are to authors with a meta-scientific perspective: Philip Kitcher, Bruno Latour and Stephen Toulmin. In Duschl (2008), of around 45 cited references, again only three are to texts in the realm of HPS (Derek Hodson, Nicholas Rescher and Toulmin). In Sampson and Clark (2008), among circa 65 references, only two 'meta-scientists' feature: Latour and Thomas Kuhn. The relationship between favouring argumentative practices in science education and metatheoretically characterising those as epistemic practices is therefore *indirect*: most authors that develop this first bridge refer to some seminal texts in didactics of science (e.g. Driver et al. 2000; Duschl and Osborne 2002; Kelly and Takao 2002) that have acknowledged the philosophical foundations of that relationship, but then do not go on developing such foundations.

45.3.2 Argumentation as a Feature of the Nature of Science

There is a substantive connection between this second approach and the first one, since a widespread hypothesis in science education considers that 'students' epistemological beliefs [i.e. their conceptions on the nature of science] are developed through their own epistemic practices of making and evaluating knowledge claims' (Sandoval and Millwood 2008, p. 85). Epistemic practices in general, and argumentation in particular, would then be, at the same time, a specific feature of the nature of science (cf., Hodson 2009, Chap. 8) and a powerful means to access to a coherent and robust conceptualisation of such nature.

Both Jonathan Osborne and Sibel Erduran, in many of their papers (cf., Erduran et al. 2004; Osborne et al. 2001), have enumerated different links between the nature of science and argumentation. Osborne and colleagues (2001), for instance, subordinate those links to the need to teach the nature of science *explicitly*,[21] since 'contact with school science is insufficient to generate an understanding of how science functions' (p. 69). For such teaching, argumentation becomes a privileged tool, insofar as it permits presenting students with opportunities to examine and discuss epistemological issues such as evidence, prediction, analytical thinking, controversy, reasoning, evaluation and critical thinking.

From a more focussed point of view, Anton Lawson points out that nature-of-science instruction should teach to science students 'that the best [scientific] argument considers all of the alternatives and explicitly includes the relevant evidence and reasoning supporting and/or contradicting each' (Lawson 2009, p. 337). He suggests introducing, in science education, what he calls an 'if/then/therefore' argumentative pattern. His theoretical framework, which he deems valid both for scientists' science and for school science,

> distinguishes among an argument's declarative elements (i.e., puzzling observations, causal questions, hypotheses, planned tests, predictions, conducted tests, results, and conclusions) and its procedural elements (i.e., abduction, retroduction, deduction, and induction). (Lawson 2009, p. 358)

---

[21] As one of the anonymous reviewers of this chapter pointed out, considering the nature of science or argumentation important goals of science education does not imply deciding to teach these issues explicitly. The contention that school scientific skills are not developed by 'exposure' and deserve 'direct instruction' is still debated; nevertheless, such contention seems to be finding some support coming from recent empirical studies (e.g. Kirschner et al. (2006), at a general level, and McDonald (2010), for the case of nature of science and argumentation).

It should be noted that Lawson provides extensive HPS backing to his framework, using the history of science in order to construct case studies of scientific reasoning, argumentation and discovery and – to a lesser extent – the philosophy of science to understand those three processes.

In my own work, I portray scientific argumentation as the textual counterpart of the epistemic operation of scientific explanation (Adúriz-Bravo 2005, 2010, 2011). I define argumentation as the *subsumption* of some phenomenon of the natural world under a theoretical model (in the sense of the semanticist family), which is seen as a good candidate to 'explaining' it (and hence there is direct connection with bridge 4). Similarly to Lawson, my argument is that some discoveries and inventions, as reported by scientists through history, can be reconstructed as cases of abductive and analogical thinking; these kinds of inferences would then be the mechanism to subsume the 'phenomenon-case' under a 'model-rule'. I distinguish between abduction *sensu lato*, as any ampliative, non-monotonic, inference producing or evoking hypotheses and abduction *sensu stricto*, as a 'reverse' deductive schema *à la* Peirce (cf., Adúriz-Bravo 2005; Aliseda 2006; Samaja 1999).

45.3.3 Argumentation in Scientific Inquiry

School scientific inquiry can be broadly conceptualised as a 'knowledge building process in which explanations are developed to make sense of data and then presented to a community of peers so they can be critiqued, debated and revised' (Clark et al. 2010, p. 1). In this sense, inquiry would function as a reconciliation of the two poles of the second (logic-dialogic) and third (explain-justify) tensions. Within this framework of ideas, argumentation nicely fits when understood as

> the ability to examine and then either accept or reject the relationships or connections between and among the evidence and the theoretical ideas invoked in an explanation or the ability to make connections between and among evidence and theory […]. (Clark et al. 2010, p. 1)

From this perspective, argumentation is seen as an artefact to develop and evaluate explanations (cf., Kuhn Berland and Reiser 2009; Osborne and Patterson 2011; Windschitl et al. 2008). In other words, in this third approach the practices of explanation and argumentation would be *complementary*:

> First, explanations of scientific phenomena can provide a product around which the argumentation can occur, as proponents of an explanation attempt to persuade their peers of their understandings. Second, argumentation creates a context in which robust explanations – those with which the community (the students) can agree – are valued. (Kuhn Berland and Reiser 2009, p. 28)

For this third bridge, it should be noted that Kuhn Berland and Reiser's (2009) paper has an extensive and developed HPS background. These authors show how several philosophers of science, in the last six decades, extended

> [t]he everyday sense of argumentation[, which] typically suggests a competitive interaction in which participants present claims, defend their own claims, and rebut the claims of their

> opponents until one participant (or side) "wins" and the other "loses". [Instead, i]ndividuals compare conflicting explanations with the support for those explanations and work to identify/construct an explanation that best fits the available evidence and logic. (Kuhn Berland and Reiser 2009, pp. 27–28)

45.3.4 Model-Based Argumentation

In model-based argumentation, scientific arguments are understood as the 'reasons for the appropriateness of a theoretical model which explains a certain phenomenon' (Böttcher and Meisert 2011, p. 103), and argumentation 'is considered to be the process of the critical evaluation of such a model if necessary in relation to alternative models' (Böttcher and Meisert 2011, p. 103). Here, the second and fourth tensions are apparent: on the one hand, models that explain are judged in terms of the reasons for their justification; on the other hand, critical evaluation of the appropriateness of those models would require the use of some analytical tools arising from classical or modern logic.

Central to this approach to school scientific argumentation is the thesis that

> [t]he model-based theory represents a suitable theoretical framework for describing arguments and argumentation referring to the similarity between models and empirical data as the central reference for model evaluation. (Böttcher and Meisert 2011, p. 137)

Derek Hodson (2009) provides a detailed description of the role attributed to argumentation in a model-based depiction of the nature of science. Closely following Ronald Giere (Giere 1988; Giere et al. 2005), he states that

> [r]eaching consensus about the most acceptable model involves a cluster of interacting, overlapping and recursive steps: (i) collection of data via observation and/or experiment, (ii) reasoning, conjecture and *argument*, (iii) calculation and prediction, and (iv) critical scrutiny of all these matters by the community of practitioners. Language plays a role in all these steps […]. As an integral part of these activities, *arguments* are constructed and evaluated at a number of different levels. (Hodson 2009, p. 259; my emphasis)

Such description, explicitly based on HPS, justifies the use of argumentative strategies within the framework of model-based science education.

From a slightly different perspective, but also stressing the role of models in scientific argumentation, Jiménez-Aleixandre (2010) focuses on 'arguments on explanatory models', stating that such arguments intend to identify cause-effect relations in the explanations and interpretations on natural phenomena.

45.3.5 Argumentation in School Science

School scientific argumentation is brought to the centre of the arena of teaching practices ('pedagogy') when the pre-eminently *empirical* conception of students' activity in the science classroom is abandoned in favour of a more theory-laden, social and discursive depiction of school science. Rosalind Driver and her colleagues (2000) accurately explain this shift in the following quote:

> Our contention is that, to provide adequate science education for young people, it is necessary to reconceptualize the practices of science teaching so as to portray scientific knowledge as socially constructed. This change in perspective has major implications for pedagogy, requiring discursive activities, especially argument, to be given a greater prominence. Traditionally, in the UK (and other Anglo-Saxon countries), there has been considerable emphasis on practical, empirical work in science classes. Reconceptualizing the teaching of science in the light of a social constructivist perspective requires, among other matters, the reconsideration of the place of students' experiments and investigations. Rather than portraying empirical work as constituting the basic procedural steps of scientific practice (the "scientific method"), it should be valued for the role it plays in providing evidence for knowledge claims. (Driver et al. 2000, p. 289)

In Mercè Izquierdo-Aymerich's work,[22] argumentation is incorporated as a central feature of her general theoretical framework for didactics of science (developed with colleagues at the Universitat Autònoma de Barcelona). She labels such framework, following Ronald Giere (1988), the 'cognitive model of school science'; this and other authors from the so-called semantic view of scientific theories in contemporary philosophy of science provide her with the conceptualisation of theoretical models that she deems to be most fruitful for science education (and hence the intersection with bridge 4).

Within this framework, school scientific arguments are cognitive and discursive tools that permit making meaningful connections between the realm of facts in the world and the models that can give meaning to those facts:

> Students reason according to their initial models, which generally have an *iconic* relationship with phenomena; a simple image may function as a model for students. Experimentation and its written reconstruction bring students to a new epistemic level, in which non-iconic (i.e., *symbolic*) signs are much more relevant. Symbols can only connect correctly with their referents if the first, more concrete step is done [...]. In order to give momentum to this process, it is necessary that students learn how to use argumentation in their discourse [...]. (Izquierdo-Aymerich and Adúriz-Bravo 2003, p. 38; emphasis in the original)

45.4 Conclusion: Towards Convergence of Argumentation with HPS

The purpose of this short conclusive section is to revisit six characterisations of school scientific argumentation with the ideas provided by an HPS-informed approach, which were discussed throughout this chapter. For each of the excerpts revisited, connections with the five bridges are made, and some HPS references (mainly from the philosophy of science) are suggested that could help in furthering the discussion only sketchily initiated here.

---

[22] See Izquierdo-Aymerich (2005), Izquierdo-Aymerich and Adúriz-Bravo (2003), and Izquierdo-Aymerich and colleagues (1999).

Sampson and Clark (2008) propose to use 'the term «argument» to describe the artefacts students create to articulate and justify claims or explanations and the term «argumentation» to describe the complex process of generating these artefacts' (p. 448). This first terminological clarification reminds us of the fact that in order to fully understand school scientific argumentation, we should consider it as *a product that arises from a highly elaborate process and is therefore shaped by the very nature of that process*. Here the connection with bridge 1 is direct: an epistemic characterisation of the argumentation process is required, be it more 'internalist', focussing on inferences (e.g. Charles Sanders Peirce, Stephen Toulmin or Nancy Nersessian) or more 'externalist', looking at social interactions within the scientific communities (e.g. Thomas Kuhn, Bruno Latour or Helen Longino).

Marilar Jiménez-Aleixandre (2010) starts her book on key ideas about argumentation with a working definition of the notion; she considers it the 'ability to relate explanations and evidences' (p. 11, my translation). In this kind of phrasing, the evidence-based character of the scientific enterprise is highlighted: *evidence (in its broadest sense) becomes a key epistemic factor, one of the cornerstones of scientists' activity.* This emphasis can lead, in science education, to fruitful discussion around the notion of rationality, with questions such as what counts as 'valid' support for scientific claims, and how is this support obtained and shared? To answer such questions, related mainly to bridges 2 and 3, a postpositivistic notion of rationality can be introduced. For this kind of discussion, ideas from Stephen Toulmin,[23] William H. Newton-Smith or Ronald Giere seem appropriate.

Rosalind Driver, in one of her posthumous papers (Driver et al. 2000), advocates for a 'situated perspective', where 'argument can be seen to take place as an individual activity, through thinking and writing, or as a social activity taking place within a group – a negotiated social act within a specific community' (pp. 290–291). When arguing, *scientists give meaning to the world and communicate such meaning to peers and other audiences*; this should be a guiding idea of the nature of science discussed in the science classroom. Again, this double cognitive and social perspective can be inspected with tools from the philosophy of science and from science studies, anchoring the discussion in selected episodes from the history of science.

Anton Lawson, distinguishing himself from Toulmin's ideas on argumentation, so hegemonic in didactics of science, prefers to see

> the primary role of argumentation, not as one of convincing others of one's point of view (although that is certainly part of the story) but rather as one of discovering which of several possible explanations for a particular puzzling observation should be accepted and which should be rejected. (Lawson 2009, p. 337).

In such preference, the explanatory and theoretical aspects of argumentation are highlighted, and this might constitute a possible connection with bridge 4. Arguments *propose a way of 'seeing' the world that is structured around theoretical views*. Here, the so-called semanticist family (Giere, Frederick Suppe, Bas van

---

[23] Here I refer to Toulmin (2001).

Fraassen), with their various conceptualisations of scientific theories, might prove a powerful background.

Izquierdo-Aymerich and myself accept a 'relaxation' of the requirements for an argument to be considered scientific, in tune with the naturalistic approach introduced in the fourth tension:

> An argumentation is formed by a set of reasons that convey a statement and reach a conclusion. Scientific arguments are hardly ever strictly formal (logical or mathematical); they are generally analogical, causal, hypothetico-deductive, probabilistic, abductive, inductive… One of their functions is to make a theoretical model plausible, convincingly connecting it to a growing number of phenomena. (Izquierdo-Aymerich and Adúriz-Bravo 2003, p. 38)

This approach reminds us that *there is variety and richness in the language games that have been used in science through history*. Studies around the linguistics of science, especially those following Wittgenstein's ideas, may be of use to reflect on the issues posed here.

In the last characterisation of argumentation that is reviewed for this chapter, Kuhn Berland and Reiser (2011) recover the centrality of the aim of persuasion when arguing:

> The process of attempting to persuade the scientific community of an idea reveals faults in the argument (i.e., evidence that is unexplained by the idea or misapplication of accepted scientific principles), and identifying these faults creates opportunities for the community to improve upon the ideas being discussed. (Kuhn Berland and Reiser 2011, p. 212)

It can be argued that scientific disciplines are such inasmuch as they have disciples: therefore, *it is constitutive of their very nature the will to communicate, convince, persuade and teach*. This last input for science education can find support in texts from the science studies, especially in those situated in pragmatic and rhetorical perspectives.

Agustín Adúriz-Bravo is Professor of Didactics of Science at the Research Institute CeFIEC of the Universidad de Buenos Aires, Argentina. He received an M.Sc in Physics Teaching from the Universidad de Buenos Aires and a Ph.D in Didactics of Science from the Universitat Autònoma de Barcelona, Spain. He is a regular Visiting Professor at several Universities in the Americas and Europe. His general research focus is on the contributions of the philosophy of science to science teacher education. He has extensively published in Spanish and English.

Chapter 46
Historical-Investigative Approaches in Science Teaching

Peter Heering and Dietmar Höttecke

46.1 Introduction

The notion of the historical-investigative approach to science teaching was first introduced by Kipnis (1996). According to his theory, teaching and learning science within a context of history and philosophy of science (HPS) should be mastered through students' practical investigations. He suggests a middle ground between highly structured verification laboratories, which aim at generating "true" results, and open-ended experiments, where students are not guided at all. The basic idea of students doing practical work while learning science, along with its history, had been developed earlier in similar ways (e.g., Pedzisz and Wilke 1993; Rieß and Schulz 1994; Teichmann 1979, 1999).

We use the notion of the historical-investigative approach here as a broad idea that characterizes a variety of perspectives for teaching and learning science with HPS. Two central aspects are tightly joined together, the first being that science is embedded within a historical context. A central objective of this idea is to broaden students' understanding of scientific concepts and theories, to promote their interest in science, and to foster their general historical awareness. These are all ideas with a long tradition (Conant 1957; Mach 1912; Ramsauer 1953). The second aspect is concerned with the development of procedural knowledge and process skills, which are often highlighted in standard documents (Barth 2010).

There is also a long-standing tradition in science education which calls for practical work to be done: students plan investigations, perform or even design experiments, collect and analyze data, draw conclusions, and discuss and negotiate their results. In particular, the idea of inquiry-based teaching and learning science is based on the analogy of students' activities to those of scientists. Inquiry refers to a diverse set of activities in which scientists study (e.g., Anderson 2007), explore, explain, or even manufacture (Knorr-Cetina 1981) the natural world. Scientists propose explanations based on both evidence and inference.

Several curricular standard documents, such as the NSES (National Research Council 2000), have stressed that learners should be engaged through scientifically oriented questions. They should prioritize evidence while proposing explanations which have to be critically evaluated, communicated, and justified. Inquiry learning and learning science with HPS share this special focus of student centeredness in science education. At the same time, inquiry learning and learning with and about HPS have both been shown to be useful means of learning about the nature of science (NOS). Research has indicated that NOS has to be addressed explicitly and reflectively in order to enhance the efficiency of teaching (e.g., Abd-El-Khalick and Lederman 2000; Seker and Welsh 2005).[1] Science teachers should confront students with their deeply held beliefs about science and how science works. During the last three or four decades, an extensive body of literature about NOS has been written.[2] Our analysis reveals that there are strong relationships of teaching and learning NOS and HPS on a curricular level (e.g., National Research Council 1996), with research and development in science education.[3]

Our analysis is based on two major threads of discourse: the discourse of research in HPS and the discourse of research in science education. Both are relevant to the HPSST community and for the development of ideas of how to teach science within a historical-investigative framework. In the second section of this chapter, a brief analysis of the recent discourse in HPS is presented, showing that experiments became an important focal point of historical and philosophical analysis in the early 1980s. Since then, from an epistemological point of view, experiments have no longer been reduced to a means for testing mere theoretical knowledge. The material and instrumental procedures in science are currently regarded as a central feature for explaining what science is all about, how science proceeds, and in which respect science is a cultural and human endeavor. The presentation of this

---

[1] For the efficacy of inquiry-based techniques for learning about NOS, see, for example, Akerson et al. (2007), Khishfe and Abd-El-Khalick (2002), and Schwarz, Lederman, and Crawford (2004). Evidence for the efficacy of HPS for learning about NOS has been presented, for example, by Allchin (1999), Clough (2011), Galili and Hazan (2001), Howe and Rudge (2005), Irwin (2000), Kruse and Wilcox (2011), Lin and Chen (2002), and Rudge and Howe (2009).

[2] For a recent and extended overview of research on students' views on NOS, see Hodson (2009). A critical review of research methods with regard to different orientations of NOS is given by Deng et al. (2011). See also Lederman (2007), Lederman and Lederman (2012), and McComas and Almazroa (1998).

[3] See, for example, Hodson (2009), Höttecke et al. (2012), Irwin (2000), and Rudge and Howe (2009).

"experimental turn" in HPS is followed by an overview of recent research in science education regarding practical work and learning demonstrating that practical work in science education has a long-standing tradition. Central problems which have been identified by research throughout recent decades will be discussed as far as they relate to the historical-investigative approach.

Based on the analysis of these two threads of discourse, a structured discussion of several approaches in science education is presented, approaches which all have one common feature: merging the idea of teaching science with HPS with practical and investigative learning activities.

46.2 The Experimental Turn in HPS

46.2.1 Investigating Science as Practice and Culture

Understanding science as a cultural activity gained increasing importance during the second half of the twentieth century. Such a view breaks with positivistic accounts, which describe the development of science and scientific knowledge as progressing towards the truth, and allows a description of science as something that is shaped or even influenced by factors which might have been regarded as nonscientific. Such a cultural perspective is closely related to a constructivist understanding of science. A number of studies aim at describing and understanding science as a sociocultural practice. Among them are laboratory studies (Knorr-Cetina 1981; Latour and Woolgar 1979), as well as social science studies (e.g., Shapin 1994). The analysis of science under a sociocultural perspective has shown, in particular, different ways in which a scientific consensus might be reached and the role that social factors, such as authority and reputation, might play in the establishment of scientific knowledge (e.g., Collins 1985; Galison 1987).

Besides social and cultural aspects of science, the role of material objects, such as scientific instruments and material procedures, received scant attention by those studying the history and philosophy of science until about 1980. Since then, they have become increasingly important for the development of a comprehensive understanding of science as a process. For decades, instruments and their use, development, and history had been an issue only for a small community of historians of scientific instruments. The recognition of material and instrumental procedures in science has been a more recent development in HPS. Accordingly, laboratory notebooks have become an important source for detailed accounts of scientific practice at the workbench.[4] The consideration and analysis of science as a visual practice is

---

[4] For discussions of laboratory notes, see, in particular, Holmes et al. (2003). See also Steinle's studies on Faraday (Steinle 1996) and Dufay (Steinle 2006). For further case studies based on Faraday's laboratory diaries, see Gooding (1990), Tweney (1985), and Höttecke (2001).

another recent tendency in HPS. Images and their role in shaping and communicating scientific ideas and results have, therefore, been analyzed in detail.[5]

Even though instruments and instrument collections have been a topic of research for quite some time, there are some recent developments in this field which deserve a closer look. Traditionally, research on scientific instruments had two major directions of impact: either there was a scope on the construction of particular instruments, since they were regarded as highly relevant to the general development of science (e.g., development of theories, confirmation of laws, instrumental procedures), or instrument collections were analyzed in order to explore and characterize distinguishing features they had in common (e.g., collections of microscopes). Accounts on the history of scientific instruments that followed one of these two research traditions remained, by and large, descriptive. The material and procedural aspects were scarcely considered to be an important issue.

Besides these two approaches, there were a few early studies which focused on experimental practices in science, probably the first one being Settle's experimental analysis of Galileo's inclined plane experiment (Settle 1961). The methodological approach that he used was particularly innovative: he reenacted the experiment with a reconstructed device. Several similar studies followed which also analyzed experiments described by Galileo (Drake 1970; MacLachlan 1973). The experimental approach, while being limited to experiments that had been described by Galileo, can be understood when the aim and context of the experimental analysis are taken into consideration. During the 1960s and 1970s, Galileo's experimental accounts were regarded as fictitious. Historians and philosophers of science held the notion that Galileo, being predominantly a theoretician, used accounts of experiments merely as devices to strengthen and clarify his theoretical arguments. It was doubted that Galileo had ever carried out the experiments he described in his publications. Consequently, the reenactments were intended to demonstrate that Galileo had, in fact, been able to carry out these experiments according to his description.[6]

Since the early 1980s, experimentation in science has received more attention than ever before from historians and philosophers of science.[7] Initially, history of science was concerned foremost with the development of theories. According to this view, the only role experiments could ever play in science was limited to confirming theories or even just providing the possibility of falsification (Popper 1934). During the early 1980s, some studies, however, began to focus on experimentation as an independent aspect of the formation of scientific knowledge, alongside the development of theoretical knowledge. In this respect, Ian Hacking's

[5] For a discussion on the role of images in the sciences, see, in particular, Heßler (2006) and Busch (2008). For discussions of images and their role in nanotechnology, see Bigg and Hennig (2009).

[6] There are, of course, some earlier examples which analyze materials, as well as practices, through reenactment. The field in which this method was likely first applied is archeology, the most prominent example being the demonstration by the Norwegian Thor Heyerdahl, in the late 1940s, of the possibility of travelling from the American Pacific coast to Polynesia with a simple raft.

[7] See, for example, Collins (1985), Galison (1987), Gooding (1990), Gooding and James (1985), Gooding et al. (1989a), Hacking (1983), Radder (2003), Schaffer (1983), and Shapin and Schaffer (1985).

dictum that "experimentation has a life of its own" (1983, p. 150) became well known. Experiments were regarded as a central element in the process of knowledge production. Manipulations of the natural world have multiple facets and cannot be used merely to test assumptions.

Such a wide view of experimentation also contributed to a new awareness of instruments in the history of science. Instruments were, at the time, considered to be artifacts which were designed and constructed according to explicit objectives, their function and shape possibly even having changed over the course of their use. They could not be taken for granted as objects anymore, as they were believed to have been a crucial part of experimental and manipulative practices of the past. Their meanings were not regarded as anything established or given anymore but as developed in laboratories and elsewhere as a result of material, social, and cultural practices. Hence, their materiality and contingent use were seen as relevant objects of historical science research.

The general experimental or even material turn in HPS described above also led to new perspectives for science museums. Historians of science criticized the restoration of a historical instrument as a mere transformation into a mint condition. During the process of restoring an old instrument, traces of its former use should be kept rather than displaying it as a cleanly polished instrument. Historical analysis focused on such traces because they were regarded as signs of the historic progression of an instrumental procedure. Instrumental procedures were not regarded as unproblematic, stable, or even fixed but as probably changing over the course of the development of an experiment.

46.2.2 Investigating Material Procedures

The experimental turn has not resulted in a diversified research focus. Various different directions and research currents can instead be identified. Research focusing on the historical analysis of scientific experimentation either emphasized the material or the methodological character of experiments. The latter idea can be "found in studies that understood science in terms of activity rather than contemplation. Science was to be understood not as a body of knowledge but as a network of embodied practices" (Morus 2010, p. 775). Such a historical perspective is related to a broader understanding of the role of experiments in knowledge production: "The aim of the experimenter is to transform … inscriptions to a stage where they seem capable of but one reading and become powerful weapons in argument" (Gooding et al. 1989b, p. 5).

A central approach can be seen in various attempts to analyze historical experiments by the method of replication. This approach follows a tradition founded by the studies of Settle, Drake, and others regarding Galileo's work, already mentioned above. The general focus of the historical investigations of experimental practice, however, shifted from a mere reproduction of experimental results presented in original papers towards detailed accounts of experimentation as both process and practice. Material manipulations, instrumental procedures, and their general relationship to the development of theories or models were under scrutiny. Yet, it has to be noted that even in his first paper, Settle had already made another aspect explicit: "To get a better appreciation for some of the problems he [Galileo, P.H.] faced I have tried to reproduce the experiment essentially as Galileo described it" (Settle 1961, p. 19). Settle's point is remarkable for his time. He identifies a central aspect of this kind of research: the idea is not to question the experimental findings but to develop an understanding of the crucial details of the experiment and the difficulties that Galileo might have had to face due, in part, to choosing adequate materials and instrumental design and to developing the respective skills that are required for a successful performance.

One of the first researchers to apply this methodology more systematically was David Gooding, who analyzed experiments described by Michael Faraday. While doing this, Gooding developed a particular focus:

> [S]ince skills cannot be recovered from the familiar literary and material forms of evidence - manuscripts, publications and instruments - historians of science should, if possible, venture beyond these, to study the activity that produced them. … Empirical results never are entirely independent of the practices that let to their production. Facts are practice-laden as well as theory-laden. … If much of what experimentalists do cannot be recorded, it cannot be recovered by reading texts or even by studying apparatus (Gooding 1989, pp. 63 f).

Besides Gooding, it was the Oldenburg group, in particular, established by Falk Rieß, which systematically developed the methodology of reenacting experiments of the past. Their so-called replication method[8] was based on the reconstruction of an apparatus as close as possible to the available historical evidence, which might be presented in written sources or even surviving instruments. Such reconstructions were used for authentically reconstructing material procedures and instrumental manipulations. The major objective was to write case studies about reconstructed and analyzed scientific practices. This replication method has been established during the last two and a half decades. Meanwhile, other researchers apply this (or an adapted) methodology, which is particularly prominent in the physical sciences.[9] There are also examples of it being used in chemistry[10] and some in biology.[11]

---

[8] For systematic discussions of the method, see, in particular, Breidbach et al. (2010), Heering (1998), Rieß (1998), and Sichau (2002). For a slightly different methodological interpretation, see Frercks (2001). Case studies are collected in Breidbach et al. (2010) or Heering et al. (2000). Moreover, see for single cases Engels (2006), Heering (1992, 1994, 2002, 2005, 2006, 2007, 2008, 2010), Heering and Osewold (2005), Hennig (2003), Höttecke (2000, 2001), Kärn (2002), Müller (2004), Sibum (1995, 1998), Sichau (2000a), Staubermann (2007), Voskuhl (1997), and Wittje (1996).

[9] See, for example, Cavicchi (2006), Fiorentini (2005), Lacki and Karim (2005), Martínez (2006), Palmieri (2008, 2009), and Staubermann (2011). The Jena group, led by Breidbach, focuses more strongly on the reconstruction of the instrument than on the practice with the instruments. For a detailed account, see Breidbach et al. (2010), as well as Frercks and Weber (2006).

[10] See, for example, Fatet (2005), Principe (2000), Tweney (2005), Usselman et al. (2005), Chang (2011), and Eggen et al. (2012).

[11] See, for example, Maienschein (1999) and Maienschein et al. (2008).

Moreover, the approach is no longer limited to the history of science; it has also gained importance in other professional fields, most notably in technology[12] and cultural studies.[13]

Manual procedures are usually hard to communicate, and complex manual procedures cannot be explicitly communicated at all because of their tacit nature (Collins 1985; Polanyi 1966). One may think, for instance, on how hard or even impossible it is to explain exactly how to ride a bike without tumbling. Detailed accounts on laboratory practice, including their tacit dimensions, require new methods. The replication method, however, allows for an analysis of the complex interactions of materials, instruments, rooms and spaces, people, their bodies, and the associated theoretical ideas. Additionally, the analysis comprises an account of the social and cultural meanings to which an experiment or instrument may be related, such as norms and values in science and beyond.

In summary, history and philosophy of science have embraced scientific experiments and instruments, as well as practical manipulations of scientists, in a new way during the last three decades. As a result, our current understanding of their role in the production of scientific knowledge and the establishment of scientific practices has increased. As we will show in Sect. 46.4, the role of experiments, instruments, and practical manipulations corresponds to recent developments in HPS-informed science education. The next step is to recapitulate briefly what we know about practical work in science education in general.

46.3 Research About Practical Work in Science Education: A Background for Historical-Investigative Approaches

Experiments and practical work are of great importance in science education. Scholars have long argued in favor of its predominant role. For natural studies, practical fieldwork became important in the USA towards the end of the nineteenth century (Kohlstedt 2010). In physics, practical work became an accepted part of high-school education in the USA by 1910 (Rosen 1954).[14] A commission of the German Society of Natural and Medical scientists released a document with recommendations (GDNÄ 1905 according to Willer 1990) in the early twentieth century. More than a 100 years ago, scholars had already emphasized the importance of practical work in science education for the enhancement of process skills, as well as for general attitudes of accuracy and exact observation. The commission emphasized that science should be taught as an exemplar of how knowledge is generally

---

[12] One of the best-known examples in this field is Wright's analysis of the Antikythera mechanism (Wright 2007); for other examples, see the contributions in Staubermann (2011).

[13] Most prominent is the discussion on the role that the camera obscura may have played in painting. For a summary of the discussion, see Lefèvre (2007).

[14] For the process of transition from textbook to practical work, see, for example, Hoffmann (2011), Kremer (2011), and Turner (2011).

acquired in the empirical sciences. While the first idea is still accepted today, the idea of a clear-cut, single epistemic methodology appears to be obsolete.[15] This does not mean that science is not driven by a limited number of methodological rules, like, for instance, the use of controlled experiments or avoiding ad hoc revisions to theories (Irzik and Nola 2011).

Even today, there is wide agreement among science educators that practical work is of general and great importance for teaching and learning science. A European Delphi study, for instance (Welzel et al. 1998), gathered empirical data on the main teaching objectives for laboratory work in science education, as recognized by science teachers at the upper-secondary and first-year university level. According to this study, the great value of experiments and laboratory courses is seen as important for reaching several educational objectives. Through them, students can learn how to connect theory and practice in science and how to test knowledge. There are opportunities for the enhancement of process and social skills, scientific thinking skills, motivation, and personality development. Besides the general appreciation of practical work in science education, the teachers in this study valued structured and guided instructions of students' laboratory activities, which were seen to be of high importance for the development of experimental skills and insights into the relationship between theory and practice.

Recent research in the history of science that focuses on experimentation has strongly stressed the idea that scientific experimentation is a multifaceted activity with many possible relationships between experimentation and observation, on the one hand, and inference and theory development, on the other (e.g., Hacking 1983; Heidelberger and Steinle 1998). The Kantian idea of an experiment where a scientist directs questions to nature like a judge to a witness can no longer be supported, since nature cannot be regarded as an unaffected and independent agency (Kutschmann 1994). According to our current understanding, a scientific experiment is, instead, an act of intervention, where questions, interests, public and private perspectives, background knowledge and skills, an experimenter's body, instruments, rooms and spaces, material and theoretical entities, and procedures interact to develop science within a cultural and societal context (see Sect. 46.2 of this paper).

The actual role and use of experiments in science education presents a somewhat problematic situation. An extended video-based study focusing on physics education in Germany has shown that experiments usually play a major role in physics teaching (Tesch and Duit 2004); however, teachers appreciate the role of experiments in science teaching only in a rather general way. Jonas-Ahrend (2004), reporting her findings from an interview study with physics teachers, asserts that the educational purpose and relationship between students' experimentation and their learning are hardly considered by teachers. Strong guidance of lab activities in science education has often been criticized as cookbook-style[16] or even as a verification laboratory (Kang and Wallace 2005; Metz et al. 2007) because it fosters a

[15] See, for example, Feyerabend (1972), Hentschel (1998), Pickering (1995), and Ziman (2000).

[16] See, for example, Clough (2006), Hofstein and Kind (2012), Hofstein and Lunetta (2004), and Metz and Stinner (2006).

portrayal of science as a rhetoric of conclusions or even indoctrinates students in correct procedures (Nott and Wellington 1996). Inquiry or "discovery" learning may pose the danger of misrepresenting science as primarily an inductive endeavor. According to Harris and Taylor (1983), a pure inductivist idea of science may bear several pedagogical pitfalls. They consider the problem that in following an inductive perspective on science, a certain chain of inferences from observations to conclusions rules out alternative explanations of phenomena. They criticize the lack of a coherent philosophy of science implicit in curricular material. Science, if outlined as inductive, might even justify an alleged "progressive" view on education, according to which the child is misleadingly regarded as autonomous and experiences practical work as authentic.

It often happens that students do not really know what the purpose of an experimental procedure they follow or the meaning of the data they collect might be.[17] According to Gallagher and Tobin (1987), high-school teachers rarely consider whether their students really understand what they are doing and what their experimental results might indicate. Science teachers hardly exhibit behavior that encourages students to think about the nature of scientific inquiry in a reflective manner. Thus, it is hardly surprising that research has indicated that students have a limited understanding of the nature and purposes of experimentation in science.[18] Concerning the current situation in science teaching, Hofstein and Kind (2012, p. 192) have concluded that "practical work meant manipulating equipment and materials, but not ideas."

Whenever students perform experiments, neither their ideas nor their performances resemble what scientists in their laboratories are actually doing. Chinn and Malhotra (2002) have compared students performing so-called "simple" experiments with scientists doing authentic inquiry. They conclude that the cognitive operations of both are rather different. While scientists generate their own questions, questions are often directed to students. Students usually investigate only one given variable, while scientists have to select or even invent variables to investigate. Students are usually told what and how to measure; scientists, however, incorporate multiple measures of independent, intermediate, and dependent variables. Whereas students usually draw conclusions from a single experiment, scientists coordinate results from multiple studies. Such differences reveal the deep gap between regular inquiry activities at school and the ways scientists perform their experiments.

This gap is also mirrored in teacher students' understanding of experiments. In a study based on focus group interviews, Gyllenpalm and Wickmam (2011) found out that Swedish university teacher students understand the notion experiment rather as a method of teaching than a method of scientific inquiry. According to this study an "'experiment' was never explicitly associated with a particular methodology for producing new knowledge about causal relationships" (ibd., p. 920) and rather used

---

[17] See, for example, Flick (2000), Hart et al. (2000), Hofstein and Kind (2012), Hofstein and Lunetta (2004), Lunetta et al. (2007), and Schauble et al. (1995).

[18] See, for example, Carey et al. (1989), Lubben and Millar (1996), Meyer and Carlisle (1996), Milne and Taylor (1995), and Solomon et al. (1996).

in an everyday sense of the word. As long as science education lays claim to the idea that the practical work of students and experiments in science should have anything in common, there is a bridge to be built between different views of experiments in science and in science education.

Scholars have stressed the role of open-ended activities within an inquiry framework, which has been shown to be superior to strongly guided practical work (e.g., Berg et al. 2003). Trumper (2003) demands that from a constructivist perspective of teaching and learning, the way that we teach in the laboratory should be rethought. Anderson (2007) summarizes the features of a new student orientation towards a becoming more self-directed learner. Under such an orientation, students process information, as well as interpret and explain data. They design their own activities, form interpretations of data, and share authority for answers. Still, inquiry learning should not be unguided since research from the field of educational psychology (Kirschner et al. 2006) warns us that the advantage of guidance begins to recede only if learners already possess sufficient prior knowledge to cope with a certain problem. Researchers have generally emphasized that science teachers should focus on a stronger process perspective, instead of the restricted perspective of scientific content (Flick 2000). Practical work in science education should aim towards an understanding of scientific evidence (Gott and Duggan 1996). The general role of metacognitive activities (Hofstein and Lunetta 2004) should be more greatly appreciated. The same holds for the teacher's supportive role in cognitive scaffolding – the interactive instructional strategy where teachers provide tailored instructions based on a diagnosis of the abilities and problems of their students.[19]

Several educational consequences follow from the view of science as a social endeavor. Scientific inquiry appears to be an activity where one makes sense of material and empirical and theoretical entities which have to be presented to a community of experts. Problems of validity cannot be solved by a single scientist in his or her laboratory. Instead, communities of peers have to criticize, negotiate, debate, and even revise the meaning and prevalence of any entity in science. Such a sociocultural view of science accompanies a Vygotskian perspective (Vygotsky 1978) of teaching and learning, one that stresses the social context of cognitive development. Students interact with each other and build communities of practice in order to promote learning. Accordingly, Duschl (2000) calls for instructional sequences in science teaching and learning to be more strongly oriented to the epistemic practices of science. Discussions, debates, and arguments about what counts as evidence deserve a more prominent role in teaching and learning.

Several approaches in science education, and especially in the field of history and philosophy of science in science teaching (HPSST), have been developed throughout recent decades. They continue the general appreciation of student-centered laboratory courses, open-ended inquiry activities, and manipulative investigations of material objects within a context of HPS. In the following section, the character and role of such approaches are analyzed and discussed.

---

[19] See, for example, Flick (2000), Valk and Jong (2009), and van de Pol et al. (2010). Tao (2003) explicitly calls for actively scaffolding students' understanding while using science stories about NOS.

46.4 Historical-Investigative Approaches in Science Education

There are several approaches to teaching and learning science which are closely related to the historical-investigative approach. Each of them stresses different aspects of teaching, learning, students' activities, experimentation, scientific instruments, or HPS in general. For each of these approaches, we will discuss the role played by HPS, on the one hand, and the role of students' investigative activities, on the other. To illustrate both extremes, some approaches strongly focus on investigative activities or inquiry-orientated learning, which is inspired only by scientific experiments of the past. Other approaches stress the role of historical context in teaching and learning science, while students' own investigations are clearly instructed by historical patterns.

In brief, historical-investigative approaches in science teaching are characterized by balancing the following aspects or a combination of them in a particular way:

- Contextualizing science with its history and philosophy
- Stressing material, social and/or cultural aspects of science
- Enabling teaching and learning about NOS
- Allowing for students' more or less guided own practical explorations of natural or technical phenomena
- Basing students' investigations on research activities related to past science
- Enabling students' critical reflections of their own actions and learning, as well as fostering their reasoning skills
- Using aspects of HPS to allow students to deduce their own meaning of their experiences with material entities and their manipulations and vice versa

In the following section, several approaches will be discussed which essentially fit into the general category of historical-investigative teaching and learning. We are aware that the authors of the work presented below might consciously have avoided the notion "historical-investigative" as an accurate account of their own work. Nevertheless, since we want to discuss the breadth of connate approaches in different educational fields without neglecting fundamental differences, we have decided on subsuming all these approaches under this common topic.

Besides the conceptual differences which will arise in the discussion below, one has to remember that science teachers favoring or rejecting a certain approach usually depend on the availability of resources and not necessarily on conceptual considerations.

46.4.1 Historical Investigations Within a Narrative Approach

Recently, stories have received more attention from educators favoring a historical approach. While most of the respective case studies clearly distinguish between a historical narration and an (independent) inquiry with modern materials, there are also a few exceptions that can be seen as a historical inquiry approach.

An example of such an approach has been developed by Metz and Stinner (2006), who have adapted the replication method. The general structure of the activities is retained, but while the replication method emphasizes a reconstruction of instruments, materials, and procedures as close to the available sources as possible, Metz and Stinner argue for a method called "historical representation." Historical representations are specific forms of case studies which recommend the reproduction of historical experiments with modern materials. A central idea is that students interact with a narrative about the history of science through the experiments they are performing. The activities they design and perform alternate between their own ideas and prior knowledge and those presented by the narrative. This means that students formulate hypotheses on their own, design tests, and, finally, compare and contrast their own ideas, experiences, and measurements with the original work. Explorations performed independently from the original are, therefore, welcomed. The use of alternative materials and innovative adaptations of the original instruments, materials, or procedures is encouraged. The experiments the students perform are not intended as verification labs but as a means to address the nature of science explicitly. The historically based investigation comprises four parts or phases: introduction, experimental design, experimental results, and analysis and interpretation of data and explanation.

Narrative approaches are, however, not without any danger. Metz and his colleagues (2007) mention that "we cannot expect students on their own to develop a critical stance towards narrative; thus mediation to guide students through a process of critical analysis should be an essential component of the narrative process" (Metz et al. 2007, p. 320). Accordingly, Tao (2003), in a study with 150 secondary-school students, found that science stories are useful contexts for students to argue for their preexisting views on NOS. As a consequence, the teacher should actively scaffold students' understandings in order to support students' cognitive development.[20]

The strategy of redoing scientific experiments of the past is also employed by Chang (2011). Here, history of science serves as a source for the exploration of peculiar and supposedly well-known natural phenomenon, which concerns accounts about how knowledge in science not only is generated but also forgotten. He demonstrates that a seemingly clear scientific "fact," such as the boiling point of water, becomes questionable or even obscured but may be demystified in the light of evidence of science from the past. Chang recovers past scientific knowledge, which has been forgotten instead of being integrated into the body of accepted knowledge we call current science. He shows that the boiling temperature of water notably depends on the form of the vessel in which the water is heated. He considers that "[g]etting involved in historical experiments will almost invariably teach students (and teachers) that things are more complicated that they had been led to be believe" (Chang 2011, p. 322). As a result, the experimental difficulties of a historical situation can serve as a basis for inquiry-based activities that focus on the peculiarities of the boiling temperature of water, yet, even without necessarily referring explicitly to the historical context.

---

[20] See footnote 19.

A thoughtful consideration of past science helps students to realize that modern science deals with a restricted range of objects, methods, and materials. Likewise, Vera and his colleagues (2011) describe a "simple experiment with a long history," the combustion of a candle in an inverted vessel that is partly immersed in water. This experiment was initially described by Lavoisier, though it can be traced back to antiquity. Similar to Chang's examples, they demonstrate the historical development of a classical experiment and expose potential difficulties that may have played a role in the historical discourse, as well as in generating a misconception about the explanation that can be found even in fairly recent textbooks. Yet, the methodological approach of Vera et al. is somewhat different in that it also involves computer simulations in communicating their experiments.

Experimental approaches of elementary-level scientific content immersed in a historical context appear to be a straightforward and unproblematic variation of a historical-investigative approach. Yet, there are some problems with respect to the historical context that, on first sight, appears to be clear and evident. A good illustration in this respect is Kipnis' discussion of Oersted's experiment on electromagnetic interaction (Kipnis 2005). He argues that Oersted's discovery of electromagnetism is an example of the role chance might play in the development of scientific knowledge. Even though Oersted's experiment is frequently described as being based on chance, this perception might be caused by a lack of an adequate consideration for the Romantic movement in physics and its role in theory development. Martins (1999), for example, argues strongly that Oersted's work has been based on theoretical considerations influenced by Romantic natural philosophy.

46.4.2 Historical Investigations Starting from Laboratory Diaries

Original manuscripts and, in particular, laboratory notes can provide an authentic basis for structuring a conceptual and procedural understanding of science. The collection of Michael Faraday (1932–1936) is a prominent example of such manuscripts due to the extensive detail and the availability of his notes and even more so because his laboratory diary was published in the 1930s. Crawford (1993), as well as Barth (2000), uses different sections of Faraday's notebooks in their classroom as a starting point for students' investigative activities. According to Crawford, there are at least three aspects that turned out to be beneficial: "In fact, some of them [Faraday's problems] were problems the pupils shared, but said that they had previously felt stupid about declaring their puzzlement" (Crawford 1993, p. 205). When following Faraday's problems, however, Crawford "had shaken their faith that someone somewhere, at least in teaching/learning situations, would eventually produce an answer. They had to think for themselves" (Crawford 1993, p. 205). The students did not only develop a conceptual understanding from these lessons but "they also learnt and recognized for themselves many things about science itself" (Crawford 1993, p. 205). Faraday's experimental accounts were used as a kind of "starter" (Crawford 1993, p. 206) of students' own inquiry-based activities.

Likewise, Barth (2000) used Faraday's laboratory diary to enhance students' understanding of electromagnetic induction. Suitable chapters from Faraday's notebook were presented to the students as a basis for their own inquiry activities on electromagnetic induction. Following Faraday's notes, the students made their own discoveries about electromagnetic induction using modern equipment while guided by Faraday's original experimental ideas. Moving back and forth between the diary and the apparatuses – reconstructions of an experimental apparatus and a modern version – the students were able to develop their own understanding. Moreover, they experienced the difficulties of stabilizing and amplifying an effect adequately, difficulties comparable to those that Faraday and his contemporaries faced. It is remarkable that Barth even managed to guide his students to the point where they developed insight into an initial mistake that Faraday had made. Faraday, in a letter to his friend, Philipps, discussed the directions of an electric current induced by a primary current in a parallel wire but then predicted the wrong directions of electromagnetically induced currents. While Faraday, himself, corrected his mistake a short time later in his official paper to the Royal Society, his initial incorrect prediction of an electric current has only been recognized by a few science historians (Romo and Doncel 1993).

46.4.3 Historical Investigations and Instruments from Past Science

Experimenting with historical or reconstructed instruments opens up new ways of understanding science as an experimental practice. Reconstructed historical devices, as well as original apparatuses, can be used in formal and informal science education. A leading approach in this respect has been recognized by Devons and Hartmann, who developed a "laboratory devoted to repeating crucial experiments in the history of physics with apparatus reconstructed according to the original descriptions" (Hartmann Hoddeson 1971, p. 924). One of the criteria they use is similar to the ones claimed in historical studies based on the replication method. According to them, "methods and materials used in these experiments are essentially those used originally" (Devons and Hartmann 1970, p. 44). Their work[21] serves as a starting point for several followers who reenacted historical experiments for educational purposes. Among the major objectives are both an enhanced understanding of experimental practice with a special focus on reconstructions of material and performative aspects of science. The approach is particularly motivated by the general objective that learners should thoroughly understand how knowledge in science is generated or even manufactured (see, e.g., Heering 2000, 2007; Höttecke 2000, 2001; Kipnis 1993; Rieß et al. 2006). Experiments do not appear to be simple devices for answering questions in a yes-or-no manner but allow for detailed accounts on how instrumental and material manipulations in science interact with theoretical and cultural entities.

---

[21] See also Devons and Hartmann Hoddeson (1970) and Hartmann Hoddeson (1971).

Reenacting historical experiments is an approach that has been systematically used by the Oldenburg group, led by F. Rieß for research in HPS (see the Sect. 46.2) and for educational purposes. The method was mainly used in physics teacher-training courses[22] although there are also some instances where this approach has been used at a secondary-school level (Heering 2000; Höttecke et al. 2012). This approach is based on replicas which were largely developed in the process of analyzing historical experiments with the replication method. Replicas of historical instruments are often characterized by material cultures of a certain time and space. Materials favored by natural philosophers of the eighteenth century, for instance, were amber, natural resin, shellac, or glass, but not PVC. Replicas, therefore, allow for new experiences with materials and their possibly peculiar qualities, with which students are often unfamiliar. Thus, this approach aims to explore the material culture of a particular time. Moreover, replicas are usually not designed for teaching purposes but originate from authentic laboratory practices of the past. Replicas still represent theoretical ideas which are embodied in instruments, materials, and the ways that they were used at the workbench. Hence, they are a rich resource for investigating the distinctive interaction between material and theoretical entities, as well as between instrumental and social practices in science. An important feature of this approach generally is that knowledge, data, and the experiences of the students working with the replicas are not isolated. The Oldenburg group used them as a rich resource for contextualizing experiments, materials, and instruments from specific cultural and societal perspectives.

During the past three decades, a rich resource of replicas, mainly from the history of physics, has been constructed. The STeT project (Science Teacher e-Training) has been looking for new ways to provide teachers with materials connected to the history of instruments and experiments (Kokkotas and Bevilacqua 2009). Among the materials are short films, which demonstrate how the replicas work in action. The project HIPST (History and Philosophy in Science Teaching) uses the idea of developing case studies. Some of the cases developed in HIPST enable teaching and learning about science and NOS with an explicit focus on students' historical investigations with replicas. A wide range of student-centered activities and materials have been developed for teaching and learning, including role-play, films, and methods for explicitly reflecting the NOS (Höttecke et al. 2012).

46.4.4 Historical Investigations with Modern Materials

Several approaches use the working principle of historical experiments for educational purposes without using replicas, historic materials, or even original instruments. For these approaches, historical context still becomes the focal point around

---

[22] See, for example, Rieß (2000), also Sichau (2000b) on thermodynamics and Höttecke (2000) on electricity.

which teaching and learning must be organized. Such approaches[23] can, therefore, be seen as modifications of those discussed in the former section.

Tsagliotis (2010) has developed a case study where primary-school students construct microscopes with modern materials, such as PVC tubes and plastic lenses. They make observations and relate them to simplified chapters of Robert Hook's *Micrographia*. Maiseyenka and her colleagues (2010) show how the historical context of cooling and ice production may be enhanced by students' own investigation of physical principles, such as the effect of the dilution of salt on evaporation or on freezing mixture. The case study is addressed with students in grades five to seven where the topic of producing and enjoying ice cream is of interest.

According to Kipnis' (1996, 2002) idea of historical-investigative teaching, science students would rather imitate scientists than use artificial or contrived experiments found in regular science education. He suggests that several modifications should be allowed to be made to the original experiments. Thus, using such an approach means that students begin their own investigations from a historical context rather than reenacting an experiment. Kipnis stresses that through this approach, students have the chance to become discoverers. Students should realize that they are capable of repeating certain important steps of famous scientists on their own. This approach enables students' decision-making regarding the proper result of historic scientific disputes. Building their self-confidence is another important expected outcome. Furthermore, students should appreciate the great discoveries of the past and learn about the strategic elements of experimenting. On the other hand, Kipnis suggests quite a strict structure for integrating experiments into historic contexts. According to his strategy, during an investigation, students formulate a problem based on a specific historical background. Then, they must identify and select relevant variables. All variables should be examined independently in order to test a hypothesis. Finally, the students must draw general conclusions based on their analysis of the variables and their effect on a certain phenomenon. While the students learn how to control variables in a clear-cut way, many aspects of scientific experimentation discussed in Sect. 46.2 are in danger of not being adequately considered. The step-by-step method aimed at "producing true results" (1996, p. 281), combined with the act of restricting experimentation to the examination of variables and test of hypotheses, hardly matches the constructive role of practical manipulations, material procedures, or explorative strategies of experimentation in science. This is not surprising since Kipnis stresses science as a "drama of ideas" (1996, p. 288).

Allchin (1999) describes an introductory science lab course for nonscience majors using history of science as a curricular guide. Within the year-long interdisciplinary course, outside the regular curricular teaching structure, instructors enjoyed significant freedom. The designed "historically inspired labs" focused, among others, on topics like basic astronomy, early medicine, density of matter, Galileo's ideas on pendulum motion, production of paint, electrophysiology, titration of vinegar, and the ballistic pendulum. Most instruments were adapted from existing introductory laboratory course materials. The instruments, even though

---

[23] See, for example, Achilles (1996), Kipnis (1993, 1996, 2002), Teichmann (1979), Teichmann et al. (1990), and Wilke (1988).

modern, were "set more explicitly in their historical context and with added emphasis on reflecting the investigatory process" (Allchin 1999, p. 620). The main objective of the course was "a coupled understanding of the content and process of science" (Allchin 1999, p. 621). Therefore, the investigatory activities were related to real science in a wider sense; for example, during a lecture, an instructor demonstrated the hydrostatic paradox, which means that the hydrostatic pressure of a water column only depends on the depth of the column and not on the shape or the volume of a vessel. After the demonstration, the students started to suggest a variety of different tubes in order to explore their effect on pressure.

While all approaches discussed in this section start with a historical context from the very start of teaching, Allchin (1999) mentions an alternative option. According to him, history of science has often been introduced retrospectively as a way of reviewing the students' investigations, their experiences, and results. Thus, history of science was not directly related to students' investigations from the outset but used as a means for reflecting experiences with instruments, experiments, and phenomena retroactively. Nevertheless, as the students indicated, the labs were integral for understanding how science works.

Lin and colleagues (2002) present evidence of the effectiveness of a teaching approach based on practical activities of students in an HPS context. They conducted a 1-year study, with grade eight students, about the efficacy of promoting students' problem-solving ability through history of science teaching. A treatment group was compared to a control group. The students were randomly assigned to one of the groups. The treatment group was taught with an emphasis on the development of scientific content. Students learned details about how previous scientists discussed, debated, and hypothesized and how they conducted experiments. Either teacher demonstrations or students' hands-on activities were analogous to the experiments and ideas of previous scientists. The students simulated historic experiments and were required to predict their results. They formulated hypotheses, explained their own reasoning, and reflected on analogies and differences between their own hands-on activities and those of previous scientists. The control group was taught in a somewhat traditional manner. There, students worked according to cookbook-style labs, aiming at getting correct answers. They had to follow predetermined procedures, listen to lectures, and solve problems presented in textbooks. Statistical analysis of pre- and posttest data indicated significant effects of the treatment regarding the problem-solving abilities of the students. Unfortunately, there is still a lack of empirical evidence about the efficacy of the practical work of students framed by the history of science. The results of this study are, nevertheless, encouraging.

46.4.5 Historical Investigations in Science Museums and Instrument Collections

Original historical instruments are rarely used in science education. A reason for this is probably their status of having historical and heritage significance. Therefore, they have to be preserved and saved from any damage. There are, however, a few examples where instruments have been used in reenacting historical experiments in science education, most notably an experiment on the decomposition of water, performed in a history of science course at the university level (Eggen et al. 2012). Here, part of the apparatus for decomposing water was borrowed from the historical teaching collection, while the voltaic pile was reconstructed according to descriptions from 1800. The authors concluded that the exercise enabled valuable insight, both into the nature of the devices they had used and the experiment as a whole. Likewise, original microscopes and telescopes are used in science museums for educational purposes. There, they illustrate the optical quality, as well as the magnification, of these devices.

Cavicchi (2008) describes the visit of a group of students with a disparate background in science education to the MIT Museum's collection of historical telephones. The students explored several historic devices, such as telephones and a nineteenth-century Voltaic pile. They even "had to innovate distinctive actions such as unscrewing a lid, releasing a crank, picking a lock" (Cavicchi 2008, p. 726) in order to surmise the workings of the telephones in relation to their construction and materiality. Lissajous figures were produced by reflecting light off orthogonal nineteenth-century tuning forks. Students' investigations were enriched through the use of historic texts. The main focus of the approach is to enable intensive experiences with physical phenomena while exploring the historical context of their emergence. Cavicchi calls her approach "critical exploration," according to earlier work from cognitive psychology. As the undergraduate students engage with complex phenomena and materials, they experience, firsthand, the relationship among the critical components: the materials, their own actions, and history. The students' actions put them in the shoes of past historical investigators who had also developed an understanding of science through experimentation with materials.

Reconstructions of past experimental instruments have also entered museums. In those cases, they might be placed close to the original items in an exhibition. Visitors are allowed to use them instead of the original devices. In this way, a similar experience as would be had with the original device can be achieved without threatening the museum curator's responsibility to preserve the heritage of the device (Heering and Müller 2002). An alternative might be to offer visitors the opportunity to reconstruct instruments on their own in a simple manner. Such a procedure is based on historical artifacts (or their reconstructions) and thus enables new insight into the material culture of scientific experimentation (Heering and Sauer 2012).

Barbacci and her colleagues (2010) present a case study called "Discovery of Dynamic Electricity and the Transformation of Distance Communications," which is designed as an informal educational activity. It is addressed to high-school students and teachers and aims to bring out interrelations between history of science and general social history. The case study has been developed and tested in the Fondazione Scienza e Tecnica's physics laboratory collection in Florence, Italy. During an interactive workshop at the Fondazione, it is possible to explore several of the central topics in electrodynamics from a historical perspective, like the invention of the galvanic battery, the use of electromagnetic coils, and the early application of the galvanoscope, galvanometer, and electromagnet. The lesson moves on to the invention of the telegraph, which is placed into a context of the development of railways, the problem of establishing standard time, and submarine telegraphy, and the sociocultural implications of these phenomena. The lesson presented at the museum follows a narrative-experimental approach: historical background information is presented together with certain scientific discoveries and their technical applications. Experiments and instruments matter on two levels, as a hands-on activity and as a presentation of original devices from the scientific instrument collection. Hands-on activities were designed to help solve several practical problems presented to the students. They built a type of Volta pile and tried to verify its operation; they repeated Oersted's experiment with a current-carrying wire in order to deflect a magnetic needle in a particular way; and they studied optical telegraphy and built a simple model of a Morse telegraph. Having been presented with the original scientific instruments, students were able to compare their own material manipulations with them and understand them as witnesses of past developments in science, their application, and their sociocultural significance.

Additionally, there have been recent attempts to teach through the analysis of historical instruments. In a fairly simple manner, this can be done by examining devices in their showcase in a museum. There have also been attempts to teach material culture through the analysis and contextualization of historical artifacts that may even be (or at least have been) part of everyday life (Anderson et al. 2011; Cavicchi 2007, 2011).

46.5 Conclusion

The analysis of several historical-investigative approaches has shown that the ideas of science as both practice and culture are often considered in science education. Over the past three decades, research into history and philosophy of science has strongly emphasized the constitutive role of experiments, instruments, and material procedures in science and their close relationship to the development of theoretical ideas. During that time, experiments in science have not been restricted to a mere means of testing ideas or hypotheses. In the aftermath of the practical and material turn in HPS, metaphors like the "mangle of practice," as Andy Pickering (1995) puts it, guide our understanding of science as a complex interaction of theoretical, material, and human agencies. Such complex views on how science works hardly match any cookbook-style idea of a single scientific method.

Straightforward epistemologies do not match what recent research in HPS has discovered about the idiosyncratic roles of experiments, instruments, and material procedures in science; hence, a single "big story" about science as a linear inductive, deductive, or hypothetic-deductive endeavor can hardly be told anymore. In this respect, the idea of a case study or a narrative about a particular event, scientist, experiment, or any other occurrence in science might actually generalize ideas about science, rather than define what science is or should be.

Even though the educational benefits of practical work in science education have been stressed for a long time, the current status of experiments in science teaching, in general, as a means for enhancing students' understanding of NOS is still weak. On the other hand, "verification labs" have been widely refuted by historical-investigative approaches. Practical work, according to historical-investigative approaches, is not restricted to the manipulation of equipment and materials or to a mere inductive endeavor. Manipulations of materials and instruments are, instead, a means for the development of the scientific ideas and skills of students who reflect simultaneously on their own investigations and their multiple relations to historical contexts.

In the practical and material turn in HPS and science studies, scholars focused more on detailed accounts of processes and practices in science. Laboratory diaries, notebooks, materials, and instruments, alongside the more traditional sources of letters and publications of scientists, become regarded as a rich resource for detailed accounts on how science works. This development is mirrored by recent attempts to make use of such resources for educational purposes. Through the analysis of laboratory notebooks and practical work with replicas of historical instruments, scientific investigations transform into a detailed process.

Alongside the practical and material turn in HPS, case studies about how science works gained increasingly more attention in science education. The Harvard case studies (Conant 1957) often have been quoted on the subject. Recently, case studies have had a stronger focus on learning about NOS in an explicit reflective manner. They offer several opportunities for students to develop their own investigations in close relation to the history of science (e.g., Allchin 2012; Clough 2011; Höttecke et al. 2012). Other approaches, like "critical exploration," (Cavicchi 2006, 2007) emphasize the role of reflected investigations of phenomena or technical devices, framed by historical contexts.

Regarding the use of instruments in science education for investigating material, as well as historical entities, a wide array of options have been offered, beginning with the use of authentic materials and instruments up to the use of modern ones. Each option has its specific advantages and suffers from particular problems. While the use of modern materials and instruments is hardly useful for reenacting and exploring the material culture of science, the use of replicas or even original instruments from the past suffer from a lack of availability or even usability for several teaching purposes. Hence, the relevance of each approach depends highly on where learning will take place (e.g., formal learning at school or informal learning in a science museum) and which teaching objectives will be targeted (e.g., NOS, conceptual knowledge, process skills).

In science museums, historical-investigative approaches appear to be quite innovative. Since the traditional goal of science museums was usually to balance the objective of protecting a heritage with that of enabling science learning, new ways for exploring the past with hands-on activities have been established which encompass both objectives. Here, approaches have been developed which allow visitors' hands-on activities, together with a careful display, or even use, of instruments of the past.

Whether or to what degree historical-investigative approaches will be disseminated and implemented widely is a matter of future research, as are the concomitant limiting factors or problems of such implementation. Scholars (Barab and Luehmann 2003; Höttecke and Silva 2011) have pointed out that teachers are the gatekeepers for any curricular innovation. Whether a wide and successful implementation will ever happen depends, at least in school science teaching, not only on the future design of curricular and standard documents but also on whether historical-investigative approaches actually will meet the needs and desires of science teachers. Therefore, materials for teaching and learning should be designed in a way that allows for a flexible and open use (Valk and Jong 2009).

Some of the above-discussed approaches explicitly refer to inquiry-based learning (Allchin 2012; Höttecke et al. 2012). From research regarding teachers' perspectives on inquiry-based learning, we already know that their general beliefs about successful science learning are linked to their beliefs about laboratory work and inquiry (Wallace and Kang 2004). Open-ended activities, which comprise discussions about scientific controversies or uncertain scientific evidence, will possibly alienate science teachers (Newman et al. 2004). Teachers often make detailed plans for instructional units which result in inflexibility in their reactions to students' ideas and products (Schwartz and Crawford 2004). This makes it a challenge to present science as inquiry or an open-ended activity (Roehrig and Luft 2004). The science teachers' expectation of having ready-made answers and safe content-knowledge (Höttecke and Silva 2011) may disincline them to accept historical-investigative approaches in science teaching. Science teachers need to know how to deal with new, emerging perspectives in the context of NOS. They should be able to organize open-ended investigations and moderate student-centered discussions. In general, they have to develop specific professional repertoires for teaching NOS successfully within any of the historical-investigative frameworks. Whether or not they succeed will depend on their readiness and willingness to leave established trails of teaching science behind and on their future professional development for teaching HPS in science education. The design of teaching materials following any of the historical-investigative approaches has to consider these conditions when planning for and establishing their successful implementation.

Peter Heering is professor of physics and physics didactics at the University of Flensburg, Germany. He completed his habilitation in history of science at the University of Hamburg in 2006, earned his Ph.D. in physics education and history of physics from the University of Oldenburg in 1995, and was initially trained as a teacher for physics and chemistry. His research interests include the history of scientific experimentation, the relation between research and educational experiments, and the implementation of history of science in science education. Among his recent publications are Heering, P., and Wittje, R. (Eds.) (2011), *Learning by doing: experiments and instruments in the history of science teaching* Stuttgart: Steiner, and Heering, P. (2010), An Experimenter's Gotta Do What an Experimenter's Gotta Do – But How? *ISIS*, 101(4), 794–805.

Dietmar Höttecke is a professor for physics education at the University of Hamburg, Germany. He earned his Ph.D. in physics education and history of physics from the University of Oldenburg in 2001 and is trained as a teacher for physics and German language and literature. His research interests include applications of history and philosophy of science in science teaching, nature of science in science education, judgment and decision-making in socioscientific issues, education for sustainable development, and science teachers' professional development. Among his recent publications are two papers about problems and solutions of implementing history and philosophy of science in science education: Höttecke, D. and Silva, C.C. (2011), Why Implementing History and Philosophy in School Science Education is a Challenge – An Analysis of Obstacles. *Science & Education*, 20(3–4), 293–316 and Höttecke, D., Henke, A., and Rieß, F. (2012), Implementing History and Philosophy in Science Teaching – Strategies, Methods, Results and Experiences from the European Project HIPST. *Science & Education*, 21(9), 1233–1261.

Chapter 47
Science Teaching with Historically Based Stories: Theoretical and Practical Perspectives

Stephen Klassen and Cathrine Froese Klassen

47.1 Introduction

In recent decades, a trend has evolved in educational literature that emphasizes the potential of narratives, especially the story, to improve teaching and learning.[1] These studies approach the subject from both a methodological and theoretical perspective. Their authors purport that science stories illustrating the related abstract concepts engage and motivate the learner emotionally and intellectually. Further to that, this chapter examines the nature and structure of the science story and its capacity to provoke certain kinds of student responses that promote the learning of science. Historically based stories, in particular, promote the desired student interest and motivation by presenting humanistic episodes that explicitly include scientific content.[2]

The reasons for incorporating stories in teaching are summarized by Noddings and Witherall, who assert that

> we learn from stories. More important, we come to understand—ourselves, others, and even the subjects we teach and learn. Stories engage us. … Stories can help us to understand by making the abstract concrete and accessible. What is only dimly perceived at the level of principle may become vivid and powerful in the concrete. Further, stories motivate us. Even that which we understand at the abstract level may not move us to action, whereas a story often does. (Noddings and Witherell 1991, pp. 279–280)

Well-constructed and effective stories stimulate students' imagination and, thereby, produce affective engagement during learning episodes. The motivating effect and the vivid and powerful perceptions of stories take place largely at the

emotional level, which is an insight in education that has only recently been explored. Yet, it has, likely, always been apparent to good teachers that stories make learning experiences memorable. The story approach originated within a general educational perspective and has, subsequently, been adapted for use in science education.

This chapter is about stories in science teaching and learning that are, at least initially, in written form and may be communicated to students in that form or narrated by a teacher or student. As readers will appreciate, the task of writing an effective story is a highly technical and challenging creative undertaking which is not the forte of every science teacher or educator. Before such writing can be carried out, the ambiguities that exist in the use of the terms "narrative" and "story" as applied in the science education context must be examined and removed. The terms "story" and "narrative" in this context are used in the literary sense and not in the broad, generic, and undefined sense that prevails in common usage.

There is significant evidence supporting the effectiveness of science stories to improve learning, and appropriate methods exist for integrating them with instruction systematically. The model of the story as the reenactment of a type of learning process and the role of the story in generating a romantic understanding of science are two pedagogical bases supporting the story approach. While stories serve, among other functions, to improve student motivation, the elaboration of theories and research on student engagement, motivation, or interest are beyond the scope of this chapter. The story form that is elaborated contains science concepts and, at the same time, emphasizes the humanistic dimension of science—an indispensible element of such stories and a critical feature of the only two empirical studies undertaken in this area to date. The humanistic aspect requires the incorporation of the historical accomplishments of notable scientists, necessitating the use of history of science to form the basis of the science stories. Stories need to be reasonably faithful to nature of science criteria, which is a reason for using history-of-science cases as the background for stories.

This chapter deals with stories that are historically based, as opposed to strictly fictional stories, in accordance with most of the literature in the field. The discovery of a good historically based story is like the discovery of a hidden treasure. Perhaps, the fascination for students arises from the romance of far-removed events with participants who had the same kinds of hopes, dreams, and struggles as we, and yet, in a very different environment. Good teachers often employ such stories in their teaching. They have found, like Swiss science educator Fritz Kubli, that "bare bones do not make an appetizing meal" for students (Kubli 2005, p. 520). Historically based stories (sometimes called "cases") are a valuable, some would say essential, part of providing a rich and diversely connected context for student learning.

Early theoretical work on stories has, to a large extent, centered on explaining why stories are expected to make learning experiences memorable. Some studies have focused on the idea that stories stimulate an emotional response in the listener or reader (Egan 1986, 1989a, b; Miall and Kuiken 1994). Others have argued that the story is a device that imposes coherence on a set of events (Kenealy 1989), which makes it a suitable vehicle for the integration of history of science in science instruction. The inclusion of historically based stories in science teaching has been advocated and attempted by a growing number of science educators.[3] Recently, a theoretical foundation for the use of narratives in the science classroom has been developed.[4] Yet, the observation of Bruner, in (1986), that "in contrast to our vast knowledge of how science and logical reasoning proceeds, we know precious little in any formal sense about how to make good stories" (p. 14) still rings disturbingly true today. This work is, in some sense, a response to the 25-year-old lament of Bruner.

47.2 An Overview of the Literature

A review of the scholarly literature on the theoretical basis, desirability, and use of stories (and narratives in general) in science classrooms over the past 15 years reveals that surprisingly little work has been done in this area (see Table 47.1). The list includes all relevant, peer-reviewed papers published in scholarly journals that deal with what are purported to be science stories, as opposed to other narrative forms. Not included in the list is the paper by Tao (2003), who used comic strips based on various historical "stories."

Bruner's early observation concerning how little was known about creating good stories was followed with his recommendation a decade later that we "convert our efforts at scientific understanding into the form of narratives" (1996, p. 125). In the literary field, "making good stories" is a matter of course, but this is not so in science education. The literature search yielded only 18 scholarly papers—which we categorized as advocacy, theoretical, descriptive, exemplar, or empirical—that have been published since Bruner's 1996 recommendation. Table 47.1 reveals that the literature on the use of stories in science teaching has been sparse up until 2005. Thereafter, the publication rate has increased, although not to a dramatic extent. Much of the literature is theoretical in nature, attempting to establish the features of stories that will likely contribute to their effectiveness in teaching science content and the nature of science. It describes instances in which stories and narratives have been used in classrooms but without a rigorous analysis of their success. In some cases, the literature is more explicit in describing the use of stories and includes the actual story used in the classroom, serving as an exemplar of the approach. The study of Negrete and Lartigue (2010) presents data of students' performance after listening to what the researchers call "stories" in comparison to factual summaries of the science content. The data, however, serve only to establish a rating scheme for the effectiveness of stories, the "stories" themselves being excerpts of much longer popular science writings that were not written to portray science in the sense being discussed here.

[3] For example, see Kenealy (1989), Klassen (2009a), Kubli (1999), Martin and Brouwer (1991), Stinner (1992), and Wandersee (1990).

[4] For example, see Avraamidou and Osborne (2009), Klassen (2010), Kubli (2001), Metz et al. (2007), and Norris et al. (2005).

Table 47.1 A listing and summary of scholarly publications on the use of stories in science teaching

Author(s)	Year	Type	Summary
Hadzigeorgiou, Klassen, and Froese Klassen	2012	Empirical	Presents the romantic understanding framework for science stories and a quasi-experimental study demonstrating significant advantages for student learning about ac electricity through the story of Nikola Tesla
Clough	2011	Descriptive	Describes the process of developing 30 historical short stories
Klassen	2011	Exemplar, descriptive	Presents the design of a historical story surrounding the photoelectric effect and describes its use in the classroom
Klassen	2010	Theoretical	Presents a theoretical description of the linkage of the science story to a type of conceptual change
Kokkotas, Rizaki, and Malamitsa	2010	Descriptive	Presents the theoretical basis and describes the classroom implementation of a historical story on electromagnetism that yielded positive results described through examples of student journal entries
Negrete and Lartigue	2010	Theoretical, descriptive	Presents an evaluation scheme for using science stories with a brief description of a classroom study using stories
Avraamidou and Osborne	2009	Theoretical	Presents a case for the use of narrative in science education as a way of making science meaningful, relevant, and accessible to the public
Klassen	2009a	Theoretical, exemplar, empirical	Develops a basis for writing historical science stories along with an example, its use in a classroom, and the results in terms of student-generated questions
Isabelle	2007	Descriptive, exemplar, advocacy	Describes a classroom study teaching through a story and recommends the strategy to teachers, although not discussing demonstrated benefits of the case at hand
Klassen	2007	Exemplar, descriptive	Describes the design and classroom use of a historical story surrounding the first Atlantic cable
Metz et al.	2007	Theoretical	Presents a basis for constructing and using stories in science teaching
Hadzigeorgiou	2006	Descriptive, exemplar	Discusses the potential of stories in teaching and learning physics and presents a historical planning framework for teaching current electricity
Kubli	2006	Theoretical	Presents a basis for effective use of storytelling in the science classroom
Norris et al.	2005	Theoretical	Presents a discussion of the problems and potential of using science stories with explanatory content and the theoretical basis of such stories
Solomon	2002	Theoretical, advocacy	Illustrates types of science stories that might be used and their purposes
Kubli	2001	Theoretical	Presents a theoretical basis which science teachers can employ to become better storytellers
Milne	1998	Theoretical	Discusses the assumptions behind certain perspectives contained in stories and the desirability of these perspectives
Knox and Croft	1997	Descriptive	Describes the use of story in a meteorology classroom with positive responses from students but did not demonstrate learning benefits

All of the literature listed in Table 47.1 utilizes or advocates historically based stories, with the exception of Avraamidou and Osborne (2009), who advocate for stories that are exclusively fictional. All of the exemplars or empirical studies are historically based.

While some of the papers overlap between or among the designated categories, as outlined in Table 47.1, overall, ten of the papers are theoretical, eight descriptive (with or without exemplars), and only two empirical. Five papers include exemplars. With the exception of Hadzigeorgiou, Klassen, and Kubli, researchers have not pursued their initial study with further research in the area. The table reflects the movement towards empirical approaches, which is vital in the development of this research area. The two empirical studies are summarized in greater detail below.

47.2.1 Empirical Studies Utilizing Stories in Science Teaching

The 2009 study of Klassen (2009a) presents a literary framework for the construction of stories that is based on Norris and coauthors (2005) and Kubli (2001). A story about Louis Slotin and the beginnings of the science of radiation protection is presented as an exemplar, and a classroom study utilizing the story as a door opener for an experimental investigation is described. Student responses to the story were gathered in the form of student-generated questions at the end of the story. Klassen sees a major purpose for using door-opening science stories as raising questions in students' minds. Not only is the raising of good questions important from a constructivist, pedagogical point of view, but also there is reason to believe that questions are implicitly involved in theory formation. Therefore, evidence for the generation of good questions as a result of listening to the story would serve as a major indicator that stories tend to enhance learning. The data presented in the study support the conclusion that good questions were, indeed, generated as a response to the story. The largest number of questions were of a type that suggested higher-level thinking, rather than simple, factual ones typically introduced by the interrogatives "when," "where," and "who." There was, however, evidence that the students were inexperienced with generating well-framed questions, as indicated by a number of questions which appeared, on the surface, to be polar questions (requiring "yes" or "no" responses).

Hadzigeorgiou, Klassen, and Froese Klassen (2012) provide details of an empirical study utilizing a story, based on Nikola Tesla's life and work, that was written to embody the elements of romantic understanding (see Sect. 47.5.2 for elaboration of romantic understanding) in order to teach the concepts of alternating current electricity. The study design was quasi-experimental, with the experimental group of students ($n=95$) only listening to the Tesla story and the control group ($n=102$) receiving conventional instruction with the mastery-teaching technique. Both groups were given the same open-ended, paper-and-pencil concept test on alternating current electricity. All students were encouraged to make journal entries.

The authors determined that the students who were encouraged to understand the concept of alternating current romantically—that is, through the story—became more engaged with the science content compared to students who were taught explicitly by conventional instruction. A quantitative analysis of students' journal entries revealed that of the students in the experimental group, 96 % made relevant journal entries, whereas only 55 % in the control group did so. Some of these students also demonstrated imagination and curiosity in their journal entries, which was not observed in the control group. Additionally, they undertook relevant independent research on their own initiative, which was indicative of the transformative effect of the storytelling instruction. This was a notable difference from the students in the control group who did not undertake any related reading outside of class, according to the analyses of the teachers' observations. The results also affirmed the effectiveness of teaching alternating current electricity through the Tesla story in the statistically superior concept-test results of the experimental group over the control group. Data on the question requiring an explanation of the concept of alternating current, for example, showed that 72 % of the experimental group versus 41 % in the control group gave an acceptable response. When the test was repeated 8 weeks later, 67 % of the experimental group versus 31 % in the control group gave an acceptable response, suggesting not only superior understanding but also greater long-term retention. A content analysis of the student journals of the experimental group revealed that at least two characteristics of romantic understanding were identified in all journals and that two thirds of the students in the experimental group made associations with the science content in their demonstration of the characteristics of romantic understanding.

The authors conclude that

> [t]he implication of this study for science education is that a particular type of a science story, that is, a romantic story, has significant potential for improving learning in the discipline. Such a story should be based upon human qualities, heroic or otherwise, that evoke wonder and give students the opportunity, through the plot, to associate science content with such qualities and simultaneously experience a sense of wonder. (Hadzigeorgiou et al. 2012, p. 1134)

47.3 Explication of Key Concepts: Narrative, Story, and Science Story

Narrative is a humanistic mode of expression that has as its core purpose the recounting of related events involving characters. In the most elementary sense, a narrative tells of someone having done something. Traditionally, narrative has been distinguished from exposition, description, and persuasion, which are other modes of communication (Connors 1981). Various scholars have used the terms "narrative" (Kubli 1998; Martin and Brouwer 1991), "story" (Egan 1989b; Kenealy 1989; Kubli 1999; Stinner 1995), "thematic" (Holbrow et al. 1995), or "storyline" (Arons 1988; Coleman and Griffith 1997; Stinner 1995) to describe their approach in using this mode in science teaching. The narrative approach has a spectrum of possible adaptations, ranging from the smallest stand-alone story element, such as the vignette

(Wandersee 1992) or anecdote (Shrigley and Koballa 1989), to the largest story-like structure, such as a curriculum unit unified by a theme (Gorman and Robinson 1998; Holbrow et al. 1995) or storyline (Coleman and Griffiths 1997; Stinner and Williams 1998). These various proposed approaches, other than the story itself, have not been put to the test in formal research studies and will not be elaborated in this chapter. There is no recent science education literature describing the use of other forms of narrative. Some time ago, Shrigley and Koballa (1989) described the anecdote and Wandersee (1990) described the vignette and its use in science teaching. Neither of these two forms was developed any further in the literature nor studied through research.

The notion of narrative is broad, and the term does not have a categorical definition in the literature, in contrast to the literary notion of story. Moreover, in the narratological literature, it is not distinguished clearly from the act of storytelling, which is intricately connected to voice, narrator, and other oratorical devices. For reasons such as these, the discussion in this chapter, of necessity, has certain delimitations. The first of these is the definition of "narrative" itself. The literature on narratives is complicated by theorists using varying terminology for similar concepts, making the task of definition challenging. Specifically, the terms "narrative" and "story" are frequently used interchangeably and then either not defined or defined in a way that is not adequate for application in a particular context. To aid in the sorting out of related and, possibly, conflated terminology, the core constituents of narrative, namely, its "raw material," will be distinguished from the delivery of narrative material, the reception and personal reconstruction of narratives, and the specific ways and contexts of using narrative material. Defining narrative in terms of core constituents has the added benefit of providing a "litmus test" for educational material that claims to be "narrative." The definition of narrative constructed here incorporates the insights of Altman (2008), who presents a particularly succinct history of narrative definitions and divides the definition of "narrative material" (p. 10) into categories.

Whereas the concept of "narrative" is broad and generic, the concept of "story" has specifically defined attributes. In concurrence with Altman (2008), this chapter makes a distinction between "some" narrative and "a" narrative (p. 17), in that "some" narrative is a narrative excerpt and "a" narrative is a complete narrative episode with a beginning, middle, and ending—one of the special requirements of a story. In this chapter, the term "story" is not used in the generic and loose sense, as in popular and even in some scholarly literature, but in its defined sense that is identified with a specific literary form. Such a story also requires a central role for the main character, who is involved in some type of conflict that compels him or her to make a critical decision, which, ultimately, determines the outcome of the story.

The definitions of narrative and story presented below additionally make use of the insights of Klassen (2009a, 2010), Kubli (2001), and Norris and coauthors (2005) but utilize only elements and characteristics that are essential for the construction of narrative on the part of the teller or writer, as opposed to its reception or its expression in particular settings or for particular purposes. In this respect, the definitions are, of necessity, based on structuralist approaches to narrative—an insight which is crucial for the operationalization of narrative theory in the science education context and which has heretofore not been recognized by researchers attempting to formulate a definition of narrative or story.

47.3.1 The Concept of Narrative

In view of the considerations presented above, narratives have five fundamental elements, as outlined below, in some instances with illustrations. Since stories constitute a class within the narrative genre, the aspects of narratives apply equally well to stories. The purpose of presenting a definition of narrative is not only for clarification but for subjecting writing that purports to be narrative, or even story, to a criterion-based test that can ascertain whether it can, justifiably, be characterized as a narrative. For writing that consists, for example, of a mixture of narrative and exposition, it would be relatively easy and uncontroversial to analyze the text sentence by sentence for its degree of narrativity. While a narrative does not necessarily contain all of the elements of a specific class of narratives, such as the story, it must, by definition, include the features of characters, actions, situations, consequential coherence, and past time.

47.3.1.1 Characters

The most basic element of any narrative is that it involves at least one character who is the representation of a person or persons. In historically based science stories, the characters are real people (usually scientists), and their story is a form of historical interpretation. Altman (2008) points out that while some definitions of narrative have omitted the role of characters and concentrate, instead, on the events which give rise to plot, characters are essential and central since they are the agents that produce the action.

47.3.1.2 Actions

The actions of the characters, sometimes called “events,” are the “raw material” of the story, but, by themselves, they produce only chronologies that lack interest; they are not narratives. In historically based narratives, the actions of the characters are obtained from the historical records. Agency, of necessity, creates a personal dimension; therefore, it becomes necessary to attribute thoughts or spoken words to the protagonist, especially. The preferable method of obtaining such expressions is to adapt them from writings of that person or other relevant historical records. If thoughts or spoken words not obtained from the historical record are added for effect, these must not contradict the history.

> *Example:* Eighteen-year-old Alessandro Volta was passionate about electricity, indeed so passionate that he announced to his somewhat startled family, "I'm not going to university! I would rather spend my time on investigating electrical phenomena."[5] Alessandro's family was used to his surprising turns.[6] As a child, Alessandro had not learned to speak until he was age four, which had led his alarmed parents to think that he might be slow-witted, but then little Alessandro suddenly began to develop at a furious pace, out-performing all his school mates.[7] In his father's words, "We had a jewel in the house and did not know it!" And so, at age eighteen, the gifted young Volta launched into a scientific career by beginning to write to the leading scientists of the day about his ideas, and, surprisingly, they replied. (Klassen 2009b)

In the above example, all of the details are historically accurate or plausible. The words attributed to Volta are plausible based on the record. The words attributed to Volta's father are a part of the historical record explicitly.

47.3.1.3 Situations

Narrative has situations or states insofar as the character responds to them or helps to create them. The situational aspects of narratives that represent a state of affairs or a state of being are often not separable from the actions from which they result. An example extracted from the story "The Soul of Solar Energy: Augustin Mouchot," written by the authors, is given here. The first segment ends with a state of being, followed by an action, followed by a changed state of affairs in the last segment. The situational sentences are italicized.

> As Augustin arose in the chill of the dawn, his thoughts drifted to what he had just been reading about the energy of the sun. Physicist Claude Pouillet had written that every square meter of the Earth's surface receives about 10 Calories of energy every minute. Augustin chuckled, "Not a very useful fact on a cloudy day like today!" Then, a flash of inspiration crossed his mind: "It's not cloudy every day. Wouldn't it be possible to heat enough water with the sun's light and spare the fire that is only meant to heat the house?" *While he made the last preparations to teach his geometry class, he could not get his mind off the energy issue.*
>
> …
>
> Over the next few months, Augustin immersed himself in his new project of building a solar energy collector despite having to teach his regular classes.
>
> …
>
> *Soon, Augustin had completed the construction of his first solar water heater, which was capable of holding three litres of water.* Lucky for him, it happened to be a cloudless day! Excitedly, he placed the boiler and mirror in the direct sunlight. To his amazement, the water, which he had initially measured to be 15 degrees, boiled in just an hour and a half. From then on—on sunny days—Augustin saved himself the bother and the expense of coal-heated water when he bathed. (Klassen and Froese Klassen 2012, italics not in original)

---

[5] The discourse is imaginary but plausible.

[6] A reasonable assumption, based on the historical record.

[7] Part of the historical record (from here to the end of the segment).

Fig. 47.1 The causal structure of a story (From Klassen 2010)

47.3.1.4 Consequential Coherence

As mentioned above, by themselves, the actions of the characters produce only chronologies, which lack interest. They are neither stories nor narratives. Narratives and stories require that the events be causally linked (see Fig. 47.1 for a representation of the causal structure of a story). The story is written in such a way that it is clear that the actions of the characters produce the changes in the state of affairs. Besides the fact that the events of the story follow one another in time, it is especially the causative linkage of events that produces the perception of the flow of time. Of course, the entire story need not be structured in a strict chronological sequence, as the story might contain flashbacks and flash-forwards; however, it must have a consequential sequence.

> *Example of a chronology without consequential coherence:*
> Ohm took up a teaching position in Cologne;
> he performed an experiment to determine resistance;
> and he published his experiment.
>
> *Example of a passage with consequential coherence:*
> Ohm understood the mathematical theory of heat;
> he applied the theory to electricity by analogy;
> and as a result, Ohm understood the mathematical theory of electrical resistance.

47.3.1.5 Past Time

The events of a story take place in the past and are recounted. The science-based story is historical, and it would be a contradiction in terms to write it in the present tense. Use of the present tense is reserved for other modes of communication, for example, exposition.

47.3.2 Science as Historical Narrative

The scientific work done and the results achieved by investigating scientists have to be communicated to other scientists. Their results cannot readily be separated from the experiments that were undertaken. The carrying out of experiments is a human endeavor, replete with false starts, errors, and frustrations. This phenomenon significantly increases the potential for historical narratives to supplement the published results in the scientific literature. R. G. Collingwood (1945) has carried this line of reasoning further by claiming that history is, in fact, a more fundamental form of thought than the science about which it reports. He writes that

> the scientist who wishes to know that … an event has taken place in the world of nature can know this only by consulting the record left by the observer and interpreting it, subject to certain rules, in such a way as to satisfy himself that the man whose work it records really did observe what he professes to have observed. This consultation and interpretation of records is the characteristic feature of historical work. … I conclude that natural science as a form of thought exists and always has existed in a context of history, and depends on historical thought for its existence. (Collingwood 1945, pp. 176–177)

What Collingwood describes about scientific work appears very much like the process of historiography. Yet, current-day scientific publications usually exclude the human dimension of the work that brought about certain scientific conclusions or theories in science. In that sense, scientific publications are a specialized, rational reconstruction of history. Perhaps, it would not be an exaggeration to say that science has become a form of dehumanized and decontextualized history. An attractive method of interesting the disinterested young student in science is to portray it differently—more realistically, from the human and contextual perspective as a specialized narrative or story.

It is important to emphasize that historical chronologies, by themselves, are not narratives, as they have no causal structure. In the absence of clearly defined criteria, such as causality, many of the terms in the scholarly literature, such as thematic approach, storyline, vignette, anecdote, or story-like structure, must be subjected to closer scrutiny. The existence of this definitional vagueness emphasizes the importance of establishing a “litmus test” for both narrative and story, in order to produce a standardized vehicle for the delivery of narratives and stories and for the purposes of research. The definitions that have been given above may be taken as such a litmus test.

47.3.3 The Concept of the Science Story

The essential elements of a story include those of narratives that have been described. Two further components are necessary to create the classification of story within the broader narrative form, namely, a defined plot structure and agency—the critical choice made by the protagonist. The science story, a classification within the class of story, includes an additional element, namely, science and NOS content. Aspects of narratives or stories that are specific to their method of delivery or to their reception by the listener or reader, while potentially important for the effectiveness of the story, are not considered as core constituents in its written form.

47.3.3.1 Plot Structure

The plot structure of a story consists of a beginning-middle-end structure that frames the story and creates a stand-alone unit. In general, the story structure typically includes an introduction, rising action that includes some sort of conflict, a climax, and a resolution or conclusion. In the conceptualization and construction of the story, planning the plot is crucial and involves a creative interpretation of the history that identifies fascinating elements in the record and combines them with the relevant science. Planning a plot requires selecting historical details to form a coherent story. Specifically, a typical plot (a) begins by "setting the scene" in some manner, (b) followed by the presentation of a problematic situation (c) which reaches a crisis, (d) necessitating a critical decision made by the main character (e) that results in a climactic moment, and (f) concludes in a resolution of the situation, which can be either positive or negative.

47.3.3.2 Agency: Critical Choice Made by the Main Character

In a story, the role of the main character is crucial and will affect the outcome of the story through a consequential, critical choice that he or she has made. Crucial choices are integral to the typical plot structure as outlined above.

> *Example:* Grabbing the hemispherical beryllium shell by the thumb-hole on the top, Lou carefully lowered the top half onto the bottom half covering a hemispherical plutonium shell, which, in turn, covered the polonium initiator, holding them apart with a screwdriver. As he rotated the screwdriver slightly this way and that, the shell moved up and down. From across the room the familiar crunching sound of the Geiger counters swelled and ebbed. Then it happened. No one knows what broke Lou's concentration, but something did. The screwdriver slipped and clattered to the floor and a blue flash filled the room as the top shell touched the bottom, releasing a torrent of neutrons and gamma–rays. Time seemed to come to a screeching halt. Almost instinctively, Lou, using both hands, grabbed the lethal assembly and flipped the bomb-shell off the table and onto the floor with what seemed a deafening crash. "Well, that does it—I'm dead!" Lou heard himself say. "Tell me this is a nightmare," he thought. *But it wasn't.* (Klassen 2009a, p. 421)

47.3.3.3 Science and NOS Content

The scientific aspects of the historical episode that are contained in the story should be embedded at the appropriate points in the story in such a way that they flow naturally with the story. In some cases, it will be possible to include the scientific concepts developed sufficiently to allow students to comprehend them fully. In other cases, the scientific questions and issues will be included as questions, issues, and problems which need to be developed more fully in activities that follow the story. Such content should be included from the perspective of the characters of the story and be interwoven in a narrative manner as much as possible.

Similar considerations reflect the NOS issues that are contained in the story. Sometimes these issues may be stated explicitly in the flow of the story, and at other times, these will be raised more indirectly and will need to be followed with a student activity that will focus on the issue and clarify it. The following example is taken from the story used for the experimental intervention in Hadzigeorgiou and colleagues (2012) (the reader is referred back to Sect. 47.2.1 for a description of the study):

> *Example of embedding science content:* In an attempt to demonstrate the dangers of AC power, Edison sponsored an electrical engineer to travel the country electrocuting animals with both DC and AC. Because the frequency of AC confuses the heart, animals that are electrocuted by AC die, whereas animals that are electrocuted by DC are stunned but survive. Edison used these so-called "experiments" to contrast the danger of AC with the relative safety of DC. We know that the effect of any type of electric current on a human being is very difficult to predict, as it depends on a number of factors (for example, the condition of the skin, amount of fluid in the body, and the point of contact). Tesla, however, had been experimenting with very high frequency currents, which, as he, showed, did no harm. With his theatrical flair, Tesla could draw sparks to his own fingers and even walk through sparks without being hurt. He had realized that the high frequency of the current kept it on his skin. It was this strange effect, known as the skin effect, which made Tesla famous. He even sent sparks to the audience, making people realize that AC current, at least as used by him, was safe. (Hadzigeorgiou, Froese Klassen, and Klassen 2011)

47.4 The Non-scripted and Scripted Approaches to Using Stories

The story approach in teaching science, as described in this chapter, is based on the use of science stories that are constructed according to the concept outlined above. What is not included in this approach is that of the non-scripted story, told spontaneously, randomly, and, perhaps, frequently. In the story-permeated approach—the spontaneous injection of non-scripted narratives—the narratives may range from a recounting of the teacher's experiences to anecdotes that may or may not pertain to curricular content or concepts. Teachers who use stories in this fashion must have expertise not only in the telling of stories, but they must have a wide repertoire of good story material at their disposal. Such an approach is largely informal and more difficult to fit into a definitive framework than the scripted-story approach. Because of the number of uncontrolled variables, this approach is virtually beyond the scope of research studies.

The scripted-story approach—the formal, planned integration of scripted stories—pertains specifically to the curricular concepts taught. Particularly teachers inexperienced in storytelling and lacking a repertoire of science-story material can enhance their instruction with the scripted-story approach. Scripts allow for a measure of structure, which is not necessarily the case for spontaneously injected narratives. The distinction between the two vehicles is fundamental to each approach for integrating narratives and stories in science instruction. A "narrative," as already defined, consists of the recounting of actions produced by characters, while a story is more rigidly defined by its structure—that the events that happen, revolving around the protagonist, must be interrelated and consequential (i.e., have a consequence for the protagonist and, possibly, others).

Both of these approaches also concern the act of storytelling itself. This chapter deals primarily with story *crafting*, as opposed to story *telling*. The latter consists of the performance aspect of storytelling where the narrator becomes the performer and requires proficiency in the relevant performance art. While it is indisputable that the manner in which the story is told plays a vital role and is certain to influence the students' level of enthusiasm and possible engagement with the story, it is not within the scope of this discussion to deal with the oral presentation of stories as it is presented in the literary or theatrical tradition (learning how to become an effective storyteller, both in terms of retelling existing stories and spontaneously creating new stories). For the storyteller of the spontaneously injected narrative, the challenge of telling the story from a first-person participant perspective is enormous, especially when coupled with the fact that this method, when dealing with historical information, already presupposes expert knowledge of the history of science on the teacher's part. Conversely, the planned injection of scripted stories demands that the teacher must become aware of the existence of available science stories that pertain to particular science concepts and be able to integrate them meaningfully and strategically. This can be performed by a novice teacher.

Both the story-permeated and scripted-story approaches share a facet of the narrative act that is largely beyond the control of the teacher, other than that he or she may provide the stimuli for it, and that element is the inner narrative taking place in the student's mind in response to any new learning from the narrative itself or the embedded concepts. This inner dialogue is affected by the manner in which the story is told or read and may influence the level of student engagement and learning. The inner dialogue, which may focus on the storytelling act alongside the story, is complex, spontaneous, and beyond the storyteller's control.

47.5 Theoretical and Pedagogical Reasons for Using Stories

There is good evidence that in order to engender meaningful learning, it is essential that teaching and learning methods be imbedded in appropriate contexts (Kenealy 1989; Martin and Brouwer 1991; Roth and Roychoudhury 1993). Historical contexts address the "why" and "how" aspects of the development of science in a way that includes the scientists as living persons who are concerned with personal, ethical, sociological, and political issues. It is generally accepted that this form of presentation is likely to engender increased motivation in students. Such historical materials must not consist of mere chronologies but rather expose the settings in which discoveries were made in the form of stories (Stinner et al. 2003; Metz et al. 2007). The use of stories to teach science has both theoretical and evidential support apart from the contextual argument.[8] It is the literary story form, in particular,

---

[8] See Egan (1986, 1989a), Hellstrand and Ott (1995), Kubli (2005), Miall and Kuiken (1994), and Norris et al. (2005).

that is known to produce consistent affective engagement (Miall and Kuiken 1994). This engagement also has a physiological basis. According to Miall and Kuiken, narrative techniques in the literary story "accentuate… activity in cortical areas specialized for affect" (1994, p. 392). The literary story adheres to the normal considerations in literature while making use of scientific and historical materials for its construction. Teachers who use such stories hope to capitalize on affective arousal in the form of increased student motivation.

The important role of the emotions in learning has been recognized only recently. Relevant, in this regard, is the research of neurobiologist Antonio Damasio on emotion and rationality. Damasio studied human subjects who had lost the ability to communicate information about emotions from one part of the brain to the other. He was able to support his hypothesis concerning the relationship between emotion and reason, which states that the emotions act as an arbitrator in rational decision-making and that without access to one's emotions, it is impossible to plan and make rational decisions (Damasio 1994). Educator Douglas Barnes demonstrates, in a research study of student group learning, that "unless pupils are willing to take the risk of some emotional commitment they are unlikely to learn" (1992, p. 87). Cognitive psychologist Pierce Howard, in a popular review of current neurobiological research, further explains the role of emotions in learning this way: "Experience arouses emotion, which fixes attention and leads to understanding and insight, which results in memory" (Howard 2000, p. 549).

At issue is the means by which emotion could be aroused in an appropriate manner in the teaching and learning situation. It is well established that stories have the ability to engage the emotions. Educator Kieran Egan (1989a, b) has long advocated the story form as the principle method of engaging students' emotions. Egan argues that the presentation of curriculum content through stories stimulates the imagination and evokes emotional response, thereby producing learning that more easily assimilates with long-term memory than learning produced by drilling and memorizing. The listener or reader engages with the story because she or he is encouraged to participate vicariously in the experiences of the protagonist. The kind of motivation produced by story is intrinsic, as opposed to the extrinsic motivation produced by a prescriptive teaching and learning episode (Mott et al. 1999). The story also provides an organizing structure for related knowledge and experiences (Mandler 1984).

47.5.1 Story as Reenactment of the Learning Process

It is noteworthy that the causal relationship of elements in a story (Fig. 47.1), which was described in Sect. 47.3.1.4, is structurally analogous to that of a type of conceptual change in the learning process (Fig. 47.2) (Klassen 2010). The schematic representation of conceptual change of Fig. 47.2 elaborates a temporal learning episode. The evolution of an event such as a scientific phenomenon (the learning episode) begins with the observation of the properties of the object (or entity) in question—the original state. The learner then observes a change in the state or properties of

Fig. 47.2 A temporal framework for conceptual change (From Klassen 2010)

the object. The enigma in the learning process is that the learner does not know ahead of time what the final state will be. There are unseen properties of the situation that resulted in or contributed to the change in state. Curiosity or the need to uncover and explain such hidden properties initiates the learning process. Provided that there is sufficient motivation, the learner will attempt to construct explanations for such unanswered questions, usually through a process of reenactment of the event on the basis of some explanatory mental model. The process can, for example, be applied to the experiment of Ohm and his subsequent attempt to explain it:

> The deflection of the magnetometer on Ohm's apparatus indicated a particular resistance to the flow of electricity;
>
> then a different length of wire was inserted into Ohm's apparatus;
>
> as a result, the deflection of the magnetometer on Ohm's apparatus indicated a different flow of electricity.

The process here consists of two experimental observations (states) with the experimenter's intervention between them. Experimental intervention often proceeds by an adjustment of one of the parameters. In order to construct a theoretical expression to explain his observations, Ohm wrote an equation that he already had good reason to believe explained the observations. Ohm replayed his series of experiments on paper by first assuming that the current flow through the wires was analogous to the flow of heat, which he understood. As the historical record shows in Ohm's own words (Magie 1965), Ohm was able to reproduce his experimental results by recalculating his model with the parameters set at suitable values, showing that his explanation was a good one. In this way, Ohm justified his theory. Ohm's method can be viewed as the process of reenactment of his theoretical expression using suitable parameters that resulted in a reproduction of the experimental observations. Clearly, the minimal story sequence of Fig. 47.1 is followed; however, the usual requirement that a story involve the state of a human agent is not met. What changes in the case at hand is an experimental observation. Of course, when the subject of explanation is an abstract concept, then the involvement of human agents occurs at a secondary level.

Klassen (2010) shows that just as the story form consists of a temporal sequence, some of the learning involves a similar temporal sequence. The story form will be most useful for learning if it becomes a part of the sensemaking process and contributes to the formation of long-term memory structures. In Ohlsson's model of sensemaking (1999), the learning process includes the reenactment of remembered events in light of new knowledge. The story form can similarly be viewed as a reenactment of the cognitive process that would normally be involved in order to learn the story content. The story consists of the recounting of a chronology of events that includes causative links between succeeding events. Remembering, retelling, hearing, or reading a story will then serve as a form of mental reenactment.

The structure of a story is just one part of the design of a good story. Other features of stories are, for example, the effect of the untold, suspense, irony, and lifelikeness, which might be designated as the story's literary qualities. These features tend to stimulate the emotions of the reader or listener. An artistically crafted story arouses emotions that, in turn, contribute to the integration of the story details with long-term memory (Klassen 2010). A well-crafted story should, therefore, contribute to better learning of a variety of content knowledge items. This is what anthropologists have maintained all along. In the distant past, stories were used as the most effective device for passing on the culture to succeeding generations (Levi-Strauss 1966). In the context of learning science, there is good reason to utilize the story as a productive application of this enduring method.

47.5.2 Story as a Stimulus for Romantic Understanding in Science

As established in Sect. 47.2, relatively little has been written or researched regarding the construction of stories in regard to their relationship to effective learning. A notable exception is the learning theory of Kieran Egan that advances the concept of romantic understanding. Romantic understanding, which by definition takes place in a humanistic context, may be defined as the ability to grasp the meaning of the features of subject matter in a manner that tends to be idealistic in expectation and glamorously imaginary, possibly even exotic and involving the potential for heroic achievement. During the period of their development when they exhibit romantic understanding (approximately between ages 8 and 15), children are attracted, for example, to literary characters who do heroic, but possible, things.

Egan identifies five vital means by which children at this stage make sense of the world and of experience and by which they mediate between the world and the mind. These means, which he calls "cognitive tools," become the specific characteristics of romantic understanding. They are (1) the humanization of meaning, arising from the realization of the humanistic dimension of all knowledge; (2) an association (even identification) with heroes and heroic qualities; (3) a focus on and confrontation of the extremes and limits of reality and experience; (4) a sense of wonder; and (5) the contesting of conventions and conventional ideas.

Hadzigeorgiou and colleagues (2012), in order to reflect these tools and the instructional strategy in the concept itself, conceive of romantic understanding as "the motivating insight that emerges through the combined engagement of the emotions and the intellect in response to a specialized text" (p. 1114). The instructional strategy of the story is the "specialized text," which specifically incorporates the various cognitive tools.

The humanization of meaning in the story is a natural outgrowth of the fact that it is human endeavor which generates scientific knowledge and that human emotions are an integral component of its creation. The human element in the science content is incorporated through the scientist's life and work. In Tesla's case, for instance, it was his personal ambitions, his humanitarian ideals, his uncommon ingenuity, and his frustration with the establishment that together contributed to his ultimate achievements (Hadzigeorgiou et al. 2012). The resulting captivation with Tesla is rooted in his admirable character traits and abilities. It is this aspect with which students identify and which inspires them to emulate notable scientists because they come to understand that they, too, can develop such qualities as they conceive of new human possibilities through the story.

Students are further attracted to the stories because they exemplify the extremes of physical reality, whether they manifest in nature, the lowest temperature or the smallest electric charge, or in the human experience, the fastest athlete or the longest flight. These extremes, along with the many fascinating and mysterious phenomena and astonishing ideas that abound in science, evoke a sense of wonder. Through this kind of experience, students become aware of their incomplete or mistaken knowledge, helping them see the science lesson in a new light and emotionally charge the new information to be learned. Another source of fascination with the story arises from the fact that many scientists had to struggle against firmly held beliefs and ideas that stood in direct opposition to their new-found knowledge. When learning about the obstacles that scientists, such as Galileo, Boyle, Volta, Tesla, Einstein, and Marconi, faced and that they stood firm in their convictions, students can realize the strength of human convictions which bring the human element into the science content.

47.6 Constructing and Utilizing Stories

47.6.1 *Utilizing History as the Raw Material for Science Stories*

The writing of a story that is meant to utilize history of science cannot proceed without considering what interpretation of history is to guide the selection and adaptation of historical materials. History of science is subject to a broad spectrum of possible interpretations. One end of the spectrum is what Herbert Butterfield (1931/1959) called the Whig approach to history in which history of science is viewed in light of current knowledge. Implicit in this approach is the assumption that current knowledge is superior to the knowledge of past scientists. Critics of the Whig approach object to applying current days' standards to history because historical figures operated in a different environment from that of today, with different assumptions and standards. There are also internal histories of science written primarily by scientists, some of whom participated in the events about which they wrote many years later. The purposes of such histories are to legitimize the science, to aid in the socialization of novices, and to provide exemplars that will be used as

Table 47.2 An evaluative list of features for the construction of a science story

Character(s) taken from history of science
Actions that are consistent with the historical record
Situations or states
Consequential coherence of the characters' actions
Past time
Plot structure with rising action and climax
Critical choice made by the main character
Appropriate science and NOS content

models for problem-solving (Kragh 1987). Internal history often provides an official version of the roots of the discipline that tends to romanticize the events and portray science as an inevitable consequence of the force of progress. Exposing students only to this version of history encourages a distorted view of the nature of science, not to mention of the history, itself. The other end of the spectrum of approaches is the localized view in which history is interpreted only in light of the knowledge and context of the time and place in question. This approach, referred to as horizontal history by Mayr and diachronical history by Kragh, has been criticized on the grounds that history cannot be interpreted when comparisons to the larger context cannot be made (Kragh 1987; Mayr 1990). Furthermore, it has been claimed that purely diachronical history, consisting of a chronology of events restricted to the local context (Kragh 1987; Mayr 1990), is uninteresting to the nonspecialist.

For the purposes of writing a story to serve as an introduction to, or framework for, the teaching of a topic in science, aspects of all of the historical interpretations mentioned may be present to a certain degree. Certainly, the overriding consideration will be to portray the history accurately by using the best original and secondary sources. Any account must also be sensitive to the practices, beliefs, and social mores of the time, albeit, taking into account the limited identification with these on the part of current-day students. Any story arising from the history must be sensitive to such possible areas of misunderstanding by students, all the while not implying current superiority. Of course, the history of an event in the discipline that has been written for students of the discipline cannot help but provide some degree of legitimization and socialization. The goal is to portray scientists as human beings, "warts and all" (Winchester 1989, p. v), in order to give students the opportunity to become affectively involved in the story of science. Usually, the listeners to such stories will have a substantial degree of empathy for the protagonists of the stories.

47.6.2 Guidelines for the Construction of a Story

Story construction is a creative process and should not be formulaic or constrained by a fixed format; however, it must contain essential elements that meet the criteria for a story. A framework for the writing of a science story as described in this chapter should be guided by its characteristic features. The elements that were elaborated in Sect. 47.3 comprise an evaluative list and are summarized in Table 47.2. These can be taken as guidelines against which to judge any science story.

47.6.3 A Framework for Incorporating Stories in Science Teaching

In the case of science teaching, the type of instruction being described here corresponds to *contextual science teaching* (Klassen 2006). The contextual method is described, in detail, elsewhere (Klassen 2006) and is called the story-driven contextual approach (SDCA). A brief overview of the method and its framework will be provided here. Klassen identifies five important contexts that are a part of effective science lessons. These are the (1) practical, (2) theoretical, (3) social, (4) historical, and (5) affective contexts. Each of these contexts should relate, in some way, to the scientific concept being taught and contribute to the overall meaningfulness of the learning episode and to the degree of engagement of the students.

47.6.3.1 The Practical Context

The practical context provides hands-on, laboratory-style investigative activities for the students. Ultimately, the practical context is meant to replace traditional "labs" in the "normal science" curriculum. Students who are potential scientists benefit from practicing as novice scientists, since they are only one step removed from being apprentices. Even students who have no intention of becoming scientists benefit from participating in an authentic activity that includes creativity and some intellectual challenge beyond guessing what the lab manual wants.

47.6.3.2 The Theoretical Context

Each lesson should, if possible, also contain a theoretical element. Research or paper-and-pencil type questions that can be formulated in a brainstorming session after the presentation of a science story tend to be meaningful and memorable for students. Here students are challenged to answer conceptual "why" and "how" questions about the issues raised by the story. In a typical class, students should perform both practical and theoretical investigations.

The manipulation of ideas in the theoretical context is meant to replace paradigm exemplars of the type that students learn in normal science education. Normal science education relies heavily on end-of-chapter questions to provide student learning experiences. These problems are usually contrived and remote from students' life experiences. In contrast, problems in the theoretical context emerge as a natural necessity in the course of investigations. Ideas or concepts take on meaning as they are naturally generated by the context. The theoretical context, however, is dependent on the practical context to provide a well-rounded learning opportunity. As in the practical context, students are cast into the role of being novice researchers.

47.6.3.3 The Social Context

The benefit of cooperation in assisting learning is a relatively uncontroversial fact, and the ability to work together productively in small groups is a skill recognized by science curriculum developers. The benefits are likely to accrue not only in the form of improved learning of academic content but also in the learning of scientific and life skills related to social organization and leadership. In our context, making use of the benefit of cooperative learning requires careful attention to the structuring, organizing, and evaluating of group activities that are a part of the larger context. Working productively in groups is a developmental process which can significantly enhance the individual student's level of learning. It is possible for the social context to be applied to assessment by having group oral presentations to the entire class after they have completed their practical and theoretical investigations.

47.6.3.4 The Historical Context

The historical context is the basis of the science story, as discussed, in depth, above. It will portray science in a more realistic and humanistic light and make learning science a more attractive endeavor for most students.

In view of the preceding discussion, history of science that is to be used for pedagogical purposes must tread a fine line through the pitfalls of extremes that could conceivably arise in interpreting history. Obviously, the origins of ideas must relate to the current understanding, which is the point from which history must, of necessity, be approached in education. A merely logical reconstruction of past events that produces pseudo-history must be avoided. History must be placed in its original context, while relating it to our current views, in a manner that respects the originators and portrays them in a fair and balanced way. The objective of accuracy or faithfulness to the historical record must, in turn, be balanced against the demands of a curriculum that limits the depth to which the history can be probed. It should be realized that the place of history is not only to make a conceptual point but also to introduce the humanistic element into the process of learning science. Portraying scientists as human beings and giving students the opportunity to become affectively involved in the story of science are worthy goals in themselves.

47.6.3.5 The Affective Context

The affective context is provided in numerous ways, initially by the story itself. Good stories are known to engage the emotions and enhance memory. The ability of the story to rouse emotions has already been discussed earlier in this chapter. While the affective context must be recognized, it is not a discrete context, as the social and practical contexts, for example, through aspects such as group work and hands-on activities, can play a notable role in generating student interest and contribute to

Fig. 47.3 A schema for incorporating stories in science teaching: the SDCA

increasing their motivation and level of participation. It is influenced further by the teacher, not only in her or his posing of questions, which may engender curiosity and wonder, but also in the telling of the story and the design and execution of the instructional activities.

47.6.3.6 Operationalizing the SDCA Framework

The story may be used as a starting point for a lesson, or it may be used in segments to motivate a series of student activities. Figure 47.3 (adapted from Klassen 2006) presents the process of integrating the science story into a lesson. The teacher supplies the story as a motivating, organizing, and contextualizing structure for the lesson. Students naturally bring their prior ideas, attitudes, knowledge, and experiences to the learning episode, which may be relevant to the concepts or abilities addressed. The presence of the various contexts will assure a heightened degree of engagement with the material of the lesson. The teacher contributes supervision in the role of a research leader, establishing the direction of the activities and acting as a resource for required information. After any successful lesson or series of lessons, students will have acquired various new ideas, attitudes, knowledge, and skills relating to the concepts or abilities that are being promoted by the lesson, which will influence the next lesson or series of lessons in an ongoing cycle.

Stories when used as door openers (Kubli 2005) are not used for the primary purpose of explanation but for the purposes of making the science concept being taught more memorable, reducing the distance between teacher and students and illuminating a particular point being made (Kubli 2005; Metz et al. 2007). Door-opening science stories provide “reasons for needing to know.” Another, perhaps more significant, purpose behind such stories is to raise questions or leave the student with unresolved problems or issues which form a significant part of the science material being taught. These questions arise not only from the story itself but also from the scientific issues and concepts that the science story contains. According to Gil-Pérez and coauthors (2002), questions play a central role in constructivist pedagogy. In their words, "[f]rom a scientific point of view it is essential to associate knowledge construction with problems: as Bachelard (1938) stresses, 'all knowledge is the answer to a question'" (p. 14). One would then expect that well-told stories would provide an incentive for students to raise a number of questions that they consider both interesting and important.

47.6.3.7 The Science Story as a Stand-Alone Implementation of the SDCA

The five contexts as identified in the SDCA are inherent in science instruction that incorporates well-designed stories in a well-conceived manner. The historical and theoretical contexts rest in the story itself. Since the science is elaborated within the story text, the practical context can be generated through the students' imagination, as shown in the Hadzigeorgiou and colleagues' (2012) research study. It has also already been demonstrated that the affective context emerges in the response to the story in the form of engagement, motivation, and long-term retention. Given that the told story raises questions in the students' minds and produces ongoing group discussion, the social context is developed within the learning environment, as well. The degree to which this is developed is largely in the hands of the teacher who determines in what kind of cooperative learning experiences his or her students will engage.

47.7 Conclusion

Theories of narrative are diverse and do not necessarily precipitate a set of common features of narrative. Because of the complexity and different understandings of narrative and story, a distillation of the common elements among various expositions of narrative theory does not result in a definition that can be applied practically in science education. The analysis of the literature and recent research reveals that the writing of good stories must focus on the structural elements of the story and include the relevant narrative features. The construction of such a list derives particularly useful insights from the narrative theory of Altman (2008) who emphasizes character and distinguishes elements relevant to the writing of a story. The story centers on the character who, in our case, is a real scientist, and the details are provided predominantly by the historical record. The consequential choices made by the scientist have the effect of raising human interest that, for example, stimulate the romantic understanding of students, as demonstrated in the study of Hadzigeorgiou and colleagues (2012). Such stories should also include an interwoven elaboration of the related science concepts. Provided that the story is well written, students can gain, from the told story alone, all the conceptual knowledge that they would have gleaned from conventional classroom instruction and demonstrate improved learning and better long-term retention of knowledge (Hadzigeorgiou et al. 2012). A story containing all the characteristics required to produce an effective contextual learning environment is also likely to rest in or produce the contexts essential to ensure sound science instruction. While the historical and affective contexts are always supplied by the story, teachers can opt to supply the theoretical, practical, and social elements separately from the story when they use it in the role of door opener to the instructional episode in conjunction with the questions that are naturally raised by the story.

Although the past decade has seen significant development in the definition and practical implementation of stories in the science classroom, the definitional structure of story that has been presented here requires wider dissemination and more diverse application. In order for research among various researchers to be comparable, there needs to be a standardized vehicle or framework of story structure and delivery, and the current chapter provides one such implementation method. Without a certain degree of standardization, it will not be possible to judge the effectiveness of the use of stories in science instruction nor to assess the anticipated progress in this research area.

Recent research on the effectiveness of stories in science instruction has already raised topics for further research; for example, the relative effectiveness of the story approach in different curricular contexts, in different national and cultural settings, and among different age groups of students needs to be investigated. The implementation process, of itself, raises additional research imperatives. Among these are the assessment of existing so-called stories, the writing of new science stories that correlate to specific curricula, and the collection and dissemination of such science stories that meet the criteria established in this chapter.

Acknowledgment The writing of this chapter has been supported by a research grant from the University of Winnipeg.

Cathrine Froese Klassen (B.A. Hons., B.Ed., M.A.) is an Instructor in the Faculty of Education at the University of Winnipeg, with a teaching assignment in Gifted Education. She began her career as a high-school teacher. Besides holding key leadership roles in provincial curriculum committees and professional associations in the Gifted Education, German, and English areas, she was English Department Head, Advanced Placement Coordinator, and Coordinator for Gifted and Talented Programming and Critical Thinking in her school division in Winnipeg. From 2007 to 2011, she held the position of Executive Administrator of The World Council for Gifted and Talented Children at its Headquarters at The University of Winnipeg. She has taught courses in Gifted Education, German Language, and German Curriculum, Instruction, and Assessment at the University of Manitoba and the University of Winnipeg. Her publications include two volumes of conference proceedings, as editor, and numerous articles in the field of gifted education, as well as in science education, particularly on the use of stories in teaching science.

Stephen Klassen is Associate Professor at The University of Winnipeg where he teaches physics and holds an appointment in the Faculty of Education. His Ph.D. (University of Manitoba) is in Science Education, and his background is in experimental physics. Dr. Klassen's current research is on the writing, analysis, and use of stories (from the history of science) in science teaching and the analysis of physics textbooks for their portrayal of the history of science. His work, in part, is published in *Science & Education* (11 papers), *Science Education*, *Interchange*, and the *Canadian Journal of Science, Mathematics, and Technology Education*. Since 1997, he has presented papers at the International Conference on History of Science in Science Education (ICHSSE) and has contributed significantly to its organization, especially in cochairing the Planning Committee. As of 2001, he has been actively involved in the International History, Philosophy, and Science Teaching Group (IHPST) by having presented at each of its conferences, having served as Program Chair in 2003, and joining its governing Council in 2010 and the Editorial Committee of *Science & Education* the following year.

Chapter 48
Philosophical Inquiry and Critical Thinking in Primary and Secondary Science Education

Tim Sprod

48.1 Introduction

This chapter considers two related, yet nonidentical, issues in science education: the role that can be played by philosophical inquiry and the place of critical (or indeed other types of) thinking.

The relationship between the two issues is clear, if you accept the claim by Lipman (1991) that philosophy is the discipline whose central concern is thinking. On this basis, he argues that philosophy should, therefore, be taught in all schools as a means of (among other things) improving the thinking of school students. Broadly accepting Lipman's claim, this chapter assesses its strength in relation to science teaching in schools.

This chapter starts with consideration of educational research into the nature of thinking, exploring the extent to which it is context bound, the problem of transfer across contexts and the nature of excellent thinking. Drawing on this work, I then turn attention to thinking within the context of science education. We shall see that the evidence suggests that present methods of science education, by and large, are not as good as they could be in developing the scientific thinking of students.

Next, I survey three programmes which have shown considerable promise in not only improving the scientific thinking of school students but also in having a positive impact on other desirable outcomes of science education: the Cognitive Acceleration through Science Education (CASE) programme, the Conceptual Challenge in Primary Science project and the Philosophy for Children (P4C) suite of approaches. Behind the success of these approaches seem to lie some common features: they provoke puzzlement or cognitive conflict; they depend heavily on a certain style of classroom discussion which is recognizably philosophical; they make metacognition explicit; and they have ways of encouraging transfer to other contexts.

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_48,

Finally, this chapter draws together the matters discussed, looks at some possible objections and considers the implications in four areas: for future research on effective programmes for scientific thinking and the other outcomes mentioned above, for investigating the impact of attributes of teacher on such programmes, for the provision of training for teachers in the delivery of effective programmes and on the need for the development of more materials to support teachers.

48.2 Thinking

48.2.1 Is Thinking General or Context Bound?

The first issue that arises is the generality of the good thinking at which we aim. Ever since Spearman (1927) introduced the notion of general intelligence *g*, there has been disagreement among theorists as to whether good thinking is a generic capacity (see, e.g. Ennis 1989, 1990), able to be turned to any discipline or whether good thinking is embedded in particular contexts or situations (McPeck 1990) so that a good thinker in science may not be able to think well in other disciplines. On the answer to this puzzle rests a more practical issue: should schools make space in the curriculum for separate 'thinking' classes, or should thinking be taught within each discipline? It should be noted that this is not an 'either-or' situation: it is possible that both are needed.

More recently, the discussion about whether thinking is domain specific or not has become more nuanced. No longer do theorists and experimental psychologists line up to defend either side. Rather, there seems to be more agreement that there is truth in both accounts. In a recent survey, Adey and colleagues (2007, p. 78) state that '[w]e can find no support in the current psychological literature for either of these extreme views… What emerges from the vast literature that exists on the structure of general abilities [is] that both general and specialised processes are interwoven in the human mind'. Despite this convergence, there still exists considerable difference as to the nature of these two and of the ways in which they interact. Perkins and Saloman conclude:

> The approach that now seems warranted calls for the intimate intermingling of generality and context-specificity in instruction. … We forecast that wider-scale efforts to join subject-matter instruction and the teaching of thinking will be one of the exciting stories of the next decade of research and educational innovation. (Perkins and Saloman 1989, p. 24)

To claim that there is such a thing as general thinking ability (or general cognitive ability, or intelligence) is not to deny that all thinking is contextual, in the sense that it must take place in some context, using some content. Rather, it is to claim that there is a core set of capacities and dispositions which have the potential to be applied across a large variety of contexts. These general abilities are then augmented by capacities that are more specialised to particular contexts and applications.

Moreover, there is growing agreement that complex thinking in a domain requires a reasonable grasp of content (Bailin 1998; Paul and Elder 1999; Willingham 2007).

In relation to education in science, two questions arise that will be addressed later in this chapter. Firstly, there is the question of transfer. If students develop the capacity to use a certain type of thinking well in one context, how easily can they transfer that capacity to different contexts? If such transfer does not happen spontaneously, then what are the conditions and classroom activities that will enhance such transfer? Secondly, there is the issue of plasticity. Do individuals have a genetically determined capacity for good thinking, or is their ability susceptible to environmental influences, including educational ones? Does the development of general cognitive capacities run according to a set timetable, or can educational interventions speed up their acquisition?

Before we turn our attention to these questions, we need to survey the ways in which good thinking has been characterised.

48.2.2 *What Is Thinking, and What Makes It Good?*

If we are aiming to improve the scientific thinking of school students, then we had better have a clear idea of the target. This is, however, less easy than it might seem on the surface, since there is considerable disagreement about what to call such thinking, let alone of what it consists. Lipman (1991), for example, in a chapter interestingly titled ‘The cornucopia of cognitive performance’, talks variously of higher-order thinking, good thinking and excellent thinking.

The title to this chapter has used what is probably the most popular name: critical thinking. The popularity of this name probably stems from John Passmore’s highly influential article ‘On teaching to be critical’ (1967). Yet, within what might be called the critical thinking movement, there exists quite a bit of internal disagreement about how exactly ‘critical thinking’ should be characterised, particularly at the level of specific characteristics a critical thinker has.[1] Despite this diversity, different theorists often mention the same or similar elements, differing more on their arrangement or interrelations. A common thread that runs through many of these accounts is a distinction between capacities (or skills, or capabilities)[2] and dispositions (or habits, or traits). The former refer to cognitive moves that can be made, and the latter to the desire to make them. It is commonly claimed that a good thinker needs both.

The label critical thinking, however, has been questioned for an overly rational emphasis (de Bono 1986). Some of the critical thinking theorists – see, for example,

---

[1] See, for example, Ennis (1987), Paul and Elder (2007), Resnick (1987), and Siegel (1990).

[2] Some theorists object to the term ‘thinking skills’ (e.g. Hart (1993); see also Lipman (1991, pp. 78–80),where he discusses Hart), as reducing a complex, interwoven human activity to a series of atomistic technical skills. I will not enter into this discussion: in what follows, I will use ‘skills’, ‘capacities’, ‘capabilities’ and so on interchangeably.

Siegel (1990) – claim that critical thinking is a very wide concept, including all cognition and quite a bit beyond, such as the affective. Others prefer to confine the adjective 'critical' to the rational, convergent type of thinking and to refer to the more imaginative, divergent type as creative thinking (Swartz et al. 1998). In these accounts, it can seem as though there are two distinct types of thinking. Lipman (1991), whose favoured term is higher-order thinking, prefers to talk about the critical and creative *aspects* of higher-order thinking, saying 'there is no creative thinking that is not shot through with critical judgments, just as there is no critical judgment that is not shot through with creative judgments' (p. 193). He also added a further aspect – caring thinking (Lipman 1995) – to acknowledge the important role of the emotions in higher-order thinking. In my own work, I argue for the term 'reasonableness' and identify five aspects: critical, creative, committed (roughly equivalent to Lipman's 'caring'), contextual and embodied thinking (Sprod 2001).

Lipman (1991, pp. 50–51) makes the point that good thinking is contextual and nonhierarchical. By this, he means that skills which may seem to be low level in one context may be crucial in another. Further, a good thinker not only has the capacity to use skilful thinking and the disposition to do so but also must have the judgement and discrimination to recognise the appropriate moment to call upon each skill. Using the analogy of the carpenter, Lipman (1991) comments that it is not enough to know how to wield a hammer and a plane skilfully: the judgement to know which situations require a hammer, and which a plane, is also essential. Ritchhart and Perkins (2000, p. 30) analyse the dispositions needed to think well as having three aspects – the inclination to think well, the ability to do so and the sensitivity to know where and when to use those abilities – making what appears to be the same point in somewhat different language.

Further, Paul and Elder (2007) point out that thinking which is good by technical standards (pragmatically successful) can be 'intellectually flawed' if not grounded in 'fair-mindedness and intellectual integrity'. The former may merely involve 'the technical perfecting of isolated cognitive skills' (Lipman 1991, p. 51).

Characterising accurately the nature of thinking is well beyond the scope of this chapter, but the foregoing discussion has highlighted that, if we have the aim of teaching good thinking in science, we need to be aware that the sort of thinking we are seeking to encourage and inculcate is quite a complex set of capabilities and dispositions, backed by sound judgement. It is now time to turn our attention to a matter that merges the concerns of these last two sections: the nature of scientific thinking.

48.2.3 Scientific Thinking

We have seen above that there are differences of opinion as to whether good scientific thinking is good general thinking applied to science[3] or is a distinctive type of

---

[3] Huxley (1894) is often quoted giving his opinion that science is 'nothing but trained and organised common sense'. See also Royer (1987).

thinking.[4] Once again, many commentators seem to be converging on a view that scientists utilise many general thinking skills and dispositions but also have developed more specific ones that either relate more to scientific contexts or have been developed to a greater and more precise degree by scientists.[5]

Adey and colleagues (2007) make a powerful case that we can consider scientific (and indeed, all) thinking as a combination of central, shared competence (which they call general intelligence *g*) and a suite of subsidiary competences that are much more subject specific. Exactly how these are related is less certain, and they survey a number of models. We should note in passing here that it is hard to see how a sharp distinction can be drawn between the central and the subsidiary elements of thinking. Are some of them merely more sophisticated versions of general thinking (e.g. ability to discriminate), while others are rather different from any skills of general thinking (e.g. statistical inference)? Is there a difference in kind that separates the drawing of distinctions between characters in literary analysis and distinguishing between possible confounding variables in science?

Research scientists at the cutting edge have clearly developed their scientific thinking to a high degree. It is also clear that the precise mix of capacities used in expert scientific thinking will vary from one field to another within the sciences – the development of these subsidiary competences depends heavily on the requirements of the field.

Much work has been done on the acquisition of scientific thinking by children as they mature and are educated,[6] yet only a small proportion of it extends beyond the middle years of schooling. I am unaware of any study that traces in detail the development of scientific thinking in the transition from senior secondary school student to fully fledged scientist (though there are studies that take single-stage 'snapshots', particularly in early undergraduate years). Indeed, such a study would be a major one, requiring a very long-term longitudinal design. Moreover, much of the research focuses on, as Zimmerman (2007) puts it, 'the three major cognitive components of scientific discovery: Searching for hypotheses, searching for experiments (i.e., data or evidence from experiments or investigations more generally), and evidence evaluation'. Thus, the model of scientific thinking here is quite narrow, being based on a singular conception of The Scientific Method.[7] Nor is it clear that searching for

---

[4] Wolpert (1992) argues that 'science involves a special mode of thought and is unnatural for two main reasons … Firstly, the world just is not constructed on a common-sensical basis. This means that 'natural' thinking – ordinary, day-to-day common sense – will never give an understanding about the nature of science.… Secondly, doing science requires a conscious awareness of the pitfalls of 'natural' thinking. For common sense is prone to error when applied to problems requiring rigorous and quantitative thinking ….'

[5] See, for example, Adey et al. (2007), Adey (2006), Bailin (2002), Ennis (1990), Gazzard (1993), McPeck (1990), Norris (1992), Paul and Elder (2007), Perkins and Saloman (1989), Siegel (1989), and Siegel (1991).

[6] See, for example, Kuhn et al. (1988), Kuhn and Pearsall (2000), Zimmerman (2000), and Zimmerman (2007). The latter is a recent, comprehensive survey of such work.

[7] Many school science texts refer to what I am calling here 'The Scientific Method', which takes experimental work with tightly controlled variables as the model for all science (Lederman and Lederman 2004). See further discussion in Sprod (2011, pp. 4, 66).

possible explanations, seeking data to test them and evaluating the evidence adduced are skills that apply solely to science.

Searching ERIC with the descriptors 'science education' and 'thinking skills' returns 649 matches. Using the above terms with a variety of words derived from 'category', 'type' and 'taxonomy' revealed no empirical studies that tried to categorise the different scientific thinking skills that students develop through their science education. There were, however, quite a few studies[8] that took a particular thinking skill – or, occasionally, disposition – and studied the ways in which some intervention may strengthen it. Hence, researchers and teachers clearly have some typology of scientific thinking on which they draw.

The most comprehensive typology of science thinking skills that I could discover on the Internet (Table 48.1) is found on the Boston Museum of Science (2001) site. The single source that they quote for their list is the Californian State Department of Education (1990) document 'Science Framework for California Public Schools' (see Table 48.2). The members of the team who wrote the document appear to have compiled this list by drawing on their own experience and ideas, judging by the lack of references to any papers which have developed a typology of science thinking skills.

Again, a perusal of the lists in Tables 48.1 and 48.2 leads one to wonder if any or, at the very least, many of these skills are unique to science. Certainly, in their more developed guises, such skills as categorisation may become much more sophisticated and specialised than their everyday counterparts, but it is hard to see how their roots can be anywhere other than in more general thinking skills that can be applied across many domains. There appears to be a need for empirical work to delineate the thinking skills that scientists actually use in their work and to explore how they develop these skills through their education, right up to the level of employment as a scientist.

Hence, we may well feel that children's scientific thinking in the early years of education leans heavily on those shared competencies that are utilised in all the disciplines and that as they grow older and become more educated in science, not only will their general competence increase, but they will also start to develop some of the more context-dependent thinking competencies that apply more specifically to science. Science education, then, ought to have the dual roles both of strengthening the general ability to think well (a role it ought to share with the other disciplines) and of developing those modes of thinking which have more specific application in science.

48.2.4 Developing Scientific Thinking in Schools

In the light of compelling evidence (see, e.g. Lyons (2006), Pell and Jarvis (2001), Tytler (2007)) that students find school science boring, largely requiring the regurgitation of facts, there have been calls, as Tytler puts it, to 'reimagine' science

---

[8] For example, Venville and Dawson (2010) on argumentation and informal reasoning, Settelmaier (2003) on ethical dilemmas, May et al. (2006) on analogical reasoning and Vieira et al. (2011) on conceptual clarification.

Table 48.1 Science thinking skills typology (Adapted from Boston Museum of Science (2001))

Seeing the unseen – observation
Becoming active observers
Using all senses in making observations
Developing observational skills
Awareness of strengths and limitations of observations
Using tools to extend senses
Transferring observational skills to other contexts
Finding the pattern – classification
Observing, comparing and sorting objects and phenomena in meaningful ways
Recognising that systems for organising and classifying objects and phenomena reveal underlying meaning
Using organised material collections to answer questions and solve problems
Searching for the 'hidden' meaning in objects and phenomena
Making models – description
Recognising the presence and value of models
Becoming familiar with several types of models: physical models, conceptual models, mathematical models and computer simulations
Practising four specific science thinking skills associated with making and using models:
Recognising the similarity between models and the things they represent
Assessing the strengths and limitations of models in explaining and predicting the behaviour of the objects or phenomena they represent
Using models to raise questions, communicate ideas and test hypotheses in many different contexts
Creating models to explain things they cannot be observed directly
Testing the theory – experimentation
Formulating and testing ideas about the world
Asking questions and generating ideas
Formulating hypotheses
Gathering and weighing evidence
Using instruments to design experiments
Recording and interpreting data
Drawing conclusions
Being aware of what it means to experiment
Transferring scientific habits of mind (curiosity, respect for evidence, scepticism and open-mindedness) to other settings
Participating in ongoing scientific research
Putting it to work – application
[No list of component skills given]
Playing with ideas – imagination
[No list of component skills given]

education. One of the common phrases used in these calls is to make science lessons more 'minds-on' (Sprod 2011). Such a characterisation builds on a broad-brush history of science education which sees the early approach as 'ears-and-eyes-on' (lectures and demonstration experiments), to which, from the mid-twentieth century, was added 'hands-on' (student experimentation). Towards the end of the last

Table 48.2 List of science thinking skills adapted from the California Department of Education's *Science Framework for California Public Schools* (1990, p. 151)

Observing: the scientific thinking process from which fundamental patterns of the world are construed
Communicating: the scientific thinking process that conveys ideas through social interchanges
Comparing: the scientific thinking process that deals with concepts of similarities and differences
Ordering: the scientific thinking process that deals with patterns of sequence and seriation
Categorising: the scientific thinking process that deals with patterns of groups and classes
Relating: the scientific thinking process that deals with principles concerning interactions
Inferring: the scientific thinking process that deals with ideas that are remote in time and space
Applying: the scientific thinking process by which we use knowledge

century, in the light of more research (e.g. Jurd 2004; Abrahams and Millar 2008) that showed much practical work in schools was unaccompanied by little thought about the science or even the purpose of the experiment, the phrase 'minds-on' started to appear more frequently. Indeed, in much of the literature, the two latter phrases are often conjoined into 'hands-on, minds-on' (e.g. in Andre (1997), Jegede and Taylor (1995), and Pedersen and McCurdy (1992)).

So, even granted that we have some reasonably shared idea of what constitutes good scientific thinking, we can ask whether students learn this well by following a traditional science education or whether some new or different ('minds-on') pedagogical approach needs to be added to science curricula. There is quite a bit of evidence that traditional methods are not enough (Kuhn 1999), though most of this evidence is in the form of studies that show some particular intervention has a positive effect on scientific thinking skills over and above that of traditional methods.[9] The implication, then, is that those traditional methods are failing to make the most of the possibilities for developing scientific thinking.

Many of these studies are quite small scale and carried out over a relatively short time frame. Hence, methodological questions arise about experimenter effects, confounding variables, generalisability to other contexts and so on. Moreover, it is not clear that all researchers are using key terms such as 'direct instruction', 'transfer', 'inquiry method', 'scaffolding' and 'conventional teaching' in the same sense (Zimmerman 2007, p. 215), making comparisons between studies difficult.

However, perhaps the major shortcoming of small-scale studies is that they do not deal with the most important question: even granted that some statistically significant effects can be demonstrated after intervention, are these effects long lasting? In other words, do they transfer to other contexts at much later times? Only if it can be demonstrated that certain changes to teaching and learning make a real difference to children's abilities over significant timescales and, in novel situations, will there be a strong case for making those changes.

---

[9] For example, Balcaen (2008), Cavagnetto et al. (2011), Choi et al. (2010), Dawson (2010), Hand and Choi (2010), Lee and She (2010), Miri et al. (2007), Mitchell (2010), Pithers and Soden (2000), Sadler (2004), She and Liao (2010), Songer et al. (2009), and Sprod (1998). See also note 8.

There are, as mentioned, many suggestions as to what changes to scientific education need to be made. Many of these form the subject of other chapters in this handbook. In the next section of this chapter, I will survey some approaches[10] that can make claims to have demonstrated lasting changes in reasoning. As we shall see, scientific reasoning is not their sole target.

48.3 Philosophical Inquiry and Science Education

The three programmes on which this section will focus are as follows: Cognitive Acceleration through Science Education (Adey et al. 1995) and its related spin-offs; the Conceptual Challenge in Primary Science program; and approaches derived from Philosophy for Children and its methodology, the community of inquiry (Lipman et al. 1980). As stated in the introduction, programmes designed for science classes in schools which involve some form of philosophical inquiry can have many more aims that merely improve the scientific thinking of students. Nevertheless, given Lipman's claim that philosophy is the natural home of thinking, such programmes will have as one of their central aims the expansion and augmentation of students' ability to think scientifically.

48.3.1 Cognitive Acceleration Through Science Education (CASE)

If educational managers require solid empirical evidence before introducing changes to curricula, then the CASE project is compelling. CASE and the cognitive acceleration (CA) projects that grew out of it[11] have been among the most intensively studied innovations in science education,[12] with a most impressive track record.

---

[10] Unfortunately, the survey that follows will, due to my linguistic limitations, be largely limited to work published in English. Certainly, important work has been carried out in other languages – see, for example, Vieira et al. (2010). There are also many projects in science education that include in their aims the improvement of scientific thinking but for which, to my knowledge, no empirical research has been done to test the claims – for example, Aikenhead's *Logical Reasoning in Science and Technology* (Aikenhead 1990).

[11] 'Other members of the growing family include CAME (in mathematics for junior secondary), PCAME (mathematics for Years 5 and 6, ages 9–11 years), *Let's Think!* (science/general reasoning for Year 1, 5–6 year olds), *Let's Think through Science!* (for Years 3 and 4, 7–9 years) – all developed at King's College, London – and CATE (technology), and ARTS (junior secondary music, drama, and visual arts)' developed elsewhere (Adey 2005).

[12] Adey (1997, 2004, 2005), Adey et al. (2002), Adey and Shayer (1990, 1994), and Shayer and Adey (1993)

The original CASE project involved using one lower secondary science class every second week for the first two secondary school years in activities based around Piagetian-based operations such as control and exclusion of variables, ratio and proportion, compensation and equilibrium, correlation, probability, classification and formal models. In other words, the major focus was not on any particular scientific content,[13] but rather on some aspect of scientific thinking. A typical lesson moves from a ‘concrete preparation’, where new equipment and vocabulary are introduced, through an activity designed to create cognitive conflict in their students’ heads, onto the core phase where students strive jointly to construct a satisfactory explanation, paying attention to the thinking that is going on (metacognition) and seeking to apply their insights to other similar situations, all under the guidance of the teacher.

The major claim to arise from the project is that it is possible to improve the thinking skills of students significantly through this sort of programme and that the effects of these improvements can still be measured 3 years after the intervention finishes, by their effect on student performance in external examinations – not only in science but also in mathematics and English GCSEs. This is long-term, far transfer (Adey and Shayer 1994).

There are two aspects which need attention here. The first is the theoretical underpinnings of the project, and the second is the key factors which the researchers have identified as being vital to the programme’s effects.

CASE’s theoretical base lies in psychology rather than philosophy. The initial theoretical driver of the project was Piagetian stage theory. The materials were designed to accelerate the passage of students who used them through the stages, by provoking cognitive conflict and assisting assimilation. Specifically, it was thought that students could be assisted to move from the concrete operational to the formal operational stage; hence, the project was targeted at students around the age of 12 (the first 2 years of secondary school).

Drawing on the work of Vygotsky (1962) on the social nature of cognitive development and some little recognised work of Piaget and his collaborators on social interaction (Adey et al. 2007), the means for accelerating cognitive development were devised, trialled extensively and assessed in a multistage longitudinal study.

The thoughts of the principal investigators in the suite of CA projects on why the programmes work will be of primary interest to readers of this handbook.

Firstly, we have to address the question, raised in 2.1, of transfer. Does CASE really demonstrate long-term, far transfer of effects on scientific thinking, when much of the literature points to the difficulty of doing so? Adey (2006, p. 2) says ‘we can answer a clear ‘yes’: stimulating higher order thinking in science improves students’ general intellectual ability across the board’. Adey et al. argue that while

---

[13] Of course, each lesson does contain content, so that control of variables might be studied through consideration of the effects of the length, width and material of a pipe on the pitch of the note produced by blowing across it, or probability via flipping coins.

general abilities are acquired and/or practised in particular contexts, on specific content, which might be thought to limit their general application, by

> mining more deeply into the insights and models of developmental psychology and paying attention to the general intellectual processors of the mind (both 'executive' and 'central') … (Adey et al. 2007, p. 92)

we can create conditions under which transfer is much more likely. Thus,

> moving along the scale of "subject matter versus general ability" towards the direction of developing general abilities actually opens up broad opportunities for raising levels of traditional academic achievement. … you have to have both concrete content and reflective abstraction. If you teach the specifics with abstraction in mind, the general is learned, but if you try to teach the general directly, the specifics often are not learned. (Adey et al. 2007, p. 92)

These observations may give us cause to wonder: is using the CA materials necessary to get the gains their research has shown, or are there essential features of the CA approach which can be used to design other programmes or to influence teaching methodologies more generally? If so, what are the key features? In a number of articles, the team has identified these factors, calling them the pillars of CA. Here is one characterisation of the pillars:

1. *Cognitive Conflict.* Piaget suggested that one of the mechanisms by which cognition develops is through a challenge to existing cognitive structures by experiences which make demands somewhat beyond the child's current processing capability. The same idea is encompassed by Vygotsky's zone of proximal development ('the only good learning is that which is advance of development'). CASE activities are designed to provide such challenge, in scientific contexts, on a slope of increasing difficulty such that, at some point, students of different abilities all encounter cognitive conflict.
2. *Social Construction.* Both Piaget and Vygotsky stressed the role of social interaction in cognitive development, although it is Vygotsky's claim that 'ideas appear first in the social space and then become internalised by the individual' that is best remembered. CASE pedagogy emphasises the importance of collaborative learning in the class, with groups of students interacting with one another, positive argument and critical questioning encouraged and every student's contribution valued.
3. *Metacognition.* Another notion central to the Piagetian model of cognitive development, especially for the emergence of formal operations, is 'reflective abstraction', the idea that the individual reaches a higher level of thinking by reflecting on their own thinking. The Vygotskyan notion that language acts as a mediator of learning also suggests that putting thoughts into words (the conscious explication of thought) is a powerful driver of cognitive development. CASE teachers encourage their students to explain what they are thinking, what they find difficult, what they have learned, what mistakes they have made and how they corrected them (Adey 2006, pp 2–3).

To these three pillars, they have elsewhere added 'two subsidiary pillars (*concrete preparation*, introducing the topic, and *bridging* – showing how the same sort of thinking can be used elsewhere)' (Adey 2005).

One might wonder, at this point, whether the domain through which such cognitive acceleration is delivered needs to be science and, if not, whether there are advantages in doing it through science. Again the CA team has addressed such thoughts. Adey says that, while 'in principle there is no reason why such an approach should not be taken through any subject domain' (Adey 2006), 'science in schools is a domain which may be peculiarly well adapted for the development of, at least, a general understanding of problem solving which would be expected to be useful across both school domains and everyday life' (Adey 1997). This is, in part, because 'the schemata of formal operations described by Inhelder and Piaget (1958) (control and exclusion of variables, proportionality, classification systems, equilibrium, and the others) have a very science-y look to them' (Adey 2006).

Indeed, the CA team have identified several other programmes which seem to fit their pillars well[14] and which have a track record of improving cognitive functioning:

> Long ago Vygotsky claimed that all learning in school from the early years onward should be directed as much to children's cognitive development as to their subject learning (Shayer 2002). The transfer evidence from Cognitive Acceleration, Instrumental Enrichment, and Philosophy for Children suggests that the technology is now being developed to make that a practical and realisable aim. Each of these interventions clearly stimulates something much deeper than domain specific systems, and that 'something', we would claim, is general mental ability, or general intelligence. (Adey et al. 2007, p. 92)

As noted previously, one of the great strengths of CASE and related programmes is that there are a number of longitudinal studies demonstrating their efficacy in long-term, far transfer. As Adey et al. (2007) themselves comment, it is a pity that other promising educational programmes have not been the subject of similar research, particularly in terms of attempting to measure whether the effects seen in short-term studies are long lasting. Clearly, large longitudinal studies are not easy to carry out. Issues of funding, continuity of staffing and the like have been discussed in a special issue of *Research in Science Education* (vol. 35, no. 1, 2005).

Longitudinal studies also have the disadvantage, as Tytler and Peterson (2005) put it, that 'there are many points at which we wish we had gathered different or better data at the earlier stages'. For example, Adey (1994, personal communication) began to wish that the CASE team had collected more data on the use and type of discussion in CASE classes, as they realised that this second pillar was one of the more powerful features explaining the effects of the intervention.

Of interest, while considering longitudinal studies that have demonstrated robust long-term effects, is the comparison of CASE with Novak and Musonda's study of science concept learning, based on the theories of Ausubel (Novak and Musonda 1991; Novak 2005). Tytler et al. (2005) comment that '[t]he success of both interventions, situated as they are in quite different theories, gives pause for thought. They perhaps suggest the existence of common and significant principles underlying both Piagetian and Ausubelian theories'. Piaget was concerned

---

[14] There are other programmes, not identified by the CA team, that also share many of these features and have been shown to have positive effects, for example, work by Carol McGuinness and colleagues in Northern Ireland (McGuinness 2006).

with the structures of thought, Ausubel with acquisition of concepts. I would suggest that the link is that both studies also draw heavily on Vygotskyan ideas on how children internalise both the capacities of thought and concepts through social interaction.

48.3.2 The Conceptual Challenge in Primary Science Project

A second project that can be seen to share the Cognitive Acceleration pillars referred to above is the *Conceptual Challenge in Primary Science* project, originating at Oxford Brooks University in the United Kingdom (Mant et al. 2007; Wilson et al. 2004).

The four emphases in this project are:

1. Increased time spent in discussion of scientific ideas
2. An increased emphasis on the encouragement of higher order thinking
3. More practical work and investigations
4. More focused and purposeful recording by pupils, less writing (Mant et al. 2007, p. 1712)

In the first three, we can recognise the pillars social construction, metacognition and the opportunity for cognitive conflict respectively. Two key teachers from each of 16 primary schools participated in ongoing professional development sessions run by the researchers that concentrated on developing 'cognitively challenging, practical science lessons with plenty of space for thinking and discussion' (Mant et al. 2007, p. 1712). One of the major innovations was the introduction of 'Bright Ideas Time' discussion slots based on a discussion prompt (more details of the methods are to be found in Wilson and Mant 2006). The time to include more practical work and discussion sessions came largely from taking a close look at how much writing and recording students were required to do so that 'teachers focused on the *purpose* of recording by the pupils, so that although less was demanded it was of a higher quality' (Mant et al. 2007, p. 1716, emphasis added).

As with the CASE research, the main measure of effectiveness of the method was to use an externally set and marked test. In this project, the test was the UK's national science assessment test, and the relevant measure was the proportion of students achieving level 5 on the test. Specifically, the project found that, when matched against similar schools, the 16 experimental schools recorded a significantly greater average increase in level 5s of 11.8 %, against 2.0 % in the control schools. Semi-structured focus group interviews with project students showed that they rated the lessons as more challenging, active, collaborative and requiring more thinking.

In more recent research, the Oxford Brookes group has polled over 5,000 12-year-old students to identify exemplary science teachers, measured by the degree to which the students reported being engaged and motivated by science lessons. Through questionnaires administered to the students of those teachers (Wilson and Mant 2011a) and through group interviews with those teachers

(Wilson and Mant 2011b), they sought to determine the teacher-mediated factors that make science education effective. The four factors that both students and teachers agreed upon make interesting reading in the context of the concerns of this chapter: they are the use of discussion, an emphasis on thinking, more student practical work and the contextualisation of science in terms of students' lives (Wilson and Mant 2011b, p. 118).

48.3.3 Philosophy for Children (P4C) and the Community of Inquiry (CoI)

Philosophy for Children had its genesis in the work of Lipman et al. (1980). The basic structure of the programme, as Lipman initially conceived it, is a series of novels accompanied by teacher's manuals, delivered in the classroom through a community of inquiry. The initial novel, *Harry Stottlemeier's Discovery* (Lipman 1974), had a 'spine' concerned with formal syllogistic logic, though plenty of other philosophical puzzles were also woven into it. These were 'unpacked' for the teachers through explanations, discussion plans and exercises in the manual (Lipman and Sharp 1975).[15]

The community of inquiry is a specific type of whole-class discussion. Lipman (1991) identifies five stages: (I) reading a portion of the story; (II) gathering questions from the students as a means of constructing an agenda; (III) the students taking responsibility for discussion; (IV) the teacher taking responsibility for prompting the discussion to be rigorous, rich and meaningful; and (V) follow up activities.[16]

It is worth commenting on these stages. In (I), the stories have been written to contain what my son Liam called 'philosoful' hooks (Sprod 1993). However, instead of the teacher identifying them and asking the students questions about them, it is the students who set the agenda for the discussion to follow by asking questions about those incidents in the story that puzzle or interest them. In this way, the community of inquiry starts in a narrative about children which supplies the concrete situation (CA's first subsidiary pillar) and identifies those ideas that have caused cognitive conflict (CA's first major pillar) for the students – especially when they choose from the questions asked one that most students want to try to answer.

Stages (III) and (IV), which interleave, use the whole-class discussion as a means of providing social construction of concepts, thinking skills and dispositions and

---

[15] It is worth noting at this point that the Philosophy for Children field has diversified considerably since Lipman's model was devised – so much so, in fact, that different theorists and practitioners have suggested broader names, such as philosophy with children (Murris 2008), philosophy in schools (Hand and Winstanley 2009) and dialogical philosophy (Stone 2011). Moreover, there has been an explosion in classroom materials that use many different materials instead of Lipman's purpose-written novels, such as specially written short stories (e.g. Cam 1997; Worley 2011), picture books (e.g. Murris 1992; Sprod 1993; Wartenberg 2009) and film (e.g. Wartenberg 2007).

[16] The discussion that follows draws in part on a much fuller discussion of the community of inquiry in Sprod (2001), Chaps. 7, 8, and 9, especially pp. 183–189.

many more elements (CA's second major pillar). The teacher's role is vital[17]: to keep the discussion in the zone of proximal development. If the discussion loses its edge of inquiry, then the students fall below the ZPD (Gardner 1996), yet it could also lose the students by making too great a demand on their thinking so that they cannot follow.

The community of inquiry handles the third of CA's major pillars, and the second minor one, in two ways. At times, the metacognition and bridging can be tacit. For example, the teacher may label a certain student's idea as an assumption, without exploring explicitly with the students what an assumption is. At other times, though, the discussion can turn its focus on the tools of thinking being used (Sprod 2001, pp. 190–191). Using assumptions again as the example, the teacher may ask students to consider what the role of assumptions is or why it matters that we identify assumptions. Similarly, for bridging, the teacher or a student may introduce another situation when the analysis just completed can also be applied, or the teacher can ask students explicitly to think about the analysis and to find other areas in which to apply it.

From this brief outline of the key features of Philosophy for Children and the community of inquiry, we can see that it exhibits the features identified by Adey (2005) for effective cognitive acceleration. It is worth, however, considering the relation of the CA programmes to P4C in a little more detail.

One of the rich and interesting comments by Adey and colleagues, when considering the relation of CA to other programmes, is the following:

> Lipman's [sic] Philosophy for Children has shown good transfer effects with a general population but is essentially a pragmatic, under-theorised approach. Both [it and Feuerstein's Instrumental Enrichment] face the practical problem in school curriculum terms of requiring scheduled time for "thinking lessons".
>
> We suggest that the content-based approach offers more promise for large scale implementation …. (Adey et al. 2007, p. 92)

In the first sentence above, Adey and his colleagues, as psychologists themselves, clearly have psychological theory in mind when they say Philosophy for Children is under-theorised. Anybody who has seriously read Lipman's magnum opus, *Thinking in Education* (1991), as well as a host of other theoretical texts in the field,[18] would be loath to say that P4C is *philosophically* under-theorised. Indeed, I would claim that, while the CASE authors may have theorised the underlying processes of thinking in a more thorough psychological way, P4C writers have a better theoretical grasp on the philosophical bases of rigorous whole-class discussions. Clearly, each camp can learn from the other.

The second claim is that P4C requires separate 'thinking lessons'. If philosophy is not considered a central subject in a good education (philosophy commonly does not appear in curricula in the English-speaking world, but it does have a place in many other countries), then it is true that philosophical communities of inquiry may

---

[17] See Sprod (2001), Chap. 3, for a philosophical treatment of this 'pedagogical action'.

[18] For example, Hand and Winstanley (2009), Lipman (1993), Lipman et al. (1980), Matthews (1982, 1994); McCall (2009), Pritchard (1996), Splitter and Sharp (1995), and Sprod (2001).

be seen as extra add-ons to the curriculum: separate thinking lessons. Even so, they would still be ‘content based’ in the sense that Adey et al. use – the content being philosophy.

Nevertheless, there is a good point here: do we need more subjects in an already crowded curriculum? Where do we make room for separate thinking – or philosophy – lessons? As the CA programme recognises, it might be better to infuse the subjects already taught with thinking.[19] Given the specific focus of this handbook, then the case for scientific communities of inquiry needs to be explored. I will do so below.

Before doing that, though, let us look at the evidence for the effectiveness of P4C, both in terms of improving thinking and in other areas. Over many years, both theorists and teachers in P4C have sought to demonstrate empirically the effects of the programme. Anecdotal evidence is abundant, but not compelling, especially to outsiders. While many studies have been carried out,[20] most are small scale and often poorly designed. Hence, despite the near unanimity of their findings of improvement, their reliability can be questioned. A meta-analysis of 18 of the most robust of these studies (Garcia-Moriyon et al. 2004) found that there was consistent evidence of improvement in reasoning, with a mean effect size of 0.58 (p<.001). However, in no case was the intervention more than 1 year, and no longitudinal data were collected to test for retention of the effect.

Since then, a well-designed, longitudinal study has been carried out in Scotland. Prior to the intervention, a survey of ten previous studies, considered to be rigorous in methodology, found a mean effect size of 0.43, ‘indicating a consistent moderate positive effect for P4C on a wide range of outcome measures’ (Trickey and Topping 2004). Subsequent reports on the intervention (1 h per week over 16 months) found the groups exposed to Philosophy for Children had ‘significant standardized gains in verbal and also in non-verbal and quantitative aspects of reasoning’ (Topping and Trickey 2007a) and exhibited ‘increased use of open-ended questions by the teacher, increased participation of pupils in classroom dialogue, and improved pupil reasoning in justification of opinions’ (Topping and Trickey 2007c), while there was a significant gain in ‘self-esteem as a learner, significant reduction in dependency and anxiety and of greater self-confidence’ (Trickey and Topping 2006). The control groups showed no significant changes on any of these measures. Following up 2 years later, they found that ‘[t]he significant pre-post cognitive ability gains in the experimental group in primary school were maintained towards the end of their second year of secondary school’ (Topping and Trickey 2007b).

Thus, there is now robust evidence that P4C has a similar positive effect on reasoning and long-term transfer to CASE. There are some differences. Trickey and Topping did not measure effects on external examination results, but CASE did not look at the wider range of outcomes, such as classroom interaction and socio-emotional factors. The CA programmes focus fairly narrowly on cognitive and subject-specific factors,

---

[19] One might also add ethics.

[20] Citations for 74 empirical studies can be found at <http://cehs.montclair.edu/academic/iapc/research.shtml>.

while the P4C approach encompasses a much wider range of factors (as we shall see in the next section). Reasoning is not the only target.

So far, we have been considering the application of the community of inquiry methodology with philosophy as its primary focus. Let us look at the idea of bringing science to the centre.

48.3.4 The Scientific Community of Inquiry

A distinction has been made earlier between the Philosophy for Children programme – whether this be Lipman's original set of eight novels[21] or some modification using other materials,[22] but which retains philosophy as the central content focus – and the teaching methodology employed, the community of inquiry.

As a pedagogical technique, the community of inquiry (CoI) can be used with other subject areas as the core content. So, we can talk about an historical CoI, an artistic CoI, a mathematical CoI, an ethical CoI and so on. However, due to the nature of the questioning and inquiry that goes on in a CoI, many (e.g. Cam 1995, pp. 14–15; Splitter and Sharp 1995, p. 24) have argued that the CoI inevitably leads into an exploration of the philosophical roots of the central discipline, at least at times. So, as we shall see, it will prove with the scientific community of inquiry.

Compared to the wealth of materials developed for communities of philosophical inquiry, there has not, to date, been a great deal of work done on communities of inquiry in the other disciplinary areas, including science.[23] Given that Lipman derives the phrase community of inquiry from Peirce (Lipman 1991, p. 15), and that Peirce used the phrase (in *The Fixation of Belief*) in relation to inquiry within the community of scientists (Peirce 1955, pp. 5–22), this is perhaps a little puzzling.

Gazzard (1993) contends that 'Philosophy is an integral part of every discipline and therefore similarly should be an integral part of its instruction … science more than any other discipline need the complement of philosophy … for it is scientific knowledge more than most which is accepted by the general population as being true' (p. 619). To support her view, she points to the generative and fallibilistic nature of scientific knowledge, contrasting this with the teaching of science as revealed truth. Hence, science teaching should include consideration of the epistemology and methodology of science. Through the use of a scientific

---

[21] The Lipman novels, with the year group for which they are intended in brackets, are the following: Elfie (1), Kio & Gus (2–3), Pixie (3–4), Nous (4–6), Harry Stottlemeier's Discovery (5–6), Lisa (7–8), Suki (9–10) and Mark (11–12) – full details at 'http://cehs.montclair.edu/academic/iapc/docs/Curriculum_Brochure.pdf'. Each has an accompanying manual. Lipman's intention was that they be studied consecutively throughout schooling.

[22] See note 15 for some examples.

[23] However, there are a few articles discussing P4C and science education. See especially Lipman (1988) chapter 7 'Philosophy and Science Education at the Elementary School Level' (pp. 87–99) but also Clark (1994), Liao (1999), Novemsky (2003), Smith (1995), Weinstein (1990a, b, 1992) and the Ed.D. thesis of Ferreira (2004 – to be discussed below).

community of inquiry, she says, ‘students [will] … realize *for themselves* that science does not provide answers in the sense of closure … and that science itself is perhaps best conceived of as perpetual inquiry’ (p. 624, italics in original). This is not to say the CoI should supplant science instruction, but it should complement it (p. 629).

Despite this call, only a few people have gone on to develop materials in the science area. Often, the materials are one-off ideas for discussion starters, or local applications where the materials have not been made more widely available.[24] One of these was intensively researched for a doctoral dissertation (Ferreira 2004; see Ferreira 2012, for a summary).[25] Using chapter 1 of Lipman’s *Harry Stottlemeier’s Discovery* (1974) as a starting point, Ferreira wrote four additional chapters with a focus on classification, observation and inference in science. She then used the stories, accompanied by multisensory practical activities, in a semester-long Year 5 Brazilian science class, integrated into the school’s normal science (biology) programme. Using mainly qualitative methods, Ferreira showed that the use of these stories, within a community of inquiry, facilitated children’s learning of the target science process skills as well as other thinking skills, and encouraged reflection on those skills. Moreover, the students identified with the fictional characters, used them as models for their own thinking and also increased their abilities to self-correct and to build on the ideas of other students.

Below, I shall explore four programmes that have taken a more systematic approach to the use of a scientific community of inquiry (a fifth is explored in Hunt and Taylor’s article in this handbook). As we shall see, each of these approaches follows the Lipman classroom pattern of stimulus material, question gathering and discussion phase pretty closely, with the major variation between them being the nature of the stimulus.

48.3.4.1 Lipman’s *Kio & Gus*

The first is one of Lipman’s novels, *Kio & Gus* (1986), and its accompanying manual *Wondering at the World* (Lipman and Sharp 1986). To say this is a science programme is a little misleading, though there is a considerable emphasis on zoology and ecology, as the title of the manual implies. Aimed at children of around ages 7–8, the novel contains a wealth of philosophical and ethical hooks, as well as the scientific ones. In the preface to the manual, Lipman and Sharp

---

[24] For example, the UK-based website p4c.com, which contains a resource area onto which teachers can upload materials they have developed, contains 20 one-off P4C science lessons. Web searches unveil references to other uses of the CoI in science education, e.g. Ling (2007), Cunningham (2011) and Phillipson and Poad (2010), but I have not been able to see the classroom materials used, beyond the description in the papers cited.

[25] Ferreira, now at the Universidade de Brasília, Brasília, Brazil, is overseeing several projects developing further P4C-based science education materials and researching their contributions to science education.

state that 'it is designed to be a complement to these sciences, rather than a substitute for them' (p. 1).

They canvass two ways in which the scientific community of inquiry can help: firstly, by providing 'logically disciplined, reasonable discussions' in which children can test their scientific hypotheses, models and concepts (at times, against the standard scientific ones). Just inviting them to 'exchange their myths for the truths offered them by science' is not enough: they must be 'allowed to think these matters through for themselves' (pp. 1–2). Special attention is paid to scientific concepts. They comment that 'scientific concepts, while generally definable by means of specific criteria and classificatory procedures, tend to appear to the early elementary student as inert rather than dynamic' (p. 3: one might extend this observation to much older students as well). However, scientific concepts need to be assimilated into the child's present understanding, and so 'exercises are provided to compel students to reason about the information essential to the concept under discussion' (p. 8).

Secondly, children need to 'think scientifically'. Their 'cognitive skills need to be cultivated … they cannot be cultivated in isolation from the discipline to which they must subsequently be applied … efforts to strengthen thinking skills in a 'content-free' manner are futile'. Scientific thinking should be addressed within science – it cannot 'be expected to develop naturally, and … be in place when needed' (p. 2).

Having said this, it must be noted that science only sporadically appears in the rest of the Lipman corpus. Lipman was aware of this (pers. comm.) and hoped that others would take up the job of writing such material. Moreover, the science in *Kio & Gus* is restricted to the life sciences, with no physics, chemistry or earth science. Lipman's approach requires dedicated time in the school timetable, as working through the novel *Kio & Gus* would take at least a lesson week for 1–2 years. While this is feasible in the early childhood years as an adjunct to science sessions, it would become less so in upper primary, and unlikely to be possible in secondary school.

48.3.4.2 Nevers and Colleagues' *Philosophizing with Children About Nature*

A long-running project in Germany has been concerned with the use of the community of inquiry in biology teaching.[26] In this case, the leaders of the project have had a dual aim: a pedagogical one of using the community of inquiry to deepen students' understanding of biology and its ethical implications while improving their scientific thinking and a research aim of understanding the ways in which children of different ages think about such matters, with a focus on issues of environmental ethics.

---

[26] Gebhard et al. (1997, 2003), Nevers et al. (1997, 2006), Nevers (1999, 2005, 2009). Their work, in part, builds on the work of Helmut Schreier, who has been philosophising with primary school children about nature (among other issues) for many years (see, e.g. Schreier 1997; Schreier and Michalik 2008). None of his stories have, to my knowledge, been published in English.

The methodology used is similar to the Lipman approach outlined above. Purpose-written stories feature children involved in various different ethical dilemma situations characterised by a conflict of interest between a child or young person and a living organism or system. Hence, the major emphasis is on the interplay of biology and ethics. For research purposes, three sets of stories were used involving a plant, an animal or an ecosystem as the source of conflict, and each basic story was presented to different age groups (6–8, 10–12, 14–16). An example of such a story is in Gebhard et al. (2003, p. 95), and that paper, plus Nevers et al. (2006), provides copious transcripts of children's comments in discussion.

From recording, transcribing and analysing more than 150 group discussions, Nevers and her colleagues have been able to identify basic philosophical positions to which students subscribe, the nature and strength of the reasoning that they bring to bear on these positions, the consistency with which they hold them and their susceptibility to change in the light of discussions (Nevers et al. 1997, 2006).

A key finding is that children rely on anthropomorphism to moralise nature (Gebhard et al. 2003). This is effective when an animal or a tree is the source of conflict, but not with an ecosystem. In the latter case children tend to anthropomorphise individual organisms within the ecosystem and thus indirectly attribute moral status to it. Furthermore, the evidence indicates that anthropomorphism is not as apparent among older students. However, a follow-up study using a dilemma story involving trees and a questionnaire distributed randomly among university students suggests that anthropomorphic thinking is still prevalent among a large number of these students and drawn upon to moralise organisms, even if it is not expressed publicly.

In an individual case study, it was found that appealing to an aesthetically pleasing image from nature may serve to transform the discussion from unproductive circularity towards constructive compromise (Nevers 1999, p. 20; Nevers 2000).

Doctoral work by Hausberg (2012) under Nevers' supervision investigated the potential of philosophising with children for encouraging creative thinking (a sample of such work is to be found in Hausberg and Calvert 2009). The theoretical basis was a multifaceted model of creativity proposed by Urban (2004). Philosophical discussions with fifth and sixth graders were recorded and examined with a computer-supported text analysis system to identify various different categories of creative thinking and action. These included areas of cognitive thinking such as analysis and synthesis, analogy formation and metacognition as well as personal qualities such as humour and persistence. Group dynamic qualities such as the ability to elaborate and coordinate contributions from others were also identified.

A second phase attempted to assess whether the creative qualities expressed and trained by philosophising were applied in a different learning situation. Middle school students who had been philosophising in separate sessions for several years were presented with an open problem of biological nature and asked to discuss the problem in small groups, looking for possible solutions. Afterwards, the solutions were evaluated by the students in a moderated plenary discussion. Although it is not possible to conclusively demonstrate a transfer effect by these means, the evidence indicates that this is highly plausible. Almost all the forms of creative expression used when philosophising were also applied when the students dealt with an open biological problem, and solutions were proposed that went far beyond those usually found in biology classes.

48.3.4.3 University of Ulster's *Science in Society* Projects

At the University of Ulster, the *Science in Society* team has developed several packages based around the use of the community of inquiry, including:

- *Primary Community of Scientific Enquiry* (ages 7–11, for use in the subject The World Around Us, which includes science, geography and history)[27]
- *Forward Thinking* (ages 11–14, for use in science and/or citizenship)[28]
- *Community of Scientific Enquiry: Learning Science Through Dialogue* (ages 15–16, for use in GCSE Biology)[29]

While these resources are aimed at different age groups, all share a common structure: one or more starter activities; a trigger experience for students which consists of scientific information and/or experiments; a method for collecting the students' questions and deciding on the one to start discussing; an inquiry/discussion phase; and some sort of reflection on, or evaluation of, the inquiry. This is very similar to the Lipman model, except for the use of information sheets or experiments as the trigger for inquiry, instead of a story about similar-aged children discussing science.

As the overall title of the project implies, one of the emphases in the materials (particularly the *Forward Thinking* package) is on ethical implications and social impacts of science. Even with this package, though, the experience of the team is that students also want to explore philosophical questions about the nature of science and inquire into the science involved, including the meaning of scientific concepts (Dunlop 2012; Dunlop et al. 2011). The primary materials concentrate more on scientific content and processes – especially physics and chemistry – while the GCSE materials consciously target all these areas.

An integral part of the project involves evaluation of the impact of the scientific community of inquiry, though this is at an early stage. In the only peer-reviewed evaluation study published at the time of writing, Dunlop et al. (2011) present evidence that lower secondary students taking the programme enjoy their science more, engage with each other more, deepen their understanding of the science covered and correct and question each other more. Teachers agreed that better learning takes place and the quality of scientific reasoning improves and found that they had clearer access to student misconceptions. Several commented that the discussions worked best when the students had already been exposed to factual background

[29] Still in development

information, suggesting that the best time for a community of scientific inquiry may be after prior learning or research.

The materials are, at present, used by teachers involved in the project, who have engaged in training in their use and often have the in-class support of the researchers. The potential to publish the materials more widely exists, but it seems to me that they would require considerably more support material before teachers could use them effectively, independently. Such an outcome is desirable but may depend on continued funding.

48.3.4.4 Sprod's *Discussions in Science*

Finally, I have developed a suite of 18 connected short stories,[30] with teacher support material, for use in middle schooling (roughly, ages 10–14) (Sprod 2011). These include material from physics, chemistry, biology and the earth sciences and are designed to be used within a science programme, as they contain links to related experiments and theory. Their use follows the standard Lipman pattern of reading the story around the class, gathering the students' questions and entering a discussion based around the question chosen by the class. The teacher support material includes information about the scientific, philosophical, ethical and social issues that lie behind the stories, discussion guides (lists of questions that teachers may draw upon to unpack the issues) and suggestions for related activities, such as experiments or research projects.

Underpinning this approach, and in particular a number of the stories, are several research studies in which I participated. The first stories were written for an investigation of the impact of the scientific community of inquiry on students' ability to reason scientifically, which demonstrated statistically significant gains for the experimental group over a control group in a pretest/posttest design (effect size: 0.70) (Sprod 1998). Discourse analysis of the use of epistemic episodes (Sprod 1997a) in the discussion provided support for the interpretation that the improvements were due to the internalisation of improved group thinking in the class discussions. Both these papers contain transcripts of discussion excerpts from the experimental Year 7 (lower secondary) class.

The content of three of the stories in the collection are based on an investigation of how children come to understand the way light and vision are coordinated.[31] Characters in the stories represent different conceptions of the nature of light and how objects and the eye interact with light. Further stories likewise draw on a wide range of children's misconceptions, scientific theories, philosophical accounts, ethical controversies on scientific applications and my own experience of teaching science over many years.

The stories are linked through the narrative device of a group of children discussing their experiences of science and the world, trying to make sense of it. Thus, the

---

[30] These stories can be read at www.acer.edu.au/discussions-in-science/.

[31] Collis et al. (1998), Jones et al. (1997), Sprod (1997b), and Sprod and Jones (1997).

stories make use of the power of narrative, though they are different in conception from stories drawn from the history of science as discussed by Klassen and Klassen elsewhere in this handbook. Matters that are embedded in the stories include the teasing out of the meaning of scientific concepts, puzzles about scientific methodologies and the nature of science, ethical concerns about the practice and applications of science, and issues about the links between the science students are learning and their everyday lives. Throughout, both through the encouragement and modelling of rigorous thinking in the discussions and through explicit consideration, the skills and dispositions of scientific thinking are addressed.

In this list, we can see that the community of inquiry holds great promise for dealing with many of the concerns that form the subjects of chapters in this handbook. Further, by harnessing the power of narrative and drawing on the method of allowing the students to set the agenda from what they find interesting in the story, they can do so in a way that lends them ecological validity – they fit into students' expressed interests and connect to their lived experience. To pick only a handful of examples, I can instance conceptual puzzles such as those about energy (Bevilacqua), light (Galili) or ecology (Korfiatis, Lefkaditou & Hovardas); considerations of the methods and nature of science such as controversies in earth science (Dolphin & Dodick), understanding the purpose of practical work (Ford) or getting a feel for scientific inquiry (Kelly); inquiry into ethical issues (Cuoló); exploration of scientific modes of thinking such as the use of models (Kopenen & Tala), thought experiments (Asikainen & Hirvonen), coordination of the macro and micro levels (Guisasola) and the nature of scientific argumentation (Bravo); and finally links to the everyday through developing scientific literacy (Norris, Phillips & Burns) or considering multicultural issues in science (Horsthemke). All of these are raised at some level in one or other of my stories, for possible consideration in the scientific community of inquiry.

48.4 Summary

48.4.1 Survey of Conclusions

This chapter has surveyed briefly some of the research into the improvement of thinking through education and whether and how it might be taught, particularly in the context of science education.

As we have seen, the preponderance of the evidence is that thinking is complex – having at least critical, creative and emotional (caring) aspects – and always takes place within a context. Nevertheless, there is a core of general thinking that can be learned and used within one context and then, provided the conditions are right, transferred to other contexts. Moreover, considerable evidence indicates that we can improve children's thinking by developing their capacities and dispositions for higher-order thinking and strengthening their judgement. Whether we are right in claiming that we are accelerating development that would otherwise take place somewhat more slowly or that we are equipping them in ways that they may not otherwise achieve is not yet entirely clear.

The evidence also supports the view that good general thinking is supplemented by more specialised thinking capacities within different domains, though it seems these capabilities probably develop from more general ones. We might draw the conclusion from this that any general thinking skills programmes ought to be supplemented by attention to improving thinking within each discipline and hence in all subjects in schools. Alternatively, we might conclude that if each subject strives to improve thinking within its own domain, then there will be no need for a general thinking skills programme. Either way, there is a strong argument for including an explicit element designed to improve thinking in science courses at all levels of education. A meta-analysis of critical thinking courses (Abrami et al. 2008) bears this out in its finding that the most effective critical thinking courses combined an explicit focus on thinking capacities and dispositions with application to a particular content area.[32]

Concentrating further on thinking within the domain of science, we have seen that scientific thinking seems to draw on both the general thinking capacities and dispositions that apply across all domains and more specialised scientific thought processes (which are, in any case, not identical in all scientific categories). Just what the categories and attributes of such advanced scientific thinking are does not seem to have been researched in sufficient detail. Moreover, there has been little work done on exactly how young children – who in their science lessons are presumably utilising generic thinking – develop through their education (primary, secondary and tertiary) the more specialised scientific thinking required by professional scientists or, more importantly for most, scientifically literate citizens.

Nevertheless, we do have a good deal of evidence that the teaching of scientific thinking is not done particularly well in schools at present. In large degree, this seems to be because the improvement of scientific thinking needs to have an explicit focus in science lessons, while generally it does not. While there are copious case studies in the literature of individual teachers whose teaching style does encourage better thinking by making it explicitly visible to students, such approaches have not been widely implemented at a system level.

However, we have seen that there are good models, supported by robust research, for such an approach, and have looked in some detail at two: the Cognitive Acceleration through Science Education and the Philosophy for Children programmes. It seems clear that both programmes (together with the Conceptual Challenge in Primary Science project) share some important and powerful features. They 'begin in wonder' (puzzlement, cognitive conflict), as Aristotle (1998, 982b12) put it in Book 1 of the Metaphysics; use rigorous dialogue (social construction); turn attention explicitly on the thinking taking place (metacognition); and address transfer or bridging, all in the context of science. In other words, such programmes make both student and teacher thinking – and the quality of that thinking – the

---

[32] They also found that including explicit thinking outcomes in the aims of the course and providing professional development for teachers in the improvement of critical thinking were important factors.

subject of an inquiry visible to all: it is ‘minds-on’ science. The obvious conclusion is that other science programmes, provided they incorporate similar features, are likely to be similarly effective.

48.4.2 A Challenge to These Conclusions

Reconsidering his 2004 paper that largely agrees with the conclusions above, Davson-Galle (2008a, b) has called into question, firstly, whether it is legitimate to teach the nature of science and critical thinking within science at school and, secondly, even whether we can justify compulsory science courses at all. There are two major grounds for these challenges. The less radical is based on a cost-benefit analysis: would the time allocated to such aims be better spent in teaching something else – say, more science content? More controversially, he questions the legitimacy of overriding students’ autonomy in compelling them to study science. As he acknowledges, this latter challenge can be applied to much, if not all, of education.

Turning to the first challenge, I believe that Davson-Galle has created a false dichotomy: either we teach scientific thinking and the nature of science or we teach science content. Doing one can only be at the expense of the other. Consideration of the research cited above – particularly the longitudinal studies in CASE – seems to show that sacrificing curriculum time to the improvement of scientific thinking does not result in students learning less scientific content, at least as measured by outcomes in later science external exams. Rather, it makes the learning of science content faster and more effective. The evidence for learning about the nature of science is less clear cut, as it has not been as explicitly tested, but if that learning is merged with the improvement of scientific thinking, through a dialogical pedagogy, there are reasons for thinking that similar claims are justified. However, there is probably a need to test this hypothesis more directly.

Davson-Galle’s second challenge is somewhat beyond the scope of this review. However, I believe that it is based on a misconception of the notion of autonomy, which assumes that it is a characteristic that students just have. In my view, autonomy is rather a capacity which students develop, particularly through improving their ability to think well – see my analysis of communicative autonomy in Sprod (2001, especially Sects. 2.4, 2.5, and 3.2). Our justification for compulsory education is then that it is an effective way to build autonomy and that the more an educational programme contributes to such building, the more justified it is.

48.4.3 Further Work

Given that such programmes are not as widely included in science courses as perhaps they ought to be, I will finish by considering what further work is needed. It seems to fall into three categories.

Firstly, the research foundation for improving the teaching of scientific thinking could be considerably stronger. Both CASE and P4C (though, for the latter, not in the context of science education) have research to indicate that long-term, far transfer of the improvement of thinking takes place. However, these studies have not been fine grained enough to explore the relative impact of the various factors I have mentioned above, let alone variations that arise from differences in the way they are implemented or the cultural context in which they are applied.[33] Adey et al. (2007) are surely right to call for more research that uses large-scale longitudinal studies, well designed to tease out such factors, across a variety of social settings. We need to refine our understanding of the conditions that are truly effective in developing scientific thinking in all its aspects, and we need to study whether the various programmes have other desirable effects, such as strengthening learning communities, enhancing enjoyment of science, improving ethical judgement in matters scientific, illustrating the nature of science and deepening conceptual understanding.

Moreover, we can question how we ought to interpret ‘long-term, far transfer’. Certainly, both the CASE and the Tricky and Topping P4C research show measurable effects several years after intervention finishes. But is this long term enough? Surely we would want to see effects that last well into adulthood, and the research to show this has not been done (indeed, such research faces considerable practical difficulties). Additionally, the CASE studies did not test the long-term maintenance of improvements in thinking directly. Rather, results of external exams or testing were used as a proxy. We are only surmising that the experimental students still think significantly better than their control peers.

Of course, showing effects on more general tests does strengthen the claim for far transfer, especially when the CASE work shows effects outside the science domain. But we can question whether the effects extend even further: into thinking in everyday life, or in making citizenship decisions, to choose two examples.[34] Such claims are often made, but research backing for them is lacking. While it is desirable to improve students’ exam results and to foster more and better research scientists, for a far greater proportion of students, the justification for seeking to improve scientific thinking rests rather on creating thoughtful and scientifically literate citizens. We ought to be gathering evidence to allow us to ascertain whether such outcomes occur.

Secondly, one of the factors not addressed in much of the research done so far is the impact on the success of such programmes of the background, attitude and competence of the teachers who deliver the programme. Much of the research surveyed in this chapter investigated the impact of the researcher’s own teaching on thinking (especially in the small-scale studies) or that of teachers who had volunteered to

---

[33] Indeed, we should note that, as correlational studies, such research does not show conclusively that improving students’ scientific thinking through dialogue causes better science learning and hence exam results. It is possible that some other factor – such as an improved attitude to science – is at play.

[34] Note that this possibility depends on such programmes encouraging generalisation of thinking abilities across contexts – a matter discussed in Sect. 48.2.1 above.

take part, often because they were already experienced in the programme being studied or because they had a long-standing sympathy for such approaches. Clearly, such studies are open to experimenter effects. If such programmes are to be widely implemented, then teachers from all sorts of backgrounds, with a variety of prior training and quite diverse attitudes towards what constitutes good science teaching, are going to be involved. Only large-scale studies that recruit all (or a random sample of) the teachers in the study population to implement the programme are going to be able to tell us about the impacts of such teacher attributes on the success of the programmes. Indeed, the research design of such studies will need to ensure the right data are collected to give us better knowledge of teacher effects.

Such considerations bring us to the third reflection. Successful implementation of effective ways of improving scientific thinking will depend on having capable, well-trained teachers delivering them. Research repeatedly shows that teachers are the most important in-school factor in student achievement: the ‘evidence supports the assertion that the effects of teachers far exceed the independent effects of schools’ (Manzano 2000, p. 60).

Yet Adey and his colleagues comment that teaching in a way that improves students’ scientific thinking:

> is difficult to do. Teaching for cognitive stimulation is far more demanding, and seems far more risky in the classroom than is efficient instruction in content matter. Amongst others, Adey et al. (2004) have described the extent of the conceptual-pedagogical change that teachers must make to move from one form of teaching to another. (Adey et al. 2007, p. 93)

Given this, the training provided to teachers needs to be effective in helping them to make permanent modifications and additions to their practice, whether it is delivered during initial teacher training or to teachers already working in schools. Such effective professional development, of course, requires capable providers and can be resource hungry. Again, research into the efficacy of professional development and the factors that make it more effective could assist us to improve such provision.

Finally, there is a need to develop more materials to support teachers in this modified approach to science education. While the CASE materials do provide a coherent set of activities for the first 2 years of secondary school, as well as the *Let’s Think Through Science* books for 7/8-year-olds and 9/10-year-olds,[35] these activities address only parts of the science that students could be learning and are tied to the English National Curriculum. Moreover, they tend to target particular scientific thinking capabilities, rather than content areas. In the P4C field, the materials available are even less systematic. Thus, teachers looking for an activity to engage in ‘minds-on’ science that specifically fits into a unit they are developing are unlikely to be able to find one. Science teaching has multiple aims, among them ones like covering content and developing practical skills, which are probably not best approached through the discussion-based activities considered in this chapter. A teacher who is trying to put together a unit of work in science that covers all these

---

[35] See http://www.cognitiveacceleration.co.uk/resources/other_subject_resources.html.

aims will be looking for an activity that fits in neatly: at present, the choice is limited. Moreover, there is not an even coverage over all the subdisciplines of science, with perhaps an overemphasis on the life sciences.

In summary, then, this chapter makes the case that it is possible, by making the right sorts of additions to the pedagogical toolboxes of teachers, to deliver science education courses in a way that strengthens students' scientific thinking, as well as other desirable outcomes: a deeper understanding of the concepts of science, the nature of the scientific endeavour, the ethical implications of science and greater links between the science learned and the students' everyday lives – arguably, without sacrificing student mastery of scientific content and skills. At the core of the successful methods lies discussion that is recognisably philosophical.

Tim Sprod runs workshops internationally for teachers of philosophy in schools (focusing particularly on science and ethics education), and the International Baccalaureate's Theory of Knowledge programme. Previously, he was the inaugural coordinator of the IB Diploma at The Friends' School in Hobart, Tasmania. He holds a B.Sc. in geology/geophysics from the University of Tasmania; a PGCE from the University College of Wales, Aberystwyth; an M.Ed. investigating the efficacy of discussion in science teaching from the University of Oxford; and a Ph.D. exploring the role of philosophical discussion in ethics education from the University of Tasmania.

His science and philosophy teaching experience covers more than 25 years in Australia, United Kingdom, Papua New Guinea and the Bahamas, at all levels from kindergarten to university undergraduates. As a past secretary of the International Council for Philosophical Inquiry with Children and past chair of the Federation of Australasian Philosophy in Schools Associations, he has an international reputation in the Philosophy for Children movement.

Tim's most recent publication is *Discussions in Science: Promoting conceptual understanding in the middle school years*, a practical book for teachers on the use of philosophical discussion in science classrooms (ACER, 2011). Past books include *Books into Ideas* (Hawker Brownlow, 1993), *Places for Thinking* (with Laurance Splitter, ACER, 1999), *Philosophical Discussion in Moral Education* (Routledge, 2001) and *IB Prepared: approach your assessment the IB way – Theory of Knowledge* (with Antonia Melvin, IB, 2010).

Chapter 49
Informal and Non-formal Education: History of Science in Museums

Anastasia Filippoupoliti and Dimitris Koliopoulos

> *I, Clio the Renowned, eldest daughter of Mnemosyne, Muse of History, warden of memory, wish to teach men lest they neglect the past of their knowledge as of their ignorance.*
>
> (Jean Marc Levy-Léblond 2012)

49.1 Introduction

History of science has a long presence in formal science education. During the late 1960s and early 1970s, an educational movement emerged (mainly in the Anglo-Saxon literature) that argued for the benefits of using the history of science in secondary education. Initial references also carry some preliminary perspectives on the advantages and disadvantages of such a partnership (Brush 1969, 1974; Klopfer and Cooley 1963). These perspectives characterise the research field diachronically, but the issues of instructional strategy choices and methodological techniques with which history of science can be effectively linked to science education are still open research questions.

The use of history of science in formal education is related to three trends in educational research:

1. A humanistic approach to science teaching that aims to contribute to the 'broad cultivation' and scientific literacy of pupils as citizens (e.g. Klopfer 1969; Langevin 1964; Matthews 1994/2014)

A. Filippoupoliti (✉)

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_49,

2. The development of student understanding of the nature and characteristics of scientific knowledge, mainly via the 'nature of science' educational movement (e.g. Hodson 2008; Lederman 2007)
3. The cognitive development of pupils and the shift of interest from methodological to conceptual dimensions of scientific knowledge (e.g. Monk and Osborne 1997; Nersessian 1992; Strauss 1988)

Despite the increasing influence of the history of science in formal science education during recent decades, one cannot ignore the difficulties and the obstacles that a broader educational use of the history of science faces. Among these, Hottecke and Silva (2010) refer to the negative stance of educators to any proposed change to the traditional teaching culture and the boundaries imposed upon educators by the official science curriculum that either ignores or degrades the role and importance of history of science in teaching.

It is interesting therefore to examine what happens with the kind of dissemination of history of science that originates or relates closely to the modern science museum. The dissemination of history of science is related in this case with informal and non-formal educational approaches.[1] What are the aims of this sort of dissemination, how are they achieved and how are they related to non-formal and informal education? The present review aims to bring forward these issues and open a potential academic discussion. We first discuss the types of museums that have been developed; we then analyse the history of science as an exhibition and communication element; and finally, we approach the subject as an educational element. The review will not address how the science museum is being treated as a research subject itself by historians of science.

49.2 A Definition of a Science Museum and the Types of Science Museums

Museum studies have grown since the late 1960s following a considerable rise in the number and types of museums worldwide. Museum studies literature offers a wealth of definitions and classifications of museums organised mainly according to

---

[1] In the present article, the terms *informal education* and *non-formal education* are considered as distinct terms (Coombs and Ahmed 1973; Escot 1999; Eshach 2006). An *informal* educational process is not an organised and systematic one that occurs in different educational settings (schools, museums etc.). It is a process – quite often unintentional – offered by the personal environment of an individual. The interrelationship between the individual and the exhibition during a museum visit is a typical example of an informal educational process. In contrast, *non-formal* educational environments are related to autonomous cultural institutions that provide scientific knowledge, such as museums, and are environments that offer organised educational activities (as in the case of educational programmes in museums or programmes that are organised between school and museum).

the academic disciplines to which they refer through their collections, exhibitions and public programmes.

The science museum is not a homogenous entity. The nature and characteristics of the science museum can be studied through the variety of categorisations produced by both museum professionals and museum researchers. These categorisations group museums based either on the way in which these institutions confront collecting, displaying and interpretation of objects and the way they conceive exhibition space (Wagensberg 2004) or on the evolution of the science museum (de Clercq 2003; Friedman 2010). The latter are significant not solely because the history of the museum as social institution as demonstrated by the related literature on the history of museums and collections is a vital subject (Arnold 2006; Findlen 1989, 1994; Impey and MacGregor [1985] 2001; Yanni 1999), but also because this literature can be used to interpret the function of modern science museums by either researchers coming from fields of inquiry other than museum studies (i.e. science educators) or by science teachers (Koliopoulos 2003).

A history of the science museum goes back to the Renaissance collections of curiosities and learned cabinets (e.g. the cabinet of Francesco I de Medici in Florence (Findlen 2000; Pearce 1993) and the collections of seventeenth-century philosophical and scientific institutions (e.g. collections held by the Royal Society of London). During the second half of eighteenth century, along with the founding of the first public museums, a number of museums of natural history were established. Unlike the earlier cabinets, these were public institutions allowing a large number of visitors into their exhibition spaces. In addition, the galleries exhibited objects according to a classification system that was closely adapted to distinct academic disciplines.

These institutions praised the collected object (e.g. scientific instruments, natural history specimens and technological artefacts), accumulated natural curiosities and man-made artefacts and favoured the wooden or glass-case presentation. The *Musée des Arts et Métiers* in Paris is an exemplary case reflecting this exhibition philosophy (Ferriot and Jacomy 2000). There the visitor was considered a passive admirer of a glorious scientific past. The act of interpretation was not facilitated by the museum curator, although some interpretation was provided by a few means such as the object's label. In this context, scientific objects were displayed as art objects and admired by the upper class (Bennett 1995). The *Natural History Museum* in London took a similar approach.

University science collections fall into the same category given that most of them have been created to act as repositories of worn and outdated scientific apparatus once used in the teaching of physics and chemistry or collections of objects related to the natural sciences (e.g. stuffed animals). The museum of the King's College London that was founded to host the King George III science collections in mid-nineteenth-century London is an interesting case in point, yet by the end of the century it had become a mere repository (Filippoupoliti 2011).

Between the middle of the nineteenth century and World War II, another type of museum emerged that differed from the traditional museums just described. During this time, museums also embraced an explicit educational mission following the mid-nineteenth-century demand for educating the lay public. Interpretation of the exhibition was performed by presentation of a series of objects that reflected a certain scientific concept or idea, and an attempt was made to form concise units according to certain scientific themes (e.g. energy, power, physics etc.). The *Science Museum* in London (est. 1885) and the *Deutsches Museum* (est. 1903) in Munich are examples of this category, although in recent decades these museums have enhanced the exhibition space with modern design and interactive exhibits. Along with the older galleries, a series of interactive hands-on exhibits are presented to update the established scientific narrative (Durant 2000). This category also includes the *Museum of the History of Science* at Oxford (est. 1925) and the *Whipple Museum of the History of Science* at Cambridge (est. 1944), the former *Istituto e Museo di Storia della Scienza* now the *Museo Galileo* (est. 1927) in Florence and the *Museum Boerhaave* (est. 1928) in Leiden, Holland (de Clercq 2003).

Although science centres differ from science museums, they are usually treated together in the literature. A science centre has a distinct experimental philosophy that moves from the display of the authentic object to create an original/meaningful museum experience through active visitor participation. Beyond object worship, it is the exhibition space that matters more as it assimilates the laboratory, a gallery of research and a place of demonstration. Historically, this type of a science institution can be traced back to the 1930s, when the *Palais de la Découverte* in Paris was founded according to a rationale relevant to the division of academic scientific disciplines, followed by the San Francisco *Exploratorium: The Museum of Science, Art and Human Perception (*est. 1960s), which is regarded as the 'father' of science centres (Hein 1990; Cole 2009). Another example is the *Cité des Sciences et de l'Industrie* in Paris, in which the focus of exhibition activity is the social use of natural sciences and technology (Caro 1997; Zana 2005). This science centre has created a special children's science museum that offers exhibitions and activities designed to address the cognitive and emotional needs of young children (Guichard 1998).

The development of science centres has considerably influenced museological approach and museographical practice of even the most traditional museums. For example, the recently renovated *Museo Galileo* in Florence and the *Museum of the History of Science* at the University of Oxford have improved their approaches to the display of objects. They have modernised the permanent and temporary exhibitions as well as their communications approach to the public (e.g. including new interactive activities as part of an exhibition and providing virtual tours via the museum website). The hybrid form that such museums have become raises the issue of establishing a new educational identity for these institutions (Quin 1993).

We pose the following questions which we will tackle in the following section: How does each of the science museum types implement the history of science in exhibition and educational practice? What sort of interpretation do they offer? Do each of these different interpretation patterns offer the same epistemological status and give a certain communication role to the history of science? Does the history of science constitute one of the seminal elements in the diffusion of scientific knowledge communicated via science museums, or are museums designated solely for the history of science the only appropriate institutions to research, exhibit and diffuse objects, ideas and issues related to the history of science?

49.3 History of Science as an Exhibit and Communication Element

History of science is an exhibited theme found in a variety of museum types. Museums of the history of science distinctly safeguard, interpret and display the material culture of science (Bennett 1997, 2005; Camerota 2011). Museums of the history of science are usually university museums that base their foundation on collections of scientific instruments and apparatuses once used in research and university teaching or on private collections that have been donated to the museum. Two characteristic examples are the *Museum of the History of Science* in Oxford (established 1924) by the gift of the collection of Lewis Evans[2] to the University and the *Whipple Museum of the History of Science* at the University of Cambridge founded in 1956 to house Robert Whipple's[3] collection of scientific instruments and rare books (Bennett 1997; Taub and Willmoth 2006). In these institutions, the history of science is present in many ways, most importantly in the use of elements of the history of science in exhibitions in which a part or the majority of the scientific collections (authentic scientific instruments or biological specimens) are used.

How then does a museum of the history of science differ from a science museum? Bennett (2005) notes that

> museums of the history of science contain old instruments and apparatuses, just like any science museum … If it is not the nature of the collections that is different, it should be the assumptions about what the collections are for, which will inform how they are selected and how they are used. (pp. 606–607)

Because of their privileged relationship with academic history of science, museums of the history of science can certainly provide exhibitions of their collections that gain their meaning from the cognitive, methodological and cultural dimension of the history of science.

Another category of science museum where history of science is present includes those institutions whose historical tradition, collections and particular museological/museographical approaches make possible the presentation of a history of science exhibition narrative even though the history of science is not a distinct part of the institutional mission such as university museums that hold collections of scientific instruments and natural history and biological specimens (Tucci 2002; Lourenço 2005; Subiran et al. 2009). One difficulty that this type of museum confronts in presenting collections to the broader audience is the absence of a unified and coherent theme

---

[2] Lewis Evans (1853–1930) was a collector, brother of the notable archaeologist, Sir Arthur Evans, who excavated the Palace of Knossos, Crete (Greece). See also P. de Clercq, Lewis Evans and the White City Exhibitions, *Sphaere. The online journal of the Museum of the History of Science, University of Oxford,* available at http://www.mhs.ox.ac.uk/sphaera/index.htm?issue11/articl4.

[3] Robert Stewart Whipple (1871–1953) donated more than 1,000 scientific instruments to the University of Cambridge in 1944. See also S. De Renzi (1998). Between the market and the academy: Robert S. Whipple (1872–1953) as a collector of science books. In R. Myers and M. Harris (eds), *Medicine, Mortality and the Book Trad*e (pp. 87–108). St. Paul's Bibliographies: Oak Knoll Press.

topic that could become the basis of an institution recognisable by non-experts (Antoine 2010, p. 9). One such theme topic, according to Antoine (2010), is the implementation of the scientific method via elements from the history and philosophy of science.

Non-university museums such as the *Musée des Arts et Métiers* in Paris and the *Science Museum* in London that hold scientific collections are good examples of this category of museum. Although their original aim was not the dissemination of the history of science,[4] today these museums are ideal places for the display of science because of the richness of their collections. Also, institutions such as centres of scientific research and for the popularisation of science (e.g. *Royal Institution of Great Britain*), scientific institutions (e.g. *Royal Observatory*, Greenwich, England) and laboratories or the private premises of eminent men of science that have become house museums (e.g. the *Charles Darwin Down House* in England and the *Maison d'Ampère* in France) are potential places for disseminating the history of science.

The implementation of history of science can differ among museums according to their type. Studying three institutions that display collections of historic astronomical instruments, Maison (2002) suggested three different ways of exhibiting such collections. The *Musée des Arts et Métiers* emphasises the technological dimension of the displayed scientific instruments, and the exhibition is based on historical evidence that presents a holistic view of the technical culture from Renaissance to the present day. In contrast, the *Observatoire de Paris* emphasises the concepts of the physical sciences and how these are intertwined with the function of astronomical instruments. Finally, the *Royal Observatory of Greenwich* displays collections with the aim of presenting the social and economic aspects related to the development of astronomy research over time.

Finally, even though science centres don't hold any permanent collections of authentic/historical objects, occasionally they may host temporary exhibitions that present elements of the history of science. These centres seem to function as contemporary scientific textbooks that, according to Kuhn, can hide the process of how scientific knowledge is obtained. If someone replaces the word 'textbooks' with 'science centres' in the next extract, the meaning would not be twisted:

> Textbooks thus begin by truncating the scientist's sense of his discipline's history and then proceed to supply a substitute for what they have eliminated. Characteristically, textbooks of science contain just a bit of history, either in an introductory chapter or, more often, in scattered references to the great heroes of an earlier age. From such references both students and professionals come to feel like participants in a long-standing historical tradition. Yet the textbook-derived tradition in which scientists come to sense their participation is one that, in fact, never existed. For reasons that are both obvious and highly functional, science textbooks (and too many of the older histories of science) refer only to that part of the work of past scientists that can easily be viewed as contributions to the statement and solution of the texts' paradigm problems. Partly by selection and partly by distortion, the scientists of earlier ages are implicitly represented as having worked upon the same set of fixed problems and in accordance with the same set of fixed canons that the most recent revolution in scientific theory and method has made them seem scientific. (Kuhn 1970, pp. 137–38)

---

[4] Moreover, history of science as an academic discipline emerged later.

What is the mode of history of science as an *exhibition narrative*? Which one of the history of science narratives one occasionally confronts in museum exhibitions? Are historical facts explained and interpreted? Is emphasis being given to historical moments/turning points and the importance of controversies and scientific revolutions? Is it more important to research science as a social action that is formed by the social-historical-cultural context? Or is it more seminal to trace the history of science as a history of ideas or as an exploration of the material culture and non-literary traditions? A first attempt to answer these questions will be presented in the following paragraphs.

Even though history of science as an academic discipline emerged during the first part of the twentieth century, historic scientific instruments were already on display by the second half of the nineteenth century in museums such as the King's College London King George III Museum as well as in international/world exhibitions such as the Special Loan Exhibition in London in 1876. Historian Steven Conn has called the museum exhibition culture of that period an 'object-based epistemology' (Conn 2000). According to that perspective, the exhibited object (e.g. a scientific instrument) is able to confirm and support the 'scientific power' of a phenomenon or an idea and therefore as a historic object can stand as a symbol of scientific progress. For many decades in the early twentieth century, museums preserved the type of museological narrative that they inherited from their nineteenth-century predecessors. For instance, scientific instruments and apparatuses were preferably displayed in a thematic way, and their mode of display reflected an encyclopaedia of natural sciences in which each displayed object stood for a particular scientific phenomenon or process.

During the 1980s, shifts in the museological and museographical approach to science museums (Schiele and Koster 1998) in research trends in the history of science and in the increasing interest of historians of science in science collections led to important changes in the ways museum curators displayed the history of science in exhibitions. At least three epistemological approaches can be identified in these museum exhibitions. The first approach is the traditional one mentioned earlier that treats the history of science as the documentation of objects and facts. The second approach treats the history of science as a history of ideas and is not broadly used to weave a narrative into a science exhibition. In this case, the authenticity of the science collection is of minor importance (i.e. whether objects are historic scientific instruments or reconstructions). Emphasis is being given to how an idea (or ideas) is born, developed and cognitively treated in order to give meaning to objects. The *Grande Galerie de l'Evolution* of the *Muséum National d'Histoire Naturelle* in Paris focuses on the evolution of species (Van Praet 1995). Other examples of such an exhibition approach include the following: The exhibition 'Exploring the World, Constructing Worlds: Experimental Cultures of Physics from the sixteenth to nineteenth Century' in the *Museum of Natural History and Pre-History* in Oldenburg, Germany (Heering and Muller 2002), which addresses issues such as 'astronomical and experimental practice in the sixteenth and seventeenth centuries' and 'the science of precision measurement in the nineteenth century' and the Galilean exhibit of the *Exploratorium* in San Francisco, entitled ‘The Gravity-Powered Calculator’, which was also reconstructed by Cerretta (2012).

Exhibitions belonging to the above-mentioned two categories aim at disseminating the content, the process and the product of science from an internal point of view, the view of science. In contrast, a third approach considers trends in the history of science literature that view science as an example of culture with particular practices and tools that are affected, developed and transformed according to the cultural and historical context in which they have been developed, including non-scientific factors (Golinski 1998; Galison and Thompson 1999; Daston 2000).

In addition, the emergence of Social Studies of Science since the 1980s has provided researchers with fresh perspectives on understanding the intersection of scientific practice and culture (Latour and Wooglar 1986; Latour 1987). In this context, emphasis is given to how scientific practice is being formulated in the laboratory and in the performance of crucial experiments (Arnold 1996; Chittenden et al. 2004). For instance, the exhibitions hosted at the *Wellcome Collection* of the Wellcome Trust in London and the temporary exhibitions hosted in the Science Museum in London and the Nobel Museum in Stockholm are examples of cultural turns in the reading of the history of science.[5] From the perspective of science education, Pedretti (2002) also refers to the use of the history of science by science museums addressing socioscientific issues.

The above-mentioned modes of introducing the history of science in museums lead to informal education and informal learning. Museum visitors and school groups in particular can gain an interest in science as well as gain a popularised conception of the content and method of science (Stocklmayer et al. 2010). However, this kind of popularisation eliminates the systemic dimension of the meaning of scientific and historic knowledge and consequently sometimes deforms and transforms it to such an extent as to alter totally its meaning and, in still other instances, leads to paradoxical assertions (Jacobi 1999; Jurdant 2009). The risks stemming from the popularisation of scientific and historical knowledge could possibly be reduced if museums place more emphasis on the educational dimension of communication and on their function as institutions for non-formal education (Escot 1999). This issue will be analytically treated in the following section.

49.4 History of Science as an Educational Tool

Science museums are gradually increasing their emphasis on their science education functions (Teichmann 1981; Tran 2007; Stocklmayer et al. 2010). Museums produce a wealth of educational material for all types of visitors, the design of which varies according to type, content and creator. For instance, some materials are composed by

---

[5] See, for example, the Nobel Museum Centennial exhibition *Cultures of Creativity* (Stockholm, Sweden) which examines creativity in science. Available at http://www.nobelmuseum.se/en/exhibitions/cultures-of-creativity

in-house museum professionals linking the programme directly to certain exhibits and perhaps implying that an exhibit can easily be transformed to educational material.

Many science museums design programmes in collaboration with schools and other educational institutions, either because they seek to consider the concerns raised by such institutions or because they seek theoretical and/or practical tools to support exhibit design. University departments that offer postgraduate museum studies courses or science education courses provide essential support towards the design of meaningful educational programmes for museums' visitors. Does the history of science have a specific role in the design of museum educational programmes? Do science museum professionals need formal education about how to give certain meanings to science collections through the aid of history of science, exhibitions and associated narratives? Or, is non-formal/informal education sufficient to act as a means of diffusing scientific knowledge?

Our review of the educational tools used by museums to communicate the history of science elements identified four categories of educational material:

(1) *Guided tours focused on narratives from the history of science.* This is the simplest educational intervention, engaging the history of science in a sequential science museum-guided tour. These tours typically present stories of people, ideas and/or practices from the history of science field and may contribute to raising the interest of visitors for the exhibition or to making meaning from an exhibition.

    For instance, Fadel (2011) uses history of science elements in lectures given during the performance of experiments at the *Palais de la Découverte* in Paris. He notes that the history of science can be a very powerful tool for introducing a new concept, idea or theory. Sometimes, stories and anecdotes taken from history are helpful as brief breaks to keep the attention of the audience. In other cases history can help people realise how answers to questions always seem obvious when one already knows the answer but seldom are apparent beforehand (Fadel 2011).

    In formal education, the design and narration of stories that introduce elements of the history of science is a common practice (Stinner et al. 2003). Unlike formal education, during a guided tour in the museum, the guide cannot expand the narration to explain a topic in detail. In this context, guided museum tours using narratives from the history of science are the weakest type of educational programme for presenting the history of science.

(2) *Museum educational programmes/workshops.* These activities are designed mostly for students and teachers, not the general public. In many instances, these programmes are developed and performed by specialised museum educators (Tran 2007). The *Deutsches Museum* is one example of a successful implementation of history of science elements in museum educational programmes. Teichmann (1981) points out that

    > historical objects displayed are to be integrated into the other educational activities of the museum and not simply remain commemorative pieces; i.e. historical collections and modern didactics are to be united according to the following aspects: (a) often modern situations can be clarified by means of historical explanations; (b) the completely different conditions of the past and the then existing specific difficulties in the realization of new

> knowledge, can offer a valuable lesson in questioning the apparently foregone conclusions of today; (c) the incorporation of modern and historical objects into the framework of human science and cultural development, can exhibit the characteristic position of science and technology (p. 474).

Educational programmes are structured educational environments designed to acquaint students and teachers with scientific and historical knowledge in a systematic way. For example, the context for knowledge could be the experimental history of physical sciences (Sibum 2000), the construction of concepts and methods via the reconstruction of artefacts or historical experiments (Teichmann 1999; Heering and Muller 2002) or the historical development of our understanding of the taxonomy of biological organisms (Faria et al. 2012).

(3) *The collaboration between museums and formal education.* Many researchers have argued that the collaboration between school and museum can promote achieving both cognitive and emotional student outcomes. A number of studies suggest that the museum visit and the children's activities during the visit should be accompanied by school before and after the visit (Griffin and Symington 1997; Anderson and Lucas 1997; Anderson et al. 2000; Guisasola et al. 2005; Guisasola et al. 2009). Other researchers claim that the involvement of teachers in non-formal educational settings such as science museums should be part of teacher training in science and pedagogy (DeWitt and Osborne 2007).

Unfortunately, studies of the development and evaluation of educational programmes in museums that introduce elements of the history of science are few. Anderson and colleagues (2011) describe a museum workshop about the role of artefact analysis/manipulations on research and teaching in the history of science and technology. In this study students from university departments of education also addressed this subject during classroom coursework using Eotvos torsion balance, an instrument used to measure small gravitational variations. Students constructed three narratives related to the science of geodesy and discussed issues related to laboratory practice and the nature of science.

Falomo-Bernarduzzi and colleagues (2012) have developed activities related to Galileo's laboratory that are designed to take place either in the museum or in the school and explain that these

> activities do not 'incidentally' interest schools, because they happen to connect with the school curriculum, but they are thought out with each school for the school. These workshops give clues which are the starting points for classroom activities linked to the project but also part of normal school learning. (Falomo-Bernarduzzi et al. 2012)

The researchers describe projects that rely extensively on the history of science in a number of ways using primary and secondary sources, museum exhibitions, multimedia and hands-on reconstructions of historical experiments. More specifically, they present activities that are based on the exhibition 'Laboratorio di Galileo' which includes reproductions of the apparatuses designed and used by Galileo for his experiments in mechanics.

Finally, Paparou (2011) describes lecture-demonstration activities created and performed by teachers in the classroom using collections of scientific instruments from the local *Museum of History and Physics* of the first high school of Chios

Island (Greece). Examples of such lecture-demonstrations include ‘The first days of electricity’ and ‘The history of magnets and compasses’. During these programmes, participants were invited to observe and compare scientific instruments, conduct experiments and evaluate the experimental results, make explanatory hypotheses and explore historical scientific documents (Paparou 2011).

All the educational attempts that were discussed in the previous sections focus on the study of scientific instruments and experiments as tools for educating students and teachers about history of science issues in the context of collaboration between museums and formal education institutions. It is apparent that such a collaboration can play a seminal role in evaluating and transforming scientific collections (original/historical collections, digital collections or collections of reconstructed instruments) from tools of research to tools of education (Heering 2011).

49.5 Conclusion

The variety of reviews that refer to the introduction of elements of history of science in primary and secondary school (Matthews 1994/2014; Duschl 1994; Seroglou and Koumaras 2001; Hottecke and Silva 2010) indicates the systematic and continuous involvement of historians of science and science educators with the issue of introducing elements from the history of science into formal science education. In contrast, as the present review has shown, the study of the role of the history of science in informal and non-formal science education is heterogeneous and fragmentary. It is necessary to raise new research questions and construct new lines of research to investigate the subject in a more systematic way.

We have suggested three lines of research strands below:

(1) *The epistemological research strand.* This strand refers to those research questions primarily of interest to science museum professionals related to the role that history of science can play in the realisation of the communication and education objectives of museums. How and why can the history of science as presented through museum collections contribute to the rescue, preservation and diffusion of scientific heritage and culture at local, national and international levels? Lourenco (2012), for example, suggests that

> the increased interest by the historian of science creates opportunities for a more significant role of history in museums of science, potentially resulting in better documented collections, as well as more meaningful and contextualized exhibitions and educational programmes. However, more history in museums of science requires considerable structural and cultural changes in their traditional missions, roles and practices. (Lourenco 2012)

On the other hand, primary questions that in our opinion should concern science centres that aim at the diffusion and popularisation of modern scientific knowledge are the following: Is it possible, and if so, how could the history of science contribute to reducing the ever-growing gap between the production of scientific knowledge and its understanding by lay people? How could the history of science contribute to restorating the relationship between science and culture that has increasingly soured since the early twentieth century? (Bensaude-Vincent 2001; Lévy-Leblond 2004). Is it possible to incorporate the narrative of the history of scientific ideas into the narrative of the modern world and its relationship to contemporary society, or should they be considered two epistemologically incompatible narratives? These questions are also interrelated to the following research strand.

(2) *The museological/museographical research strand.* This strand is mostly related to the way in which science museums take into account the history of science and translate it into a communication and educational tool to achieve their educational mission. Historians of science, museologists and possibly science educators need to collaborate towards that end. Referring to collections and exhibitions of the *Science Museum* in London, Bud (1997) noted that

> before the Second World War the progressivism of the galleries and the inspiration of its greatest icons mostly matched the views of academics. However, the post-war years, which saw an efflorescence of paper-based historiography of science, saw too a decoupling between the interests of academics interested in intellectual process and of curators focused upon their objects. This decoupling meant that the history of science of which the Museum was the public space, was somewhat distanced from the burgeoning academic discipline. (pp. 50–51)

Bud makes clear that exhibitions of science act as important means of transformation of scientific knowledge, scientific and social practices and authentic objects to content, exhibits and forms of display, so that they could be successfully communicated to broader audiences. The concept of ‘mediating transposition’ used by Guichard and Martinand (2000) and the ‘museographic transposition’ used by Simonneaux and Jacobi (1997) constitute a proper context in which exhibitions that introduce elements of history of science used in combination with contemporary communication strategies and museographical techniques could be analysed or designed. In this context, further research questions could be posed in the following broad areas: (a) in relation to the deconstruction and reconstruction of a historical subject in science and the identification of possible related misconceptions often found in exhibitions (i.e. epistemological analysis, see Foss Mortensen 2010) and/or (b) the decoding and recoding of messages, if we regard exhibitions as pedagogical multi-modal texts (i.e. semiotic analysis, see Anyfandi et al. 2010).

(3) *The learning/pedagogical research strand.* In this noteworthy heterogeneous strand, the main issue is the investigation of learning in informal and non-formal settings and more particularly if and how cognitive progress of visitors is achieved during a science museum visit (e.g. Anderson et al. 2003; Martin 2004; Griffin 2004). Can history of science maximise visitors’ learning best when designed as a communicational element or as an educational tool? Is it better to use the history of science so that museum visitors can construct understandings of the nature of science and of conceptual elements of science? Studies addressing such questions can inform researchers in the fields of psychology and science education as well as designers of science exhibitions who seek to develop

a museological/museographical approach that maximises visitor learning. An important dimension of this research strand is developmental studies that investigate possible correlations between student learning of the official school programme and the coordinated activities that take place in schools and museums conjointly. In addition, existing didactic models that investigate how the introduction of elements of the history of science into formal education influence students' cognitive progress (e.g. Monk and Osborne 1997; Hottecke et al. 2012) could be altered to include activities in museum settings.

A necessary precondition for the establishment of the above-mentioned research strands is the acceptance of the strong transdisciplinary and interdisciplinary nature of this research and the creation of a collegial environment among the researchers involved. In other words, we need to accept that the intersection of the history of science, scientific museology and science education represents a fruitful set for the consideration of the theoretical background, the methodological approach and the social practices of science learning.

Anastasia Filippoupoliti Teaches museum education at the Department of Education Sciences in Preschool Age at the Democritus University of Thrace. She collaborates with the Hellenic Open University (Cultural Organisations Management), the University of Athens (Museum Studies) and the Eugenides Foundation. She has obtained a Ph.D. degree in Museum Studies and an M.A. degree in Museum Studies, both from the University of Leicester (UK) and a first degree in History and Philosophy of Science (University of Athens). Among her publications is the two-volume edited book *Science Exhibitions: Communication and Evaluation* and *Science Exhibitions: Curation and Design* (Edinburgh: MuseumsEtc, 2010). Her research interests are interdisciplinary and span the fields of museology, museum education, science communication and cultural history of science.

Dimitris Koliopoulos Teaches Science Education and Scientific Museology at the Department of Educational Sciences and Early Childhood Education at the University of Patras. He collaborates with the Hellenic Open University and the University of Cyprus (Department of Education). He holds a diploma in physics from Aristotle University of Thessaloniki (Greece) and has done postgraduate studies in Science Museum Education at the Jussieu University of Paris (France) and Science Education at the Jussieu University of Paris (France) and University of Patras (Greece), respectively. His research interests concern epistemological and educational aspects of the transformation of scientific knowledge to school science in formal and non-formal educational settings. He has also been involved for many years in the pre-service and in-service training of teachers in the preschool, primary and secondary education.

Part XI
Theoretical Studies: Science, Culture and Society

Chapter 50
Science, Worldviews and Education

Michael R. Matthews

Karl Marx, in the opening of *The Eighteenth Brumaire of Louis Bonaparte,* famously wrote that:

> Men make their own history, but they do not make it just as they please; they do not make it under circumstances chosen by themselves, but under circumstances directly found, given and transmitted from the past. (Marx 1851, p. 595)

Marx's appreciation of the way in which human life – its engagements, politics, culture and economic practices – is shaped by circumstances, and in turn how lives act and transform those circumstances, is a quite general claim that applies also to scientific engagements and practices. Science, broadly speaking, is the effort of people and societies to identify, understand and 'make sense of' the objects and processes in the world around them; to tabulate the properties of natural things and processes; to ascertain what and how causal mechanisms in the world operate; and to achieve some degree of predictive certainty about the course of events and some degree of control over them. Science is conducted by people living in societies in specific historic stages of scientific, philosophical, intellectual (including mathematical), religious, technological, economic and cultural (including ethical and artistic) development. All of these elements bear upon scientists and upon the science they conduct; these elements both limit and put constraints on science and also enhance it. In turn, science bears upon these circumstances: sometimes strengthening, other times modifying, sometimes overthrowing or negating different of these domains. The history of these interactions provides grounds for identifying how some scientific traditions are better than others at achieving their goal of understanding and effectively intervening in the natural world; the history allows some lessons to be learnt about the kinds of social and cultural circumstances that allow

science and scientists to flourish and conversely the circumstances that inhibit and curtail scientists and limit the scientific endeavour.

50.1 Science and Culture

Science, formerly ‘natural philosophy’, has always been a dynamic part of culture; it is affected by culture and has effects on culture; thus, science and worldviews (or *Weltanschauung*)[1] are interrelated, and a good science education should give students some appreciation of this interrelationship.[2] The educational value of such appreciation was recognised by the American Association for the Advancement of Science in its *Project 2061* publication where it said:

> … Becoming aware of the impact of scientific and technological developments on human beliefs and feelings should be part of everyone’s science education. (AAAS 1989, p. 173)

The position was elaborated a year later in its *The Liberal Art of Science*:

> The teaching of science must explore the interplay between science and the intellectual and cultural traditions in which it is firmly embedded. Science has a history that can demonstrate the relationship between science and the wider world of ideas and can illuminate contemporary issues. (AAAS 1990, p. xiv)

These expectations found their way through to the US National Science Education Standards where there was a separate content strand on ‘History and Nature of Science Standards’ (NRC 1996) that affirmed:

> Students should develop an understanding of what science is, what science is not, what science can and cannot do, and how science contributes to culture. (NRC 1996, p. 2)

And

> The standards for the history and nature of science recommend the use of history in school science programs to clarify different aspects of scientific inquiry, the human aspects of science, and the role that science has played in the development of various cultures. (NRC 1996, p. 107)

Hugh Gauch, an agricultural scientist, wrote the lead essay in a recent volume of *Science & Education* (vol.18, nos.6–7, 2009) dedicated to *Science, Worldviews and Education* where he averred that questions about science’s relation to worldviews, either theistic or atheistic ones, are among the most significant of contemporary issues for scientists, science teachers and culture more generally (Gauch 2009). Many people are vitally interested in questions such as whether God exists, whether the world has purpose, whether there are spiritual entities that have causal influence on the world, whether humans have spiritual souls which distinguish them from

---

[1] The German expression for ‘world outlook’ is more directly connected to feelings, ethics and personal and political action than the more passive Anglo term ‘worldview’.

[2] A classic account of the history of these interactions is J. D. Bernal’s four volume study *Science in History* (Bernal 1965). See also Crombie (1994), Dewitt (2004), and Randall (1962).

the animal world, whether the world is such that prayers can be answered and natural causal processes interrupted and so on. It is surely important for students and teachers to know if science can give answers, one way or the other, to these questions, or whether science is necessarily mute on the matters. Presumably knowledge of the nature of science should shed some light on whether science can or cannot answer such questions. Gauch surveys opinions of scientists, philosophers and educators and, predictably, finds disagreement within each group on the question of the legitimate purview of science.

Importantly Gauch carefully reports what position papers of the American Association for the Advancement of Science (AAAS) and the US National Research Council (NRC) say about the defining characteristics of science and thus what they say about worldviews and science. He identifies seven 'pillars' of the scientific enterprise that the AAAS and the NRC endorse. These are:

Pillar P1: *Realism.*	The physical world, which science seeks to understand, is real.
Pillar P2: *Presuppositions.*	Science presupposes that the world is orderly and comprehensible.
Pillar P3: *Evidence.*	Science demands evidence for its conclusions.
Pillar P4: *Logic.*	Scientific thinking uses standard and settled logic.
Pillar P5: *Limits.*	Science has limits in its understanding of the world.
Pillar P6: *Universality.*	Science is public, welcoming persons from all cultures.
Pillar P7: *Worldview.*	Science, hopefully, contributes to a meaningful worldview.

Gauch sees these seven pillars as, in part, amounting to the popular view that investigation of the supernatural lies outside of the domain of science; this is the widely held 'nonoverlapping magestria' (NOMA) position put forward by the late Stephen J. Gould (1999). But Gauch also finds an inconsistency with the AAAS position because at the same time the AAAS asserts that 'we live in a directional, although not teleological, universe'. For Gauch this is a denial of the fundamental worldview of the Judaic-Christian-Islamic traditions for which the world is neither purposeless nor ultimately unguided; and it is thus a statement that, contra NOMA, science is not worldview independent. He advances and defends the related thesis that:

> Science is worldview independent as regards its presuppositions and methods, but scientific evidence, or empirical evidence in general, can have worldview import. Methodological considerations reveal this possibility and historical review demonstrates its actuality. (Gauch 2009, p. 679)

The following fundamental questions arise for science teachers and curriculum writers and have been addressed by educators and by historians and philosophers of science:

What constitutes a worldview?
How do worldviews impinge upon and in turn be modified by ontological, epistemological, ethical and religious commitments?
What worldview commitments, if any, are presupposed in the practice of science?
What is the overlap between learning about the nature of science (NOS) and learning about worldviews associated with science?

What is the legitimate domain of the scientific method? Should scientific method be applied to historical questions, especially to historical questions concerning scriptures and sacred texts?
To what extent should learning about the scientific worldview be a part of science instruction?
Should science instruction inform student worldviews or leave them untouched? Should students be just 'border crossers' moving from their own culture with its particular worldviews to the science classroom in order to 'pick up' instrumental or technical knowledge and then back to their 'native' culture without being affected by the worldviews and outlooks of science?
What judgement do we make of science education programmes where the scientific view of the world is not affirmed or internalised but only learnt for instrumental or examination purposes, where learning science is akin to an anthropological study where students are not expected to believe or adopt what they are learning but merely be able to manipulate formulae and give correct answers on exams?

50.2 Science, Philosophy and Worldviews: Some Historical Developments

The celebrations in 2009 of the 150th anniversary of the publication of Darwin's *The Origin of Species* generated wide recognition of the interplay of science, culture and worldviews. Internationally – by dint of popular journals, academic symposia, newspaper articles, museum displays, books and television documentaries – the general public came to see what scholars have long recognised, namely, that the *Origin* provided not just a novel account of the origin of species by natural selection but it initiated a transformation of modern worldviews and a new understanding of the place of human beings in the natural world.[3] Versions of Darwin's evolutionary naturalism, reinforced and strengthened by modern genetics,[4] have entered into most modern worldviews, excepting those of many Christian fundamentalists, many Muslims and many indigenous cultures.[5]

Earlier in 2005 with the celebration of the centenary of Einstein's *annus mirabilis*, the public also saw and appreciated the contribution of science to worldviews. People knew, perhaps less clearly and dramatically than with Darwin, that something important began to happen in 1905 with the publication

---

[3] A 2013 Richard Attenborough television documentary series, 'The Galapagos Islands', is promoted as 'The islands that transformed our view of life on earth'.

[4] Learning that that *Homo sapiens* shares 98.4 % of its genes with pygmy chimpanzees can change a person's views of their relationship to the animal world.

[5] Of the voluminous literature on Darwinism and worldviews, see especially Dennett (1995, 2006), Greene (1981), McMullin (1985), and Ruse (1989).

of Einstein's three papers, even if few understood the details and could share the opinion of the physicist-philosopher Fritz Rohrlich that:

> The development of quantum mechanics led to the greatest conceptual revolution of our century and probably to the greatest that mankind had ever experienced. It most likely exceeded the great revolutions in our thinking brought about by the Copernican revolution, the Darwinian revolution, and the special as well as the general theory of relativity. Quantum mechanics forced us to reconsider our deepest convictions about the reality of nature. (Rohrlich 1987, p. 136)

Although Darwin and Einstein are the most recent and most widely known cases of science impacting on philosophy and culture, these impacts go right back to the very cradle of Western natural philosophy; there has been a continuous interaction between science, philosophy, metaphysics and ultimately worldviews. The 'science' (natural philosophy) of the classical and Hellenic materialists and atomists – Thales, Anaximander, Leucippus, Democritus, Epicurus, Anaxagoras and others – was in constant struggle with the dualist, teleological philosophy and purposeful worldviews of Platonists and Aristotelians. Karl Popper (Popper 1963, Chap. 5) drew attention to this 'struggle' between the early naturalist and materialist scientific tradition among the pre-Socratics and its dualist, teleological, philosophical opponents, chiefly Plato and Aristotle. The latter pair won, and the former group were for nearly 2,000 years relegated to being just 'pre-Socratics' or the philosophical 'warm-up' or targets for the main Athenian adventure. But to a small extent, their reputation has been recovered, with one representative historian of Greek philosophy writing of the Atomists Leucippus and Democritus that:

> In their atomism, their theory of motion, their distinction between primary and secondary qualities, and most of all, in their insistence that explanation of natural processes shall be mechanical, the atomists anticipated much in the world view of modern science. (Allen 1966, p. 15)

Anaximander's explanation of thunder as noise created not by heavenly Gods or spirits but by the rubbing together of wind particles well represents the division between materialist or naturalist explanatory systems and 'pre-scientific' ones.[6]

For Popper, and many others, the Scientific Revolution was a 'return to the past', a recapturing of materialist ontology and non-teleological causal relations.[7] Wallis Suchting has described these struggles in the cradle of Western science and philosophy as:

> Despite all the differences between Plato and Aristotle the latter carried on the work of the former in essential ways, like that of offering a metaphysical 'foundation' for the sciences and a teleological view of the world. Christianity took up elements of Platonic thought … but, its philosophical high-point, in Thomism, mainly appropriated Aristotle. Atomism carried on a basically marginal existence, … till it was recuperated by Galileo. (Suchting 1994, p. 45)

---

[6] Benjamin Farrington's *Science and Politics in the Ancient World* (1939) is a classic treatment of these themes.

[7] See especially Blumenberg (1987), Mittelstrass (1989), Solmsen (1960), Stove (1991), and Vitzthum (1995, Chap. 2).

The Scientific Revolution of the seventeenth century occurred in a Europe whose cultural, scholarly and religious life was permeated by Aristotelian philosophy, by convictions about ontology, epistemology, ethics and theology that were informed and judged by the texts of Aristotle. Neo-Aristotelian Scholasticism, although not monolithic in its interpretation of Aristotle,[8] dominated medieval and Renaissance universities.[9] Scholastic philosophy was intimately connected with the Catholic Church, but it also held sway in Protestant seminaries and universities (Dillenberger 1961, Chap. 2). As one commentator has observed:

> The Middle Ages mean simply the absolute reign of the Christian religion and of the Church. Scholastic philosophy could not be anything else than the product of thought in the service of the reigning *Credo*, and under the supervision of ecclesiastical authority. (De Wulf 1903/1956, p. 53)[10]

In Aristotelian-informed Scholastic ontology, things were constituted by form and by matter; this was the doctrine or principle of hylomorphism; it was fundamental to the Aristotelian tradition. Frederick Copleston has rightly noted that Aquinas, the greatest of the Scholastics,[11] 'took over the Aristotelian analysis of substance' (Copleston 1955, p. 83) and:

> According to Aquinas, therefore, every material thing or substance is composed of a substantial form and first matter. Neither principle is itself a thing or substance; the two together are the component principles of a substance. And it is only of the substance that we can properly say that it exists. 'Matter cannot be said to be; it is the substance itself which exists'. (Copleston 1955, p. 90)

It was the 'New Science' that led eventually to the unravelling of this settled medieval philosophical-theological worldview. This began with the publication in (1543) of Copernicus's astronomical work *On the Revolution of the Heavenly*

---

[8] The varieties of medieval and renaissance Aristotelianisms arose from efforts to accommodate ever new developments and discoveries in natural philosophy. See Blum (2012) and Schmitt (1983).

[9] A classic work on the doctrines and history of Scholastic philosophy is De Wulf (1903/1956). See also volumes two and three of Frederick Copleston's *History of Philosophy* (Copleston 1950). Etienne Gilson and Jacques Maritain are the best-known twentieth-century exponents of Scholasticism.

[10] Sadly this description, *sans* Church, fitted philosophy departments in most of the former communist states and philosophy departments China where 'Marxist Dialectics' is still a compulsory subject. It is also the situation of philosophy departments in many Islamic states where all philosophical positions in ontology, epistemology and ethics need to conform to state-sanctioned interpretations of the Koran. According to Sheikh Muhammed Salih Al-Munajjid, a known Islamic lecturer and author: 'hence philosophy, as defined by the philosophers, is one of the most dangerous falsehoods and most vicious in fighting faith and religion on the basis of logic, which it is very easy to use to confuse people in the name of reason, interpretation and metaphor that distort the religious texts'. In such Marxist and Islamic regimes, philosophy simply cannot be practised; the regimes are replicating at a state level what the Roman Catholic Church used maintain at a seminary level, namely, rigorous thought control.

[11] On the life and philosophy of Aquinas, see Copleston (1955), Gilson (1929), Kenny (1980), and Weisheipl (1974).

Spheres (Copernicus 1543/1952).[12] But it was almost a century later that the unravelling took dramatic shape with the publication in 1633 of Galileo's *Dialogues Concerning the Two Chief World Systems* followed 50 years later by Newton's *Principia Mathematica*. These two books, separated by a mere 50 years, embodied the intellectual core of the Scientific Revolution; they constituted the Galilean-Newtonian Paradigm, a GNP far more influential than any economic GNP has ever been.

The 'New Science' established the Copernican heliocentric account of the solar system which removed humans from their religiously and culturally privileged place in the centre of the universe; it introduced a mechanical and lawful account of natural processes; it challenged and in many places overthrew the long dominant Aristotelian philosophical system that was, among other things, intimately tied up with Roman Catholic theology and ethics; and famously the GNP caused a reassessment of the role of religious authority in the determination of claims about the world and indeed in any claims.[13]

The new science (natural philosophy) of Galileo, Descartes, Huygens, Boyle and Newton caused a massive change not just in science but in European philosophy that had enduring repercussion for religion, ethics, politics and culture. Early modern philosophers –from Francis Bacon, Thomas Hobbes, John Locke, David Hume, George Berkeley, René Descartes, Gottfried Leibniz up to Immanuel Kant – were all engaged with and reacting to the breakthroughs of early modern science,[14] as of course were the later philosophers of the French, English, German and Scottish Enlightenment; seventeenth-century science was the seed that bore eighteenth-century philosophical and worldview fruit. With the inevitable exceptions and qualifications required when talking of any large-scale transformation or revolution in thought, it can be said that all the major natural philosophers of the time rejected Aristotelianism in their scientific practice, their theorising and in their enunciated philosophy. Overwhelmingly the new philosophy to which they turned was corpuscularian, mechanical and realist – it has rightly been called the 'mechanical worldview'.[15]

In this new worldview, there was simply no place for the entities that Aristotelianism utilised to explain events in the world: Hylomorphism, immaterial substances, unfolding natures, substantial forms, teleological processes and final

---

[12] For the background, context and impact of Copernicus, see Blumenberg (1987), Gingerich (1975, 1993), and Grant (2004).

[13] A classic discussion is Dijksterhuis's *The Mechanization of the World Picture* (1961/1986). On the wider impact of the Galilean-Newtonian method, see Butts and Davis (1970), Cohen (1980), McMullin (1967), and Shank (2008).

[14] Unfortunately these early modern philosophers are frequently studied in isolation from the contemporary science with which they were engaged; early modern philosophy is presented to students as a drawn-out soliloquy, not the dialogue and debate with early modern science that it was. This theme, with texts, is developed in Matthews (1989a).

[15] For historical and philosophical elaboration of the mechanical world view, see Dijksterhuis (1961, 1961/1986), Einstein and Infeld (1938/1966), Hall (1954/1962), Harré (1964), Hatfield (1990), and Westfall (1971).

causes were all banished from the philosophical firmament. René Descartes aptly sums up the new philosophy in the conclusion of his *Principles of Philosophy* (1659) with a clear statement of the new corpuscularian philosophy:

> Nor do I think that anyone who uses his reason will deny that we do much better to judge of what takes place in small bodies which their minuteness alone prevents us from perceiving, by what we see occurring in those that we do perceive [and thus explain all that is in nature, as I have tried to do in this treatise], than, than in order to explain certain given things, to invent all sorts of novelties, that have no relation to those that we perceive [such as are first matter, substantial forms, and all the great array of qualities which many are in the habit of assuming, any of which it is more difficult to understand than all the things which we profess to explain by their means]. (*Principles* Bk.IV, art.101; Haldane and Ross 1931, pp. 297–298)

A foretaste of the coming mechanical worldview can be found in Galileo's distinction between, what will come to be called, the primary and secondary qualities of bodies. Seventy years later, his distinction was repeated by Robert Boyle and was famously articulated by John Locke,[16] and it has had an enduring presence in the subsequent history of Western philosophy. The distinction was at the heart of Galileo's theory of matter, a theory that answers such basic ontological questions as: Of what is matter constituted? And, what are the inherent and necessary properties of matter?[17]

For Aristotle and the Scholastics, matter was ultimately of the one stuff – 'prime matter' – gold, silver, timber, did not differ in their ultimate material; they just differed in how this material was arranged and what forms animated it. For this philosophical tradition, the properties or qualities of bodies were real. Colour, heat and odour belonged to bodies; the quality was a quality of the body. Heated red bodies *were* hot and they were red. These qualities are perceived by the senses, not generated by the senses. Aristotelians were realists, not subjectivists, about qualities.

In contradiction to this, Galileo reached back to pre-Socratic atomistic sources and to more recent medieval nominalist sources, for his account of matter. As a student he had read Democritus, Lucretius and possibly other early atomists such as Leucippus the teacher of Democritus. For them colour and taste were opinions, mere names; what existed in the world was atoms and the void, and atoms had neither colour nor taste. They held a material monist position – all matter was an aggregate of invisible and indivisible 'atoms' each of which was made of the same material and differing among themselves only in size and shape. It was the particular aggregate of atoms that gave bodies their tangible properties; a body's properties were not produced or caused by its form. When new substances are created from different materials, their immutable atoms are just rearranged in different ways; there is no change of form, because there was no form to change. This atomistic ontology was so comprehensively rejected by Aristotle in this *Physics* and his *Metaphysics* that it disappeared from the philosophical firmament for over a

---

[16] See Locke's *Essay Concerning Human Understanding* Book II Chap. 8 (Locke 1689/1924, pp. 64–73).

[17] On ancient, medieval and modern theories of matter, see contributions to McMullin (1963a, b).

thousand years until it was revived by some thinkers on the margins of medieval philosophy such as William of Ockham and Nicholas of Autrecourt.

Galileo's atomism is first and most famously stated in his *The Assayer* (Galileo 1623/1957) where he advances invisible 'atomic' motions as the cause of heat. He says:

> But first I must consider what it is that we call heat, as I suspect that people in general have a concept of this which is very remote from the truth. For they believe that heat is a real phenomenon, or property, or quality, which actually resides in the material by which we feel ourselves warmed. (Galileo 1623/1957, p. 274)

Galileo makes explicit his atomism, or corpuscularianism, when he says:

> Those materials which produce heat in us and make us feel warmth, which are known by the general name of 'fire', would then be a multitude of minute particles having certain shapes and moving with certain velocities. Meeting with our bodies, they penetrate by means of their extreme subtlety, and their touch as felt by us when they pass through our substance is the sensation we call 'heat'. … I do not believe that in addition to shape, number, motion, penetration, and touch there is any other quality in fire corresponding to 'heat'. (ibid)

Galileo believed that it was the shape, size, motion and collisions of minute, unseen 'atoms' or corpuscles that determined all outward and perceivable states, processes and phenomena. This was his restatement of ancient atomism. Galileo's ontology was simply inconsistent with Scholastic metaphysics and thus with the medieval worldview built upon it. Galileo's distinction between primary and secondary qualities was the beginning of the unravelling of this 'Medieval Synthesis' and its replacement by the 'mechanical' or 'corpuscularian' worldview and ultimately the 'scientific' worldview.

Newton, the greatest of all seventeenth-century scientists, was also a champion of the New Philosophy.[18] Beginning in his student days, Newton embraced Galileo's mathematical methods, his Copernicanism, his experimentalism, his rejection of Aristotle's physics, his rejection of Scholastic philosophy and his embryonic atomism.[19] In the Preface of the *Principia*, Newton identifies himself with the 'moderns, rejecting substantial forms and occult qualities' and endeavours 'to subject the phenomena of nature to the laws of mathematics' (Newton 1729/1934, p. xvii).

In keeping with Boyle's example of experimentally testing and utilising metaphysical positions, Newton in his *Opticks* gave an atomistic account of light and optical phenomena (Newton 1730/1979). After 300-odd pages of optical experiments and investigations, Newton in Query 29 of Book III says:

> Are not Rays of Light very small Bodies emitted from shining Substances? For such Bodies will pass through uniform Mediums in right Lines without bending into the Shadow, which is the Nature of Rays of Light. They will also be capable of several Properties, and be able

---

[18] Numerous works are available on Newton's philosophy and metaphysics, among them are Hughes (1990), McGuire (1995), McMullin (1978), and Stein (2002). Although an atomist, Newton distanced himself from Descartes' interpretation of the theory.

[19] For Newton's early scientific and philosophical formation, see Herivel (1965) and Westfall (1980, Chaps. 3,4,5)

> to conserve their Properties unchanged in passing through several Mediums which is another Condition of the Rays of Light. (Newton 1730/1979, p. 370)

Much can be said about atomism, its recovery by philosophical contemporaries of Galileo such as Francis Bacon and Pierre Gassendi and its role in the Scientific Revolution, but for current purposes it suffices to repeat Craig Dilworth's judgement that:

> The metaphysics underlying the Scientific Revolution was that of early Greek atomism. … It is with *atomism* that one obtains the notion of a *physical* reality underlying the phenomena, a reality in which *uniform causal* relations obtain. … What made the Scientific Revolution truly distinct, and Galileo … its father, was that for the first time this empirical methodology [of Archimedes] was given an ontological underpinning. (Dilworth 2006, p. 201)

And the role of the New Science in generating the modern worldview is well stated by Herbert Butterfield[20]:

> Since that revolution overturned the authority in science not only of the middle ages but of the ancient world – since it ended not only in the eclipse of scholastic philosophy but in the destruction of Aristotelian physics – it outshines everything since the rise of Christianity and reduces the Renaissance and Reformation to the rank of … mere internal displacements … it changed the character of men's habitual mental operations even in the conduct of the non-material sciences, while transforming the whole diagram of the physical universe and the very texture of human life itself. (Butterfield 1957, p. 7)

When Butterfield writes of the New Science changing 'the character of men's habitual mental operations', he is speaking of what the AAAS will later call the 'scientific habit of mind' (Rutherford and Ahlgren 1990, Chap. 12) and what Jawaharlal Nehru and the drafters of the Indian Constitution called for in promoting a 'scientific temper'.[21] Effects on a society's 'mental operations', 'habits of mind' or 'scientific temper' depend on citizens learning about and valuing science, on having a worldview where such ways of thinking can be exercised, and hence ultimately on effective and widespread science education.

50.3 From Science to Heresy: The Catholic Church's Condemnation of Atomism

The worldviews of science and of religion do not always sit easy with each other; accommodations usually need to be made. In recent times, worldview conflicts occasioned by disputes about Creation, Creationism, Teleology, Miracles, the

---

[20] There is a vast literature on the Scientific Revolution, including a debate on whether to capitalise the terms; an informative guide to the different assessments, literature and debates is H. Floris Cohen's *The Scientific Revolution* (Cohen 1994).

[21] The 1948 Indian Constitution makes obligatory the state's 'promotion of scientific temper' among its citizenry, not just scientific knowledge but scientific outlook or habits of mind (Haksar 1981).

existence of souls and spirits and so on have moved from academic corridors to the public domain with bestsellers (Dawkins 2006; Dennett 1995), television programmes, public debates and countless scholarly articles devoted to explicating or defending one side or other of these conflicts.[22]

Many of the major seventeenth-century contributors to the new science – Galileo, Descartes, Boyle and Newton – were believers, although in somewhat tense relations with their respective established churches (Roman Catholic for the first two, Anglican for the second two). Some believers rejected the new science; some wanted the new science but not its associated metaphysics; and some, such as Joseph Priestley, embraced both the new science and its atomistic metaphysics and adjusted their religious ontology accordingly. When the seventeenth-century natural philosophers and the Enlightenment philosophers of the eighteenth century stressed the materialism, mechanism and determinism of the new science, they brought upon themselves the ire of most contemporary religious figures who saw the emerging new worldview as anti-Christian and atheistic.[23] The historian Richard Westfall well summarises the general situation:

> Natural science rested on the concept of natural order, and the line that separated the concepts of natural order and material determinism was not inviolable. The mechanical idea of nature, which accompanied the rise of modern science in the 17th century, contradicted the assertion of miracles and questioned the reality of divine providence. Science, moreover, contained its own criteria of truth, which not only repudiated the primacy of ancient philosophers but also implied doubt as to the Bible's authority and regarded the attitude of faith enjoined by the Christian religion with suspicion. (Westfall 1973, pp. 2–3)

And Westfall proceeds to say:

> every one of the problems could be resolved in a variety of ways to reconcile science with religion. But the mere fact of reconciliation meant some change from the pattern of traditional Christianity (ibid)

These 'grand historic' reconciliations are repeated at the personal level for many science students.

Although Galileo was, in 1615, warned not to hold or teach the Copernican doctrine of a moving Earth, it was only after *The Assayer* and its endorsement of atomism was published in (1623) that he faced serious theological charges. There was a move by opponents from general disquiet to specific repudiation.

Atomism presented particular and grievous problems for Christian belief, but the most basic and important one was the central Roman Catholic, Greek Orthodox and Eastern Uniate teaching on Christ's presence in the Eucharist, the doctrine of Transubstantiation. The Eucharist was the sacramental heart of the Catholic Mass, and the Mass was and is the devotional heart of the Church. Belief in the Real Presence of Christ, brought into being by the priest's consecration of the communion host, underwrites devotional practice and doctrinal authority. Denial of the Real

---

[22] See Michael Ruse (2011) for one informed account of these debates and also the careful review of this book by Peter Slezak (2012).

[23] See, for instance, Brooke (1991, Chap. V), Israel (2001), and Porter (2000).

Presence was a capital offence. It was a litmus test in the Inquisition, where failure to affirm the belief meant a horrible death at the stake.

Scholastic philosophy, with its Aristotelian categories of substance, accidents and qualities, could bring a modicum of intelligibility to this central mystery of faith, as it could also bring a modicum of intelligibility to doctrines such as the Incarnation, the Trinity, and immortality of the soul. Scholasticism held that at consecration the substance of bread changed to the substance of Christ's body, but the accidents remained that of bread. So Christ became truly present, even though no sensible, observable change was apparent.

Thomas Aquinas formulated the orthodox doctrine as:

> All the substance of the bread is transmuted into the body of Christ… therefore, this is not a formal conversion but a substantial one. Nor does it belong to the species of natural mutations; but, with its own definition, it is called transubstantiation. (*Summa Theologica* III, q.75, a.4, in Redondi 1988, p. 212)

This Thomist formulation, along with the Aristotelian philosophical apparatus required for its interpretation, was affirmed as defining Catholic orthodoxy at the Council of Trent in 1551.

The nature of the heresy charges against Galileo, and the degree to which atomism was at odds with established religiosity and theology, can be seen in a condemnation brought anonymously by Father Giovanni de Guevara, a Vatican confidant of Pope Urban VIII. Guevara was a priest of a contemplative order whose very life revolved around adoration of the Eucharistic sacrament. He had minimal philosophical training but enough to see the conflict between Galileo's atomistic position and the orthodox interpretation of the Real Presence – for Guevara they could not both be true (Redondi 1987, pp. 166ff). In his 1624/1625 deposition he charged that:

> [Galileo's position] is in conflict with the entire community of Theologians who teach us that in the Sacrament remain all the sensible accidents of bread, wine, color, smell, and taste, and not mere words, but also, as is known, with the good *judgment* that the quantity of substance does not remain. (Redondi 1987, pp. 333–334)[24]

The charge of atomism against Galileo, with its direct implications of heresy, was made in 1626 by Father Grassi, a prominent Jesuit professor of mathematics and astronomy at the Collegio Roman. Grassi made clear the gravity of the philosophical point by adding that transubstantiation 'constitutes the essential point of faith or contains all other essential points' (Redondi 1987, p. 336).[25] Descartes' matter theory was likewise condemned in 1671 because its categories did not allow an intelligent rendering of the doctrine of Transubstantiation.

John Hedley Brooke, an historian sympathetic to the positive contribution of religion to science, recognised the problem that atomism posed 'especially for the

---

[24] A translation of the deposition, and discussion, is also available in Finocchiaro (1989, pp. 202–204).

[25] This contention echoed through all Catholic teaching and devotional practice; as one Catholic Handbook states the matter: 'The Catholic belief is that the sacrifice of the Mass is the sacrifice of the body and blood of Christ *under the form of bread and wine*' (Lucey 1915, p. 93).

Roman Catholic Church, which took a distinctive view of the presence of Christ at the celebration of the Eucharist' (Brooke 1991, p. 141). He writes:

> With an Aristotelian theory of matter and form, it was possible to understand how the bread and wine could retain their sensible properties while their substance was miraculously turned into the body and blood of Christ. …. But if, as the mechanical philosophers argued, the sensible properties were dependent on an ulterior configuration of particles, then any alteration to that internal structure would have discernible effects. The bread and wine would no longer appear as bread and wine if a real change had occurred. (Brooke 1991, p. 142)

50.4 The Decline of Atomism: Scientific or Philosophic Causes?

No sooner had Newton ceased writing than the philosophy of atomism, and its associated mechanical worldview was augmented and modified. This history is a case study of the relation between science and metaphysics: To what extent did the metaphysics change for philosophical reasons and to what extent did it change for scientific reasons?[26] To the scientific ontology of atoms and the void there was added, after considerable struggle, attractive and repulsive forces. Leibniz famously denounced Newton's attractive forces because he thought they reintroduced Scholastic occult entities to the ontology of natural philosophy (Hall 1980). In the nineteenth century, to this expanded scientific ontology were added magnetic and electric fields. The formulation of electromagnetic field theory by Maxwell, Boltzmann and Hertz fully stretched, and then ruptured, the atomistic ontology; and the energeticist interpretation of thermodynamics had the same result; and at the end of the century Mach, for example, abandoned atoms and denounced the atomic hypothesis as metaphysics.[27] This then provided the full range of scientifically legitimate explanatory and causal entities, at least until the advent of quantum theory.

The expansion of the ontology of science is a case study in the interaction of science and metaphysics. The atomists held on *philosophical* grounds that all legitimate explanation had ultimately to be in terms of the properties of atoms and of their movements and interactions. Their science was constrained by their philosophy. Clearly the addition of forces and fields to the class of existent things was not done on philosophical grounds but on *scientific* grounds; it seemed that only recourse to the latter entities enabled consistent scientific explanation and progress.

This expanded ontology was inconsistent with the metaphysics of *physicalism*: Forces and fields did not have mass; they could not be bumped into; and they had no

---

[26] On the history of atomism and its connections with science on the one hand and with philosophy on the other, see Chalmers (2009), Pullman (1998), and Pyle (1997). An older historical study that concentrates more on the philosophical side of atomism is Melsen (1952).

[27] There are many good accounts of the modification, and eventual breakdown, of the mechanical worldview. See especially Einstein and Infeld (1938, Chap. 2), Harman (1982, Chap. 6), Hesse (1961), and McMullin (1989).

colour. They were not physical objects, the things that physicalism maintained were the only kinds of existing entities. It was also inconsistent with *materialism* in as much as this philosophy maintained that all entities with causal powers were material.[28] But the enriched ontology was consistent with *naturalism*, the view that only those kinds of entities exist that science reliably demonstrates as having consistent, causal and explanatory power. Thus things can be natural while not physical or material. The Mechanical Worldview survived the demise of atomism: There were still pushes and pulls, nature was not unfolding Aristotelian-like from within, but the deterministic pushes and pulls were no longer just those of colliding bodies, but gravitational and electric forces were added (Westfall 1971).

50.5 Philosophy as the Handmaiden of Theology and of Other Systems

Joseph Priestley, one of the luminaries of the British Enlightenment and a lifelong Christian believer, well expressed the ill ease felt about cloaking Christian doctrine in Scholastic clothes. In 1778 he wrote to the Jesuit 'materialist' philosopher Abbé Roger Boscovich saying that:

> the vulgar hypothesis [Aristotelian matter theory], which I combat, has been the foundation of the grossest corruptions of true Christianity; and especially [those] of the church of Rome, of which you are a member; but which I consider as properly *antichristian*, and a system of abominations little better than heathenism. (Schofield 1966, p. 167)

Despite such criticisms, the Catholic Church was guided by the medieval view that 'philosophy was the handmaiden' of theology; philosophy was to be subservient to religious and theological purposes. This was the import of the sixteenth-century Tridentine decrees and curial decisions right through to the twentieth century.[29] Pope Leo XIII promulgated his encyclical *AEterni Patris* that gave the name *philosophia perennis* (perennial philosophy) to Thomism and directed Catholic educational institutions to base their philosophical and theological instruction upon it. In 1914 Pius X issued his *Doctoris Angelici* decree, stating that:

> We desired that all teachers of philosophy and sacred theology should be warned that if they deviate so much as an iota from Aquinas, especially in metaphysics, they exposed themselves to grave risk. (Weisheipl 1968, p. 180)

---

[28] On the history and philosophy of materialism, see Bunge (1981) and Vitzthum (1995).

[29] One hundred years *after* Priestley's complaints to Boscovich, Joseph McCabe, a former Franciscan priest and professor of philosophy who left the Church in the 1890s, well described the state of Roman Catholic theology when he said derisively of his theological training that:

> The various points of dogma which are contained (or supposed to be contained) in Scripture, were first selected by the Fathers, and developed, generally by the aid of the Neo-Platonic philosophy, into formidable structures. The schoolmen completed the synthesis with the aid of Peripatetic philosophy, and elaborated the whole into a vast scheme which they called theology. (McCabe 1912, p. 73)

A few years later, the *Code of Canon Law*, promulgated by Pope Benedict XV in 1917, reinforced the position by requiring that all professors of philosophy hold and teach the method, doctrine and principles of St Thomas. The papal endorsement of thirteenth-century philosophy continued through to 1950 when Pope Pius XII in *Humani generis* demanded that future priests be instructed in philosophy 'according to the method, doctrine and principles of the Angelic Doctor' (Weisheipl 1968, p. 183). It was only in the final years of the twentieth century, with Pope John Paul II's 1998 encyclical, *Fides et Ratio*, that the Catholic Church relaxed its attachment to Thomism as official Church philosophy. Thomism was downgraded from Absolute Truth to Highly Probable Truth.[30]

The Thomist tradition had enormous cultural and personal impact in Catholic Europe (especially Ireland, Portugal, Spain, Italy, Poland), Latin America,[31] the Philippines and elsewhere. For centuries Thomism was marshalled to support Church teaching on contraception, abortion, masturbation and homosexuality; where the Church exercised political power and influence, these teachings transferred into national law with the immoral acts becoming illegal and punishable by the State and not just for Catholics but for all citizens. In all cases the reason for condemnation was that the activity was 'unnatural', this whole conceptualisation coming from Aristotle's understanding of objects and actions as having natures which left alone unfolded 'naturally' and when interfered with unfolded 'violently' or 'unnaturally'.[32]

Clearly Thomism and Scholasticism and more generally Aristotelianism survived the Scientific Revolution; belief in the core metaphysical and ethical positions has survived to the present day.[33] Indeed neo-Aristotelianism is perhaps the most substantial and lively current of thought in contemporary ethical theory, with exponents such as Alasdair McIntyre, Elizabeth Anscombe and Martha Nussbaum all contributing substantial books to the Aristotle-sourced project of 'virtue ethics'. But the success of modern science has meant that Thomism in particular and Aristotelianism more generally has had to engage with science. Some have done this while preserving Aristotelianism (van Laer 1953, 1956; 1962; Maritain 1935/1951; Mascall 1956); for others the engagement has led to

---

[30] On John Paul II's encyclical and how it reviewed and revised the status of Thomism, see Ernst (2006).

[31] Concerning early twentieth-century Thomist philosophy in Colombia, Daniel Restrepo wrote: 'To the extent that the Columbian State was governed by theocratic criteria, philosophy, conceived as "servant of theology", played the role of ideological mediator in the political action and principles of those who had held power since 1886' (Restrepo 2003, p. 144). Late into the twentieth century, passing 'Thomism I' was still a requirement for progression in many Latin American universities. Much like passing 'Dialectics I' is such a requirement in present day China.

[32] As an example of this reasoning and mindset, for Aquinas sexual intercourse was 'naturally ordained for procreation' (*Sentences* 4.31.2.2), so even indulging in coitus for reasons of health (a good purpose) nevertheless rendered the act unnatural and thus sinful as it was not done for its primary end. On all of this, see Noonan (1965, Chap. viii).

[33] See, for instance, arguments and literature in Ashley (1991) and Lamont (2009). The philosophy journal *New Scholasticism* was published from 1927 to 1989, *The Thomist* journal has been published continuously since 1939 and *The Modern Schoolman* has been published continuously since 1925. And of course numerous non-Anglo 'scholastic' philosophy journals are still published.

rejection in whole or part of Aristotelian philosophy.[34] This is a substantial example of the impact of science on philosophy and culture and of culture's responses and reactions to such impacts.

The same dynamics have played out in the Muslim world where the medieval view of philosophy as the servant of the Koran still holds. It is simply not possible for a Muslim to entertain or commit to any philosophical system that cannot be reconciled with the assumed ontology, epistemology and ethics of the Koran. The project of 'Islamisation of knowledge' is widely accepted as simply a part of Islam and of being a Muslim. Its purpose is to counter the humanistic and secular foundation of the Western education and culture, which it sees as based on five core principles:

1. The sovereignty of man, as though supreme (humanism)
2. Basing all knowledge on human reasoning and experience (empiricism)
3. Unrestricted freedom of thought and expression (libertarianism)
4. Unwillingness to accept 'spiritual' truths (naturalism)
5. Individualism, relativism and materialism

A representative Islamic appraisal of the Scientific Revolution is Seyyed Nasr's claim that the new science of Galileo and Newton had tragic consequences for the West because it marked:

> The first occasion in human history when a human collectivity completely replaced the religious understanding of the order of nature for one that was not only nonreligious but that also challenged some of the most basic tenets of the religious perspective. (Nasr 1996, p. 130)

Nasr repeats Western religious and Romantic criticisms of the new science when he writes:

> Henceforth as long as only the quantitative face of nature was considered as real, and the new science was seen as the only science of nature, the religious meaning of the order of nature was irrelevant, at best an emotional and poetic response to 'matter in motion'. (Nasr 1996, p. 143)

The engagement of philosophical systems with science has been especially urgent when the systems are tied to political and institutional power, as Thomism has been with the Roman Catholic Church. The same situation has applied with Marxism within the former Soviet state,[35] Maoism and dialectics in contemporary China,[36] Confucianism in Chinese history,[37] National Socialist philosophy in Hitler's

---

[34] The survival of Thomism and the dynamics of its engagement with modern science is discussed in Matthews (2009b, pp. 718–720). In a recent publication, a neo-Aristotelian moves philosophy of science away from philosophising on the content of science to philosophical reflection on the activity of science (Marcos 2012).

[35] For 'official' philosophy in the Soviet Union and its contested relationship to science, see Graham (1973).

[36] 'Introduction to Dialectics of Nature (IDN)', based on Engels' book, was under Mao, a compulsory course for all Chinese graduate students. Under Xiaoping Deng, the course remained compulsory but in 1987 was rebadged 'Philosophy of Science and Technology (PST)' with the same IDN teachers. For the relationship of philosophy, politics and science in China, see Chan (1969) and Gong (1996).

[37] See Kwok (1965).

Third Reich,[38] Hindu philosophy at different times and in different states in modern India[39] and Islamic philosophy in Muslim countries[40] and more loosely when custodians of traditional belief systems control what can be thought and taught in traditional indigenous cultures.

In all of these cases, local science and philosophy was and has been made to answer to the dominant, institutionalised philosophy and worldview; and educational bodies were forced to accept such 'direction from above' as being in the interest of the nation, religion or culture. This cultural-political circumstance poses acute questions for the classroom science teacher: Should they foster independence of thought in their students or become functionaries of whatever the dominant ideological power might be? These are matters requiring a thoughtful and informed philosophy of education, unfortunately something mostly ignored in contemporary science teacher education where not only philosophy of education, but most foundational subjects have been progressively removed and replaced with training in pedagogical technique, classroom management skills and use of new technologies; the 'apprenticeship' model of teacher education allows little opportunity for 'reflection on principles' or for understanding the history and philosophy of the discipline being taught.[41]

50.6 Philosophy and Modern Science

Despite revolutions, paradigm changes, commercialisation and much else, modern science is continuous with the New Science of Galileo and Newton and prompts the same range of philosophical questions: Science and philosophy continue to go hand in hand.[42] Peter Bergmann expressed this point when he said that he learnt from Einstein that 'the theoretical physicist is … a philosopher in workingman's clothes' (Bergmann 1949, p. v, quoted in Shimony 1983, p. 209).[43] One commentator on the work of Niels Bohr remarked that 'For Bohr, the new theory [quantum theory] was not only a wonderful piece of physics; it was also a philosophical treasure chamber which contained, in a new form, just those thoughts he had dreamed about in his early youth' (Petersen 1985, p. 300). It is no accident that many of the major physicists of the nineteenth and twentieth centuries wrote books on philosophy and

[39] See Nanda (2003).

[40] On the tensions and accommodations between science and Islam, see Edis (2007) and Hoodbhoy (1991).

[41] On philosophy of education in science education, see Schulz (2009) and his contribution to this handbook; on the larger issue of educational foundations, see contributions to Tozer et al. (1990).

[42] Some useful studies on the philosophical dimension of science are Amsterdamski (1975), Buchdahl (1969), Burtt (1932), Dilworth (1996/2006), Smart (1968), Trusted (1991), and Wartofsky (1968).

[43] Paul Arthur Schilpp's anthology on Einstein is titled *Albert Einstein: Philosopher-Scientist* (Schilpp 1951).

the engaging overlaps between science and philosophy.[44] Many less well-known physicists also wrote such books teasing out relations between their scientific work and the ontology, epistemology and ethics that it presupposed and for which it had implications.[45] And not just physicists, many chemists and biologists have made contributions to this genre.[46]

This is not, of course, to say that all these good scientists wrote good philosophy or drew sound conclusions from their scientific work: Some did, others did not. Eighty years ago, Susan Stebbing wrote a classic critique of the hugely influential idealist philosophical conclusions drawn by the renowned British physicists James Jeans and Arthur Eddington (Stebbing 1937/1958). Mario Bunge has developed comparable arguments against the idealist and subjectivist conclusions drawn from quantum mechanics by David Bohm, Niels Bohr and many proponents of the Copenhagen school (Bunge 1967, 2012). The point is not that the major scientists drew common philosophical conclusions, it is rather that they all philosophised; they all reflected on their discipline and their activity, and they saw that such reflection bore upon the big and small questions of philosophy. This fact supports the contention that philosophy is inescapable in good science;[47] it should also suggest that philosophy is inescapable in good science education.

The Oxford philosopher, R. G. Collingwood in his landmark study *The Idea of Nature* wrote on the history of mutual interdependence of science and philosophy and commented that:

> The detailed study of natural fact is commonly called natural science, or for short simply science; the reflection on principles, whether those of natural science or of any other department of thought or action, is commonly called philosophy. … but the two things are so closely related that natural science cannot go on for long without philosophy beginning; and that philosophy reacts on the science out of which it has grown by giving it in future a new firmness and consistency arising out of the scientist's new consciousness of the principles on which he has been working. (Collingwood 1945, p. 2)

He goes on to write that:

> For this reason it cannot be well that natural science should be assigned exclusively to one class of persons called scientists and philosophy to another class called philosophers. A man

---

[44] See, for instance, Bohm (1980), Bohr (1958), Boltzmann (1905/1974), Born (1968), Duhem (1906/1954), Eddington (1939), Heisenberg (1962), Jeans (1943/1981), Mach (1893/1960), Planck (1932), and von Helmholtz (1995).

[46] For instance, Bernal (1939), Birch (1990), Haldane (1928), Hull (1988), Mayr (1982), Monod (1971), Polanyi (1958), and Wilson (1998). One recent contribution to the genre is by Francis Collins, the geneticist and leader of the Human Genome Project (Collins 2007).

[47] There are countless books on the worldview of modern physics: see, for example, contributions to Cushing and McMullin (1989), especially Abner Shimony's contribution 'Search for a Worldview Which Can Accommodate Our Knowledge of Microphysics' (Shimony 1989). See also the contributions to the special issue of *Science & Education* dealing with Quantum Theory and Philosophy (vol. 12 nos. 5–6, 2003).

> who has never reflected on the principles of his work has not achieved a grown-up man's attitude towards it; a scientist who has never philosophized about his science can never be more than a second-hand, imitative, journeyman scientist. (Collingwood 1945, p. 2)

What Collingwood says about the requirement of 'reflecting upon principles' being necessary for the practice of good science can equally be said for the practice of good science teaching. Liberal education promotes just such deeper reflection and the quest to understand the meaning of basic concepts, laws or methodologies for any discipline (mathematics, history, economics, theology) being taught including science.[48]

50.7 Science and the 'Invisible World'

The world's major religions have had an ongoing engagement with science, investigating how their own ontological, epistemological, anthropological and ethical commitments – their worldviews – are to be reconciled with both scientific findings and scientific worldviews. Religion is the most publicly discussed and debated aspect of the science and worldview interaction and the one that most often occupies educators in their writing of national and provincial curricula, in their arguments about multicultural and indigenous science, in their debates about textbook selection and in their classroom teaching and interactions with students and parents. Because modern science emerged out of Christian Europe in the seventeenth century, the arguments and adjustments between Christianity and science – over Creation, Evolution, Providence, Miracles, Revelation, Authority – have been debated longest in this religious tradition, and hence it will be the focus of this chapter.[49] This section of the chapter will deal with just one of the many issues and debates that have arisen in the field: the putative existence and powers of spiritual agencies, spirits, ghosts, poltergeists and angels, inhabitants of what John Wesley, the founder of Methodism, called the 'Invisible World'.

50.7.1 Abrahamic Religions

Belief in a spirit-filled, invisible world is fundamental to the Judaeo-Christian-Islamic tradition. Jewish society simply took over the heavily populated world of demons that the Mesopotamian and Hellenic worlds also recognised with their ontology of beings intermediate between gods and men, these were the *daimones*. The Judaeo-Christian explanation of this realm of troublemakers and evil inducers

---

[48] The Philosophy for Children movement has shown that this reflection and quest can begin in Elementary school (Lipman 1991; Matthews 1982; Sprod 2011).

[49] Among a veritable library of relevant books, see Barbour (1966), Brooke (1991), Haught (1995), Jaki (1978), Mascall (1956), and contributions to Lindberg and Numbers (1986).

was of course the expulsion from heaven of Satan and his fallen angels (Genesis 6:1–4). This was a more than satisfactory explanation of their existence, powers and inclinations. Jinn, or spirits and angels, were an integral part of the Judaic tradition, everyone in pre-Islamic Arabia believed in them; they lived in a world unseen to humans; they eat and drink and procreate; some are righteous while others are evil. Illness, unusual events, misfortunes, catastrophes and so on were attributed to this host of other-worldly ne'er-do-wells.

The New Testament and the early Christian Church which was a sect of Judaism simply carried on belief in the reality and powers of demons, or 'unclean spirits' as they are also called. These demons were responsible for false teaching (1 Timothy 4:1); they performed wonders (Apocalypse 16:14); they rule the kingdom of darkness (Ephesians 1:21, 3:10); and so on.

Of particular account in New Testament demonology is the widespread and frequent occurrence of possession of people by the devil or evil spirits. This continued a Judaic and Mesopotamian belief in diabolical possession, one that routinely attributed psychic illness (as now understood) to such a cause (Mathew 8: 16, 12:27; Mark 1:34; Luke 7:21, 11:19; Acts 19:13–16). The apostles exorcised evil spirits where they could, with the most graphic instance being the exorcism in the Gerasa cemetery where the demons fled the person and possessed the herd of swine that they then drove to their death in the Sea of Galilee. Converts such as Paul also had such powers and exercised them effectively such as when he drove the evil spirit from the girl from Philippi (Acts 16:16). Sometimes they were not successful, as with the boy now seen to be most probably an epileptic (Mathew 17:14–21; Mark 9:14–29; Luke 9:37–43).

John McKenzie, a Catholic commentator (from whom the foregoing textual references are taken), has written: 'The belief in heavenly beings thus runs through the entire Bible and exhibits consistency' (McKenzie 1966, p. 32). And further adds:

> But while the use of popular imagery should be understood to lie behind many details of the New Testament concept of demons, the Church has always taught the existence of personal evil spirits, insisting that they are malicious through their own will and not through their creation. (McKenzie 1966, p. 194)

The Protestant tradition held comparable views. Martin Luther wrote:

> Demons live everywhere, but are especially common in Germany. On a high mountain called Polterberg there is a pool full of them: they are held captive there by Satan. If a stone is thrown in a great storm arises and the whole countryside is overwhelmed. Many deaf persons and cripples were made so by the Devil's malice. Plagues, fevers and all sorts of other evils come from him. As for the demented, I believe it to be certain that all of them were afflicted by him. (In Mencken 1946/1930, p. 244)

John Wesley wrote in his *Journal* in 1768 that: 'The giving up of witchcraft is in effect the giving up the Bible'. He regarded witchcraft as 'one great proof of the invisible world'.

It is hardly surprising that half of all Americans tell pollsters that they believe in the Devil's existence, and 10 % claim to have communicated with him (Sagan 1997, p. 123). The extent of such belief has been more recently documented in the findings of the large-scale 2008 Pew Report on religious belief and practice in the USA.[50] This survey of 35,000 US adults, most of whom would have completed the high school science requirement, found that belief in some form of God was nearly unanimous (92 %) and that this God was not the remote, untouching God of eighteenth-century Deists, but a God who was actively engaged in the affairs of people and of processes in the world. Nearly eight in ten American adults (79 %) agree that miracles still occur today as in ancient times. Similar patterns exist with respect to beliefs about the existence of angels and demons. Nearly seven in ten Americans (68 %) believe that angels and demons are active in the world. Majorities of Jehovah's Witnesses (78 %), members of evangelical (61 %) and historically black (59 %) Protestant churches and Mormons (59 %) are *completely* convinced of the existence of angels and demons.

Belief in such a rich spirit-populated world 'invisible world' is a requirement for the world's 1.5 billion Muslims. Belief in angels is the second of Islam's six Articles of Faith. In Islam, Jinn are spirits made by Allah from smokeless fire; some Muslim scholars say that Jinn populated the earth 2,000 years before the creation of humans out of clay. The Islamic philosopher Seyyed Nasr writes:

> To rediscover the body as the abode of the Spirit…is to re-establish our link with the plants and animals, with the streams, mountains and the stars. It is to experience the Spirit in the physical dimension of our existence. (Nasr 1996, p. 262)

The whole constellation of traditional religious beliefs, especially those affirming an active ongoing engagement of God, angels and spirits with human affairs, requires that the world, including human beings, be constituted in certain ways; that the world has a certain ontology; and that the human beings are so constituted that it can know of and interact with these supernatural agencies. All of this amounts, in part, to a religious worldview, a view about how the world and human beings need to be constituted so as to enable, or ground, religious belief, experience and practice.

Henry Gill, a Catholic priest, philosopher and physics lecturer, gave succinct expression to the kind of worldview held by many of the above-mentioned religious believers:

> It will be useful to recall briefly the Catholic teaching as to the existence of spirits. The Scripture is full of references to both good and bad spirits. There are good and bad angels. Each of us has a Guardian Angel, whose presence, alas, we often forget. Angels, as the Catechism tells us, have been sent as messengers from God to man. Our Lady, at the Incarnation, St. Joseph before the flight into Egypt, both received messages. Our Lord Himself was tempted by Satan …. Finally, it is the certain teaching of the Church that the conditions which depend on whether the human being to whom it belonged has or has not lived according to the dictates of conscience and quitted this life in friendship or at enmity with God. (Gill 1944, pp. 127–128)

This statement implies and presupposes certain ontological, epistemological, anthropological and theological positions which rolled together constitute a statement of the traditional Roman Catholic worldview, a worldview that was 'at home' in

---

[50] The survey was conducted between May and August 2007 and published in June 2008 in the Pew Report at www.pewreport.org.

Thomism and Scholasticism and is professed by a goodly number of the world's 1.2 billion Roman Catholics. The constituent domains of a worldview are meant to cohere. If one's ontology has angels and spirits existing with certain powers, then one's epistemology has to account for the possibility of this knowledge, and further it needs to indicate how the truth or falsity of claims about spirits can be ascertained. Is the epistemological ground for such claims Intuition? Authority? Religious Experience? or Revelation? It is rarely claimed that the ground is Science.

Despite being everywhere and being endowed with amazing powers and being variously credited with causing tsunamis, AIDS, schizophrenia, adultery, paedophilia and much else, such angels and spirits do not show up in laboratories or scientific texts; they have not gained a place in the scientific understanding of the natural, social or personal worlds. This gives rise to a certain disconnect. Such claims are then either discordant with, or orthogonal to, the worldview and conduct of science.

50.7.2 Traditional Societies

In traditional or indigenous cultures, these convictions about the 'invisible world' and interactions between this supernatural world and the everyday world are usually bolstered with animist beliefs where plants and natural objects are endowed with intelligences and spiritual attributes and where natural processes can be swayed by rituals, incantations, charms, potions, magic, sorcery and spells. In most such cultures, spirits are everywhere and have immense powers; they feature in traditional stories, legends and myths and underwrite a wide variety of social and medical practice.

Papua New Guinea is a representative case. In the early months of 2013, there had been a series of horrific sorcery-related gruesome murders committed. In January outside Mt Hagen, the capital of the Western Highlands, a 20-year-old mother was accused of sorcery, doused in petrol and burnt alive atop a pile of rubbish and car tyres. She supposedly had used her powers as a witch to kill a boy who had been admitted to hospital with chest pains. In March a highlands man ate his newborn son in order to bolster his sorcery powers. The same month in the Southern Highlands, six supposed witches were tortured with hot irons and one roasted to death. In April in Bougainville, two elderly women, accused of being witches and causing the death of a school teacher, were tortured for 3 days then beheaded in front of a large mob that included police officers. In just one Highland province, Simbu, there are 150 sorcery-inspired attacks per year.[51]

At the same time, the PNG government released a report on the AIDS epidemic in the country detailing the prevalence, and uselessness, of traditional treatments such as having sufferers sit atop huts inside of which is burnt 'special fires' in expectation that the rising smoke would carry off the evil spirits inhabiting the

---

[51] See accounts and interviews in Elliot (2013).

person and causing the sickness. Such practices are widespread in the country where things are believed to happen not just for physical reasons because there can always be some non-natural trigger or cause for the happening; indeed the latter are so commonplace that to refer to them as 'non-natural' fails to understand the traditional worldview where 'white' and 'black' magic (*Sanguma*) are just part of how things are; *Sanguma* is everywhere and is recognised in the legal code. As one commentator remarked on these practices:

> In a remote world lacking scientific explanation, in which life could be brutish and short, it was natural that people sought not only a way to understand how their world worked, but also to find a way to take a measure of control over it. (Callick 2013, p. 11)

The reality and efficacy of sorcery is recognised in the 1971 *Sorcery Act*. A 1977 PNG Law Commission study on 'Sorcery in PNG' concluded:

> We have written some general ideas about sorcery we know from our own experience as Papua New Guineans. In order to get a balanced view of sorcery we would like to say that sorcery is very much a matter of the innermost belief of the people. Fear of, or the practice of sorcery or various occults is a world-wide phenomenon. Sorcery or black magic exists in Europe, in Asia, in Africa and in North and South America as well as the Pacific.
>
> Major world religions claim the reality of forces or personalities greater than the human and animal powers. Whether these powers or personalities can be shown to exist is often quite irrelevant to the belief. From these beliefs many practices and procedures follow. (Narokobi 1977, p. 19)

The 2013 revision of the legal code is moving to deny the reality of such powers and make supposed *Sanguma* bashings, torture and killings criminal offences.

A long-time PNG Catholic priest, Philip Gibbs, recognised the incompatibility of Enlightenment-informed scientific worldviews and biblical worldviews when he described PNG culture as having a:

> Pre-Enlightenment, or Biblical, worldview … They don't believe in coincidence or accidents. When something bad happens, they don't ask what did it but who did it. (Elliot 2013, p. 18)

The situation with PNG traditional society is repeated in sometimes more and other times less extreme forms in most traditional societies and other societies, where the spirit world looms large and where centuries, if not thousands of years, of tradition, folklore and superstition are embedded.

Ancient rock art of the Australian aboriginal Worrorra people has recently been re-discovered in the spectacular Kimberley country in north-west Australia. The recurrent image is of Wandjinas, the supreme spirit who created the country during the Dreamtime. The Worrorra belief is:

> The Wandjinas created the animals and the baby spirits that live in the rock pools or sacred Ungud places throughout the Kimberley, and they continue to control everything that happens on the land, sea and sky. (http://wandjinatours.com.au/)

It is routine in most Southeast Asian countries for residential and other buildings to have 'spirit houses' prominently placed so that spirits disturbed in the construction have a new home; a home where food and offerings are left so the annoyed spirits do not do mischief. Some such beliefs and 'the practices and procedures' based on them are benign, while others are dramatically less so.

'Smoking' ceremonies where Australian aboriginal people gather and burn special leaves so the spirit of a deceased can be released and be carried upwards with the smoke to 'heaven' are a benign example.[52] The case of a New Zealand Maori couple who in November 2007 gouged out the eyes of their 14-year-old daughter in order to allow the escape of a bad spirit who supposedly possessed the girl is a less benign example. This 'exorcism' was witnessed by 40 relatives.[53] Of course these beliefs and practices are not just those of 'traditional' societies: Not long after the Maori episode, the Vatican's official exorcist, Father Gabriele Amorth, who has conducted 70,000 exorcisms, claimed that many paedophilia cases were the direct work of devils who possessed or otherwise influenced the offending priests (Amorth 2010).

When politicians, doctors, nurses and educated community members deny the efficacy or existence of 'bad' spirits or devils, they are involved in proto-science. The basic claim is that 'there is no evidence' for such possession and that the evidence (paedophilia or children dying) can be accounted for by other natural causes. This basic claim moves discussion into the field of science and evidence appraisal. But once that move is made, then why not extend the examination to the efficacy or existence of 'good' spirits and angels?

50.7.3 Feng Shui

Non-scientific, and in some cases anti-scientific, worldviews are widespread in advanced economies and cultures where commitment to astrology, parapsychology, levitation, clairvoyance, mediums, extrasensory perception, the paranormal, telepathy, astral travel, Thiaoouba consciousness and so on are common.[54]

One entrenched practice and theory that does not attract the attention it warrants is feng shui (Rossbach 1984). Millions of Chinese believe in its principles, and increasingly it is being adopted outside of the Chinese community. Feng shui advising is a thriving business with thousands of consultants, and law courts determining whether correct or incorrect feng shui advice was given in cases where poor business returns or illness follows occupancy of feng shui-certified commercial and residential buildings.

Feng shui, or Chinese geomancy, derives from an ancient Chinese system of rules, concepts and principles that endeavours to explain the impact on people's lives of the layout and design of their business and home. Its origins lay in the 3,000-year-old writing, *I Ching*, of the ancient sage Fu His who had the inspiration that the diverse fundamental forces of the universe were mirrored in the orderly markings on the shell of the tortoise which when arranged in threes gave eight

---

[52] There is a parallel use of incense in the Roman Catholic burial liturgy.

[53] *Sydney Morning Herald* November 27, 2007

[54] On this phenomena, see Dawkins (1998), Sagan (1996), Shermer (1997) and the classic study by W. E. H. Lecky (1914). Hundreds of thousands of websites are devoted to these 'alternative' science practices and 'theories'.

trigrams corresponding to Heaven, Earth, Fire, Water, Mountain, Lake, Wind and Thunder (Spear 1995, Chap. 5).[55] Unlike the case of chaotic and inconsistent good or bad spirits, feng shui purports to describe regular, lawful natural processes in just the same way that science does. But over and above the mundane energy of science, there is another universal life force called Chi or Mana. One feng shui exponent explains that:

> Chi is the vital force that breathes life into the animals and vegetation, inflates the earth to form mountains, and carries water through the earth's ducts … Without chi, trees will not blossom, rivers will not flow, man will not be. (Birdsall 1995, p. 37)

But chi is a peculiar kind of vital energy as:

> Doors are seen as the entrance of chi for any place. A building, house or room takes in its chi through the doors and, to a lesser extent, the windows. If the doors are too small then not enough chi will get into a place too many doors down a corridor may affect and confuse the flow of chi. (Birdsall 1995, p. 129)

And being more precise:

> One of the classic rules of feng shui…is that if you have a toilet in the wealth corner of your home or business, then you are likely to have financial or abundance troubles. (Birdsall 1995, p. 117)

However there is a correction for such faulty construction:

> Place a crystal in the window of the bathroom to draw in the universal chi. (Birdsall 1995, p. 118)[56]

And so on for 200 pages of this popular book. But the author moves from relatively trivial and harmless nostrums to something more arresting:

> Science can no longer dismiss the concept of our energetic body existing outside our physical bodies, as the former can now be photographed and analysed by Kirlian photographs. Often disease can be seen in the auric body before it shows in the physical body. (Birdsall 1995, p. 38)

But these high-energy photographic effects have everything to do with effects of changes in proximal humidity around bodies and nothing to do with supposed auras; as water vapour is progressively removed from around a hand or head, the aura image disappears. Basing medical diagnosis and treatments on such foolery can do damage, quite apart from wasting people's money.

With its commitment to ontological, epistemological and axiological principles that guide behaviour, feng shui counts as a worldview, one that is held by millions of people. As one advocate writes: 'More than just the practice of geomancy, placement, or spatial arrangement, feng shui is also a philosophy or a way of seeing the world' (Spear 1995, p. 15). And where it is not a self-contained worldview, it is a component that its believers' wider worldviews need to accommodate.

---

[55] There are over 100 English translations of the basic text, *I Ching*.

[56] Another advocate who addresses this problem does admit that 'no feng shui cure can be as powerful as a properly placed, flawless diamond to activate chi in an environment' (Spear 1995, p. 131).

Following feng shui ‘principles’ often does no harm. It is like the fabled Notre Dame football coach who said that God most answered the team’s prayers when ‘the forwards were big and the backs were fast’; or knowing that ‘with an uncle’s blessing and one dollar, you can ride the subway’. So if you build in such a way that your living quarters receive natural sunlight, then it is just a bonus that the room also falls on a good chi line and has auspicious bagua. Ditto if your bedroom has a window that does after all let in fresh air. But feng shui belief can do harm, and it is a distraction: Sometimes illness is caused by an infection, and poor profit results are the outcome of bad business decisions. In such cases rearranging the furniture or putting in an extra door, mirror or even a diamond will make no difference to the malady.

If teachers have some training in history and philosophy of science, the philosophical implications of feng shui can be drawn out. There are a host of questions and tasks that can usefully occupy students:

What are the claims of feng shui and are they scientifically testable?
Do other theories have the same implications and thus are they equally supported by whatever experimental evidence might support feng shui?
Where there are two, or more, such theories consistent with the empirical evidence [people in sunny houses feel well and suffer less colds] can any crucial experiment be devised to evaluate the theories?
Are feng shui predictions and theory elaboration all ad hoc? And what is wrong with ad hoc adjustments in theory?
Is feng shui a progressive research programme making novel claims or a reactive or degenerating one which only embraces claims made on other grounds?
How can the cultural, social and economic pros and cons of feng shui be explicated and appraised?

And this drawing out can be done by social science and science teachers working together.

For science teachers in cultures where feng shui is part of the social fabric, such questions can be used as a way into better understanding of the nature and methods of science, including the question of the function of naturalism in science and in culture. And orthodox religious belief, traditional cultural beliefs, astrology, psychokinesis, aura therapy, psychoanalysis and anything else can be substituted for feng shui in the foregoing questions. Each question draws on routine discussion in philosophy of science, and so each question can be the occasion for elaboration and learning of the latter.

50.7.4 Education and the ‘Invisible World’

Thus far no such traditional, or other, spirits have been identified by science as having any causal interaction with the world. Yet they are very much a central part of the worldviews of several billion people. The educational question is what to do about such beliefs? Should nothing be done and the cultural status quo retained unaltered? Should students be encouraged to believe just in good spirits and not in bad ones?[57] And if they are to believe in good spirits, should they believe for ontological reasons (there actually are such things) or for instrumental reasons (such belief is harmless and part of the cultural or religious tradition)? Or not believe in spirits at all?

The last was the choice of Joseph Priestley, the famed eighteenth-century English scientist, historian, philosopher, theologian and Dissenting Church minister[58]:

> The notion of madness being occasioned by evil spirits disordering the minds of men, though it was the belief of heathens, of the Jews in our Savior's time, and of the apostles themselves, is highly improbable; since the facts may be accounted for in a much more natural way. (Rutt 1817–1832/1972, vol. 7, p. 309)

For Priestley, Jesus was simply mistaken when he attributed the cure of madness to driving out evil spirits because subsequent science and philosophy had shown there were no such things to be driven out.[59]

Whether the Abrahamic religious traditions or 'indigenous' traditions can abandon belief in all, most or just some of 'the invisible world' is an engaging theological and cultural question, but the grounds for such discussion can usefully be prepared by discussions in philosophy of science about what constitutes 'hard-core' commitments in a research programme and how these are separated from 'protective belt' commitments – to use the terminology of Imre Lakatos (1970). Philosophers of science have for long dealt with the questions of what are the 'core' commitments of a research programme and what are 'optional' commitments, and familiarity with these discussions and analyses can inform comparable discussion about religion and important cultural beliefs.

50.8 Multiculturalism and Science Education

Examples of spirit-laden cultures and traditions have been given above. It was pointed out that such belief constellations were either discordant with or orthogonal to science, with the latter depending on whether spiritual, or supernatural, agencies had engagement with the world. In these latter cases, the relationship is not orthogonal; once it is claimed that the 'invisible world', or supernatural agencies, connect to the world and have worldly impacts, then they enter the domain or 'magestria' of

---

[57] In March 2013 Indonesia's criminal law statutes were being rewritten so as to make the practice of black magic (where people are harmed by sorcery) illegal but keep white magic legal. This raises not just ethical questions but engaging philosophical ones as well. Does a 'guilty' verdict acknowledge that such powers of mind over matter were exercised?

[58] The basic texts for Priestley's life, writings and achievements are Schofield's (1997, 2004). See also de Berg (2011), Matthews (2009c).

[59] In passing it is worth noting that every account of Priestley's life shows that a deeply 'spiritual' life is possible without any belief in spirits.

science. It was also suggested that students can be encouraged to engage in a number of routine philosophical questions about such belief systems. Such questions and pedagogy raise important matters about the purposes of science education and the distinction between *understanding* science and *believing* science. Some maintain that science education should leave cultural beliefs untouched, that students should simply leave their culture's worldview (ontology, epistemology, metaphysics, authority structure, politics and religion) at the classroom door, then enter inside to learn the instrumentally understood content of science, then go back outside and become again full-believing participants in their culture. This is close to advocating an anthropological approach to learning science. Just as anthropologists can be expected to learn *about* the beliefs and practices of different societies without any expectation that they adopt or come to believe them, some say that students can learn science in the same way, a sort of 'spectator' learning where one learns but does not believe.

Glen Aikenhead, in a much cited paper, has advocated such a strategy calling it 'border crossing' (Aikenhead 1996, 2000). Just as tourists when they cross borders do not lose their cultural identity even though they temporarily adopt foreign customs about driving, eating, dressing and language, so also science students should not lose their cultural identity (as a traditional Catholic, a fundamentalist Christian, an Intelligent Designer, a PNG highlander, a feng shui enthusiast and so on) just because the science laboratory has no place for their own rich beliefs. This 'border-crossing' option is a form of pedagogical NOMA; it is a profoundly anti-Enlightenment view.

Early modern and Enlightenment philosophers thought much would be gained if the method of the New Science might be applied to the seemingly intractable social, political, religious, philosophical and cultural problems of the times. During the period of Galileo's most productive work, the terrible 30 Years' War (1618–1648) raged all over Europe – in German states, France, Italy, Spain, Portugal and the Netherlands – and was also fought out in the Indies and in South America. It is widely accepted that between 15 % and 20 % of the German population, Catholic and Protestant alike, were killed. Along with ferocious religious wars witch crazes also engulfed Europe with the worst excesses occurring in France, Switzerland, Germany and Scotland. In the Swiss canton of Vaud, in the 90 years between 1591 and 1680, 3,371 women were tried for witchcraft and all were executed (Koenigsberger 1987, p. 136). The Salem witch trials took place in Massachusetts in 1692, 5 years after publication of Newton's *Principia*. As late as 1773, nearly 100 years after publication of Newton's *Principia*, the Presbyterian Church of Scotland reaffirmed its belief in witchcraft; but Catholic Spain has the distinction of being the last European country to burn a witch at the stake, this being in the early nineteenth century. And the lamentable practice still goes on in Papua New Guinea, Africa and doubtless many other traditional societies untouched by science and the Enlightenment.

Newton believed that there would be beneficial flow-on effects if the methods of the New Science were applied to other fields. As he stated it: 'If natural philosophy in all its Parts, by pursuing this Method, shall at length be perfected, the Bounds of

Moral Philosophy will be also enlarged' (Newton 1730/1979, p. 405). David Hume echoed this expectation with the subtitle of his famous *Treatise of Human Nature* which reads *Being an Attempt to Introduce the Experimental Method of Reasoning into Moral Subjects* (Hume 1739/1888).

The contrast between the aspirations of the Enlightenment philosophers and contemporary 'border-crossing' science educators is profound and speaks to a major divergence in their appreciation of science. This indeed is the case, with Glen Aikenhead maintaining that 'the social studies of science' reveal science as:

> mechanistic, materialist, reductionist, empirical, rational, decontextualized, mathematically idealized, communal, ideological, masculine, elitist, competitive, exploitive, impersonal, and violent. (Aikenhead 1997, p. 220)

This claim is as puzzling as it is disturbing. Is the claim meant to describe the work of Galileo? Newton? Huygens? Darwin? Mendel? Faraday? Mach? Thompson? Lorentz? Maxwell? Rutherford? Planck? Einstein? Bohr? Curie? Does it describe the work of Edward Jenner in developing smallpox vaccine? Or the achievements of Jonas Salk and Albert Sabin in developing polio vaccine? We are not told whose science warrants the description. It is clearly a composite or collage that requires unpicking, but this is not done – the good, the bad and the ugly are all lumped together. Unfortunately there are numerous cases of corrupt science – Nazi and Stalinist science being the best-known examples – but these do not warrant generalisations, they warrant correction. From Aikenhead's undifferentiated description, it is doubtful whether science should even be in the curriculum; it certainly should be rated X, with even border crossing being dangerous for minors. Other prominent and influential science educators share Aikenhead's unfavourable estimation of science. Consider, for instance, the demand that teachers need to:

> deprivilege science in education and to free our children from the 'regime of truth' that prevents them from learning to apply the current cornucopia of simultaneous but different forms of human knowledge with the aim to solve the problems they encounter today and tomorrow. (Van Eijck and Roth 2007, p. 944)

Or the claims made in a contribution to a current major science education handbook that:

> … one of the first places where critical inquirers might look for oppression is positivist (or modernist) science … modernist science is committed to expansionism or growth … modernist science is committed to the production of profit and measurement …modernist science is committed to the preservation of bureaucratic structures. (Steinberg and Kincheloe 2012, p. 1487)

> Science is a force of domination not because of its intrinsic truthfulness, but because of the social authority (power) that it brings with it. (Steinberg and Kincheloe 2012, p. 1488)

> Modernism refers to a way of understanding the world produced by Enlightenment thinkers and employing a scientific methodology and the concept of rationality Drawing on dualism, scientists asserted that the laws of physical and social systems could be uncovered objectively; the systems operated apart from human perception, with no connection to the act of perceiving …. This separation of mind and matter had profound and unfortunate consequences. (Steinberg and Kincheloe 2012, pp. 1490, 1491)

Such appraisals demonstrate the need for science educators to be careful and considered in their reading and studies of history and philosophy of science; clearly a little knowledge is a dangerous thing. The above accounts, apart from being confused and contradictory, cannot be sustained. Taking the subject *out* of the picture and relying on measuring instruments (rulers, scales, thermometers, barometers, clocks) instead of subjective appraisals of length, weight, temperature, pressure and duration; utilising mathematics; introducing idealisations and abstractions; valuing objective evidence; and being public, communal, publishing, criticising and debating are all the things that enabled the Scientific Revolution to occur in seventeenth-century Europe and progress to its current international status. And of course Copernicus and Galileo had no social authority enforcing their heliocentricism, on the contrary; while Lysenko had all the oppressive authority of Stalin behind his non-Mendelian genetics and it counted scientifically, and ultimately, for nothing. All of this is missing in the accounts of science given by the above science educators.

50.9 Philosophical Systems and Religious Belief

The juxtaposition of scientific and religious worldviews brings into focus a number of enduring philosophical, religious and cultural issues, among which are at least the following:

1. Do religions make metaphysical claims? Are there preferred philosophical systems for the expression of such claims? Are particular religions tied to such systems?
2. Is there a need for religious claims to be made intelligible and testable? Or is Faith deeply personal, experiential and indefinable? Is Faith apart from and beyond Reason?
3. Should philosophical systems be judged by their theological adequacy or compatibility?
4. Should religious establishments (churches, priests, ministers, imams, ulama) have the authority to proscribe philosophical systems or metaphysics to their co-religionists? Should they be able to proscribe to others outside their religion when their religion exercises or influences state power?

These issues were argued within the Christian churches; they were debated in the Enlightenment and are still debated.[60] For example, Claude Tresmontant in his *Christian Metaphysics* argues that:

> The thesis which I submit to the critical examination of the reader is that there is *one* Christian philosophy and one only. I maintain, in other words, that Christianity calls for

---

[60] For representative literature on this topic of ‘Christian Philosophy’, see Mascall (1966, 1971), Plantinga (2000, 2011), Tresmontant (1965), and Trethowan (1954). The suitability of Thomism as a vehicle for the interpretation of Christian doctrine is discussed in McInerny (1966). The same debates and literatures can be found in Islamic, Judaic, Hindu and other traditions.

> a metaphysical structure which is not any structure, that Christianity is an original metaphysic. … [it is] a body of very precise and very well-defined theses which are properly metaphysical …. (Tresmontant 1965, pp. 19–20)

The Catholic priest, philosopher and historian of philosophy, Fredrick Copleston wrote of his celebrated 1949 debate with A. J. Ayer that:

> After all, my defence of metaphysics was largely prompted and certainly strengthened by what I believed to be the religious relevance of metaphysical philosophy. (Copleston 1991, p. 63)

One such common metaphysical position, vitalism, is clearly stated by another Catholic priest and philosopher:

> That there is a fundamental difference between living and non-living matter is obvious. Catholic philosophers hold that an organized or living substance is distinguished from inanimate matter in that the former is informed by a 'vital principle' which confers on it the characteristics we associate with life. (Gill 1943, p. 73)

Such a position might be labelled 'privileged' in as much as the metaphysics comes from outside of science, not from within. Privilege for such metaphysical positions is usually derived from Revelation, Theology, Religious Experience, Philosophy, Intuition or Politics. Such privileged metaphysical views can be found enunciated by advocates of Judaic, Islamic, Hindu, Buddhist and a host of other religions, as well as advocates of the maintenance of indigenous belief systems and worldviews. These traditions would formulate the above four fundamental issues in their own terms. For instance, if 'Marxism-Leninism' is substituted for 'religion' and the 'Central Committee' substituted for 'religious authorities', then the above list of issues is applicable to the situation that pertained in the Soviet Union and its satellites and still pertains in China. No authoritarian state, since the Athens that put Socrates to death, has welcomed open and free philosophical study and debate.[61]

50.9.1 Compatibility of Science and Religion

When considering the compatibility of science and religion, we need to distinguish a number of sometimes conflated issues[62]:

First, whether religious claims and understandings have to be adjusted to fit proven scientific facts and theories. There really is no longer any serious debate on this issue; sensible believers and informed theologians acknowledge that religious

---

[61] Anthony Kenny, the British philosopher and former Catholic priest, depressingly relates in his autobiography how as a doctoral student at Rome's Gregorian University he needed his supervisor's permission to read David Hume's *On Religion* and that his degree would not be awarded unless he affirmed an anti-Modernist oath (Kenny 1985, p. 146).

[62] Different taxonomies or ways of classifying science/religion relationships are developed in Barbour (1990), Haught (1995) and Polkinghorne (1986). These, and others, are discussed in Mancy et al. (in press).

claims need to be modified or given a nonliteral interpretation to fit with proven or even highly probable science. Joseph Priestley, the eighteenth-century Enlightened believer, told the story of ‘a good old woman, who, on being asked whether she believed the literal truth of *Jonah* being swallowed by the whale, replied, yes, and added, that if the Scriptures had said that *Jonah* swallowed the whale, she would have believed it too’. Priestley thought that such convictions simply indicated that the term ‘belief’ was being misused in the context: ‘How a man can be said to *believe* what is, in the nature of things, *impossible*, on any authority, I cannot conceive (Rutt 1817–1732/1972, vol.6, p. 33). All serious thinkers on the topic, since St Augustine, agree with Priestley.[63]

Second, whether religious believers can be scientists. Again, at one level, there is no debate on this matter. As a simple matter of psychological fact, there have been and are countless believers of all religious stripes who are scientists.[64] But this sense of compatibility is of some but not determinate philosophical interest. The arguments and evidences put forward by these numerous eminent and believing scientists are relevant to the question of rational compatibility but not just the fact that there are such believers. Undoubtedly some scientists are astrologers, others channel spirits, some might think they are Napoleon reincarnated, some are racist and others are sexist and so on for a whole spectrum of beliefs that, as a matter of fact, have been held by scientists. No one doubts that science, as a matter of psychological fact, is compatible with any number of belief systems – recall that the Nobel laureates Philipp Lenard and Johannes Stark were both Nazi ideologues. Scientists are humans, and humans notoriously can believe all sorts of crazy things at the same time; but such psychological compatibility has no bearing on the rationality or reasonableness of their beliefs or the philosophical compatibility between science and belief systems. The latter is a logical or normative matter. The philosophically interesting question is whether a scientist can be a *rational* religious believer (or astrologer, diviner, reincarnationer, racist, sexist, Nazi, etc.).

Third, whether religion is compatible with the metaphysics and worldview of science. Where there is incompatibility between scientific and religious

---

[63] There has been debate about just what degree of proof a factual scientific claim needs to have before it triggers a revision in a competing factual religious claim – Augustine thought revision was needed only in the face of absolutely proven ‘scientific’ claims. The details of this debate do not bear on the present argument; for the arguments and the debate’s literature, see McMullin (2005).

[64] John Polkinghorne, an Anglican priest, could be picked out as an exemplar of a research physicist and believer (Polkinghorne 1986, 1988, 1991, 1996). Many such individuals can be found contributing to journals such as *Zygon: Journal of Religion & Science*. For just one compilation of contemporary Christian scientists, see Mott (1991). There are comparable compilations of Hindu, Islamic, Mormon and Judaic scientists. There may even be compilations of Scientologist scientists and Christian Science scientists. These lists are relevant to the question of the psychological compatibility between scientific and religious beliefs, but not their philosophical or rational compatibility.

metaphysics and worldviews – as in the case of atomism and traditional Roman Catholic doctrine developed above – the options usually taken to reconcile the differences are to claim that:

1. Science has no metaphysics; it deals just with appearances and makes no claims about reality. This is the option made famous by the Catholic positivist Pierre Duhem.[65] It is the claim made by many fundamentalists who say, specifically of evolution, that 'it is just a theory'.
2. The metaphysics of science is false; at least any such purported metaphysics that is inconsistent with religious beliefs. This is the option advocated by the Scholastic tradition discussed above; by Claude Tresmontant and Seyyed Nasr who are quoted above; and by philosophical theologians such as Alvin Plantinga (2011), E. L. Mascall (1956) and numerous others.
3. There can be parallel, equally valid, metaphysics. This is an old option given recent prominence by Stephen Gould in his NOMA formulation (Gould 1999).

Gould's much-repeated claim was that:

> The magisterium of science covers the empirical realm: what the Universe is made of (fact) and why does it work in this way (theory). The magisterium of religion extends over questions of ultimate meaning and moral value. These two magisteria do not overlap, nor do they encompass all inquiry (consider, for example, the magisterium of art and the meaning of beauty). (Gould 1999, p. 6)

The problem for NOMA is that, apart from classical Deists for whom God stays remote in His heaven and has no dealings with His creation, the core conviction of religious traditions is that the two realms overlap: that the supernatural has engagement with the natural; that God engages with His Creation; that certain texts (Torah, Bible, Koran, Book of Mormon, Sikh scriptures) are inspired, if not divinely written; miracles occur; prayers are answered and so on. However as soon as claims are made for supernatural engagement with the natural world and processes, then they come within the magestria of science: The cause might be of another world, but the effect is of this world. Such causal claims need not and should not be ignored by science; science can test claims about miracles, supernatural interventions and even Divine authorship, just as it can test claims about putative paranormal and psychic occurrences.[66]

50.9.2 *Scientific Study of Scripture*

Because so much hinges upon it, the very possibility of a 'scientific' or scholarly investigation of sacred texts or Scriptures has always been contentious in all

---

[65] See extensive discussion and bibliography in Martin (1991).

[66] The anti-NOMA view that science can test supernatural claims is convincingly argued by many, including Boudry et al. (2012), Fishman (2009), Slezak (2012), and Stenger (1990, 2007).

'scripture-based' religious traditions. One historian of the origins of modern biblical scholarship writes that:

> Thus it is not surprising as may be thought that we can turn firstly to two *scientists* (this shows the importance of the Copernican revolution for the beginning of the historical-critical method) who are not usually thought of in this connection at all: Johannes Kepler and Galileo Galilei. (Andrew 1971, p. 95)

Galileo's 1615 *Letter to the Grand Duchess Christina* was perhaps the first clear statement in the Christian tradition of the view that Revelation should be investigated in the same way that other cultural artefacts and natural objects were investigated, namely, scientifically (Galileo 1615/1957). Galileo, in order to defend Copernicanism against those bringing scriptural objections to a rotating Earth, argued that Scripture had to be interpreted by Reason, and where there was conflict between Scripture and claims established conclusively by Reason, then Scripture had to be reinterpreted accordingly. Galileo was appealing to a well-established interpretative tradition in the Catholic Church going back at least to St Augustine, a tradition that acknowledged that not everything in Scripture was to be read literally as many things simply could not have occurred: Moses authoring the entire Pentateuch including the story of his own death; Jonah surviving in the whale; Methuselah living for 969 years; a flood that covered the whole earth, but of which other nations knew nothing; iron axe heads floating on rivers; numerous people rising from the dead; and so on. These stories had to be read metaphorically or poetically. But the Church was the authority that decreed what text was literal and what was poetic.

Baruch Spinoza's 1670 *Tractatus Theologico-Politicus* (Spinoza 1670/1989) is widely regarded as the first comprehensive attempt to state the exegetical principles of modern, secular, historical study of the Judaeo-Christian scriptures; the study of biblical history removed from theological dogma. He wrote in Chap. 7: 'the method of interpreting Scripture is no different from the method of interpreting Nature, and is in fact in complete accord with it' (*TTP* 3.98). This meant first, attention to the text only and not to tradition; second, adopting the primacy of 'Natural Reason' in interpretation of scriptural text. As a consequence in an ecumenical display, Calvinist ministers and Jewish rabbis combined to drive Spinoza from Amsterdam.[67] Some Enlightenment figures, Edward Gibbon and John Toland, for instance, thought scripture so imperfect that the advance of human reason simply dissolved revelation. Toland claimed that 'there is nothing in the Gospel contrary to reason' and then crucially added 'or above it' (Hyland et al. 2003, p. 60). The postscript ruled out recourse to affirmations of unanchored faith.

The addition was crucial because Kepler, Galileo and others admitted that scripture asserted things that were 'beyond human understanding' and so not contrary to human understanding; in the latter cases, scripture had to be reinterpreted, and in the former, there was no need to do so. This meant a cleavage in the reach of the Galilean method. For Toland and most Enlightenment thinkers, the 'beyond human reason'

---

[67] On Spinoza and the adoption of 'scientific method' in biblical studies, see Bagley (1998) and contributions to Force and Popkin (1994).

category was not countenanced; science was the arbiter separating literal from poetic in biblical texts.

In the mid-nineteenth century at the time of Pius IX, the German schools of Hermeneutics and higher Biblical criticism represented the more radical wing of Enlightenment views about the scholarly study and interpretation of Revelation. The Pope was particularly outraged by Ernest Renan's just published *Vie de Jésus* (Renan 1863/1935)[68] which he said ought to have been suppressed by the French government; it was so suppressed, along with most of the Enlightenment canon, in the Papal States and in other Catholic countries where the Church yielded political and judicial influence.

Salman Rushdie, the Muslim apostate who was condemned to death by the Iranian spiritual leader Ayatollah Khomeini, has recently written that:

> What is needed is a move beyond tradition – nothing less than a reform movement to bring the core concepts of Islam into the modern age. … If, however the Koran were seen as a historical document, then it would be legitimate to reinterpret it to suit the new conditions of successive new ages.

In saying this, Rushdie is claiming no more than what, informed by modern science, European Enlightenment figures of the eighteenth century asserted. One can only believe that the ensuing working out of this claim, to see Scripture as a historical text, will be the same in Islam as it has been in Christianity and in Judaism where the claim has been grappled with for four centuries. For some the Divine content of Revelation will evaporate, for others what will be revealed will be what Reason permits to be revealed, and for others such as those holding to some version of the 'Inerrancy of Scripture' doctrine, there will be some uneasy accommodation between Reason and Revelation.

50.10 Science and Naturalism

The conduct of science presupposes at least methodological naturalism (MN). This is the view that, when doing science, whatever occurs in the world is to be explained by natural mechanisms and entities and that these entities and mechanisms are the ones either revealed by science or in principle discoverable by science. This methodological presupposition does not rule out miracles or Divine interventions or other non-scientific causes; it just means that such processes cannot be appealed to while seeking scientific explanations. There has been historically a transition from more open or mixed methodology to having MN function as a defining principle of scientific investigation. As Robert Pennock states the matter:

> … science has completely abandoned appeal to the supernatural. In large part this is simply the result of consistent failure of a wide array of specific 'supernatural theories' in competition with specific natural alternatives. (Pennock 1999, p. 282)

---

[68] Other contributors to this 'higher criticism' or scientific study of texts were Friedrich Schleiermacher (1763–1834), F. C. Bauer (1792–1860) and David Strauss (1808–1874).

A stricter version of naturalism is ontological naturalism (ON), which sometimes is called metaphysical naturalism. This is the view that there is a scientific explanation for all events, that supernatural explanations (e.g. Divine interventions, miracles) simply do not occur. Many see ON as pure dogmatism, and it can be if it is held in advance as a philosophical principle. But it can be held on less dogmatic two-step grounds:

(i) Thus far no credible evidence has been advanced for the existence of any putative non-natural entity, or entity not within the scientific realm.

Many of course reject (i), and that is a whole separate argument. But some accept (i) and nevertheless say that ON does not follow from it or only follows dogmatically, as no one knows that evidence might turn up. But the nondogmatic holder of ON can add a second step to their argument:

(ii) Do not believe things for which there is no evidence.

If (ii) is granted, then ON does indeed follow. Then the dogmatism claim moves back to belief in (ii) rather than belief in ON. But belief in (ii) need not be dogmatic; it can be the 'default' position and its opposite, namely, the holding of beliefs for which there is no evidence, is dogmatic. This was in essence Bertrand Russell's 'teapot' argument.

> I ought to call myself an agnostic; but, for all practical purposes, I am an atheist. I do not think the existence of the Christian God any more probable than the existence of the Gods of Olympus or Valhalla. To take another illustration: nobody can prove that there is not between the Earth and Mars a china teapot revolving in an elliptical orbit, but nobody thinks this sufficiently likely to be taken into account in practice. I think the Christian God just as unlikely. (Russell 1958)

Both science-informed methodological and ontological naturalists admit the existence of whatever kinds of entities (e.g. atoms, fields, forces, quarks) science reveals as having regular causal relations with the rest of nature. But ontological naturalists do not admit the existence of spiritual or Divine entities or any kind of entity that does not enter into scientifically demonstrated lawful and causal relations with nature.[69] Traditional religious believers must reject ontological naturalism, but of course religious scientists routinely adopt methodological naturalism in the laboratory; to do otherwise would put them outside of the scientific enterprise.[70]

Materialists are a subspecies of ontological naturalists, but they are less relaxed about what can exist. Basic or 'old-fashioned' materialists grant existence only to

---

[69] Although often confused, there is a difference between realism and naturalism (including Materialism). Realism simply asserts that there is a world independent of human thought. Such an independent world might include spirits, minds, universals, mathematical objects, forms or any other independent existent. Realism neither rules in or rules out any particular kind of putatively existing being. A theological realist about angels believes that angels exist, not that the word 'angel' is shorthand for 'makes people behave' or 'strengthens our cultural bonds'. Naturalism is a subspecies of realism, it asserts that the only existing things are the things that science postulates and incorporates into successful and mature theories; materialism in turn is a subspecies of naturalism.

[70] On naturalism see Martin Mahner's contribution to this handbook. See also Fishman and Boudry (2013), De Caro and Macarthur (2008), Devitt (1998), French et al. (1995), Mahner (2012), Nagel (1956), and Wagner and Warner (1993)

material, physical, ‘three-dimensional’ objects, the kind of things that can be tripped over. They reject the postulation of nonmaterial scientific entities, believing that such postulation is a failure of scientific nerve and it is the slippery slope to idealism.[71] This is clearly as much an a priori metaphysical position as it is a deduction from scientific practice. Emergent materialism is a more sophisticated version where the world is seen as material but stratified. The properties of material aggregations are greater than, and different from, the properties of the building blocks. So cells have different kinds of properties than molecules, brains have different properties than neurons, societies have different properties than individuals and so on. For emergent materialists, the world is changing and evolving, and new properties emerge from more complex material formations.[72]

50.11 Worldviews and Philosophy in Science Classrooms

To state the obvious: It is important for teachers to recognise how science lessons engage with the religious beliefs and worldviews of students. Much has been written on this topic.[73] It needs to be remembered that the more profound philosophical dimensions of science can be approached in classrooms and curricula through small steps; there is no need to go in at the deep end. Any science textbook will contain terms such as ‘observation’, ‘evidence’, ‘fact’, ‘controlled experiment’, ‘scientific method’, ‘theory’, ‘hypothesis’, ‘theory choice’, ‘explanation’, ‘law’, ‘model’, ‘cause’, etc. As soon as students discuss and teachers explicate the meaning of these terms, and related concepts, then philosophy has begun. And the more their meaning, and conditions for correct usage, is investigated then the more sophisticated a student’s philosophising becomes. The pupil who asks: ‘Miss, if no one has seen atoms, how come we are drawing pictures of them?’ has raised just one of the countless philosophical questions to which science gives rise (the relationship of models to reality). Likewise the student who wants to know whether after seeing 20 white swans they can conclude that ‘all swans are white’ touches upon another enduring philosophical dispute (the problem of induction and evidential support for theory). Similarly the student who, having been told about the force of gravitational attraction that exists between bodies, asks why we cannot see it, touch it, smell it or trip over it is highlighting yet another core philosophical issue (the realist versus instrumentalist debate about theoretical terms).[74]

---

[71] This was Lenin’s argument against supposed idealist movements in early twentieth-century science and philosophy (Lenin 1920/1970). On the history and philosophy of materialism, see Vitzthum (1995).

[72] On emergent materialism, see Broad (1925), Bunge (1977, 1981), and Sellars (1932).

[73] See at least Erduran and Jiménez-Aleixandre (2008), Cobern (1991, 1996), Yasri et al. (2013), Preston and Epley (2009), Taber et al. (2011), and Stolberg (2007).

[74] For further discussion of the role of philosophy in science teaching, see Matthews (1994/2014, Chap. 5).

With knowledgeable teachers, all of these questions can be further explored, elaborated and connected to studies in other subjects such as economics, history, theology and so on. And such philosophical preparation or exercises can usefully lead on to the more profound questions concerning science, worldviews and religion; without philosophical and historical preparation, the latter discussion too readily becomes merely the exchange of hot air and the advancement of not much at all.

50.11.1 From Physics to Metaphysics: The Law of Inertia

Consider the law of inertia and its related concept of force. The law is the foundation stone of classical physics which is taught in school to every science student. A representative textbook statement is:

> Every body continues in its state of rest or of uniform motion in a straight line except in so far as it is compelled by external impressed force to change that state. (Booth and Nicol 1931/1962, p. 24)

It might be 'demonstrated' by means of sliding a puck on an air table and a puck on an ice sheet or by utilising a version of Galileo's inclined plane demonstration.[75] In a purely technical science education, the law is learnt by heart, and problems worked out using its associated formulae: $F = ma$.

Technical purposes might be satisfied with correct memorisation and mastery of the quantitative skills – 'a force of X newtons acts on a mass of Y kilograms, what acceleration is produced?' – but the goals of liberal education cannot be so easily satisfied.

Just a little philosophical reflection and historical investigation on this routine topic of inertia opens up whole new scientific and educational vistas. The medieval natural philosophers were in the joint grip of Aristotle's physics and of common sense beliefs resulting from their routine everyday experience; indeed Aristotle's physics was more or less just the sophisticated articulation of common sense. Aristotle's empiricism is evident when he says that 'if we cannot believe our eyes what can we believe'. A contemporary Aristotelian says that:

> Aristotle began where everyone should begin – with what he already knew in the light of his ordinary, commonplace experience. …. Aristotle's thinking *began* with common sense, but it did not *end* there. It went much further. It added to and surrounded common sense with insights and understandings that are not common at all. (Adler 1978, pp. xi, xiii)

These understandings resulted in the medieval commitment to the principle of *Omne quod movetur ab alio movetur*: the famous assertion of Aristotle, Aquinas and all the Scholastics which translates as 'Whatever is moved is moved by another (the motor)' and its inverse, if a motor ceases to act, then motion ceases. The principle

---

[75] On Galileo's inclined plane experiments, see Palmieri (2011); on their classroom use, see Turner (2012).

grew out of daily experience, common sense and Aristotle's physics. Clagett summarised Aristotle's conviction as:

> for Aristotle motion is a process arising from the continuous action of a source of motion or 'motor' and a 'thing moved'. The source of motion or motor is a force – either internal as in natural motion or external as in unnatural [violent] motion – which during motion must be in contact with the thing moved. (Clagett 1959, p. 425)

Given the fact of motion in the world, then the principle led Aristotle to the postulation of a First Mover. Aquinas and the Scholastics took over this argument and made it an argument for the existence of a prime mover who they identified as God.[76]

Medieval impetus theory was an elaboration of Aristotelian physics: The mover gave something (impetus) to the moved which kept it in motion when the mover was no longer acting (the classic case of a thrown projectile). Some, like da Marchia, thought this impetus naturally decayed, and hence the projectile's motion eventually ceased. Others, like Buridan, thought that the transferred power was only diminished when it performed work, and as pushing aside air was work, then the projectile's motion would also eventually cease. Both theories were consistent with the phenomena: When a stone is thrown from the hand it goes only so far then drops to the ground.[77] Galileo performed a thought experiment by thinking through Buridan's theory to the circumstance of there being no work performed, in which case the projectile once impressed with impetus (force in modern speak) would continue moving forever. But for Galileo it would follow the Earth's contour. He repeated this circumstance with his experiment of a ball rolling down one incline and up another; as the second plane was gradually lowered towards horizontal, the ball moved further and further along it. He supposed that with the smoothest plane and the most polished ball, the ball would just keep moving on the second plane when horizontal; this was the visualisation of his theory of circular inertia.[78]

Galileo had no idea of a body being able to move off the Earth in a straight line away into an infinite void. Like everyone else, Galileo was both physically and conceptually anchored to the Earth. It was only Newton who would make this massive conceptual leap sufficient to have a projectile leave the Earth and move in an infinite void; he moved conceptually from a 'Closed World to the Infinite Universe' (Koyré 1957); by doing so Newton laid the foundation of modern mechanics. The whole 2000-year history of the development of the law of inertia reveals a good deal about the structure and mechanisms of the scientific enterprise, including the process of theory generation and theory choice.[79] Working through this history of argument bears fruit for arguments about worldviews and science.

---

[76] See the elaborate and informative discussion in Buckley (1971).

[77] The classic works on medieval impetus theory are Clagett (1959) and Moody (1975).

[78] The classic treatment is Clavelin (1974).

[79] See Ellis (1965) and Hanson (1965) for excellent discussion of Newton's formulation of inertia. On force, see Ellis (1976), Hesse (1961), Hunt and Suchting (1969), and Jammer (1957).

Apart from interesting and important history, basic matters of philosophy arise in any good classroom treatment of the law of inertia and the concept of force:

Epistemology – we never see force-free behaviour in nature nor can it be experimentally induced, so what is the source and justification of our knowledge of bodies acting without impressed forces?
Ontology – we do not see or experience force apart from its manifestation, so does it have existence? What is mass? What is a measure of mass as distinct from weight?
Cosmology – does such an inertial object go on forever in an infinite void? What happens at the limits of 'infinite' space? Were bodies created with movement?

These are the sorts of considerations that prompted Poincaré to say: 'When we say force is the cause of motion, we are talking metaphysics' (Poincaré 1905/1952, p. 98). And as every physics class talks of force being the cause of acceleration, then there is metaphysics lurking in every classroom, just waiting to be exposed by students who are encouraged to think carefully about what they are being taught and by teachers who know something of the history and philosophy of the subject they teach. Such exposition and engagement of school classes in the fundamental ontological, epistemological and methodological matters of philosophy that are occasioned by teaching and learning the law of inertia can be seen in a number of excellent texts.[80] In a recent publication, Ricardo Lopes Coelho discusses both the historical and pedagogical literature on this topic (Coelho 2007). All of this prepares the ground for a more nuanced and informed discussion of the big issues of science, worldviews and religion.

Thinking carefully and historically about basic principles and concepts is a quite general point about the intelligent and competent mastery of any discipline, be it Mathematics, History, Psychology, Literature, Theology, Economics or anything else. They all have their own, and overlapping, concepts and standards for identifying good and bad practice and judgements; consequently there are philosophical questions (epistemological, ontological, methodological and ethical) about each discipline; there is a philosophy of each discipline. The intelligent learning of any discipline requires some appropriate interest and competence in its philosophy; that is simply what 'learning with understanding' means – an obvious educational point made by Ernst Mach (1886/1986) and more recently by Israel Scheffler (1970).[81] If serious scientists, such as listed earlier in this chapter, feel it important to write books on the philosophy of their subject, then assuredly science teachers and students will benefit from following their example and engaging with the same questions.

---

[80] See especially those of Arnold Arons (Arons 1977, Chaps.14–15; 1990, Chap. 3), Gerald Holton and Stephen Brush (Holton and Brush 2001, Chap. 9) and the Harvard Project Physics texts (Holton et al. 1970).

[81] Mach's argument is discussed in Matthews (1989b), and Scheffler's argument is discussed in Matthews (1997).

The arguments of Mach and Scheffler have belatedly and independently found expression in the wide international calls for students to learn about the ‘nature of science’ while learning science. One cannot learn about the nature of science without learning philosophy of science, which was precisely Mach and Scheffler’s argument.

50.12 Conclusion

Science has contributed immensely to our philosophical and cultural tradition, this is part of the ‘flesh’ of science; however too often science teaching presents just the ‘bare bones’ of laws, formulae and problems, the ‘final products’ of science. This is one reason why, notoriously, advanced ‘technical’ science is so often associated with religious and ideological fundamentalism and bigotry.[82] The cultural flesh of science should be part of any serious science programme.

Carl Sagan’s undergraduate experience at the University of Chicago in the 1950s is no longer available to many students, but it is worth recalling as an ideal and something which might be striven for:

> At the University of Chicago I also was lucky enough to go through a general education program devised by Robert M. Hutchins, where science was presented as an integral part of the gorgeous tapestry of human knowledge. It was considered unthinkable for an aspiring physicist not to know Plato, Aristotle, Bach, Shakespeare, Gibbon, Malinowski, and Freud – among many others. In an introductory science class, Ptolemy’s view that the Sun revolved around the Earth was presented so compellingly that some students found themselves re-evaluating their commitment to Copernicus. … I also witnessed at first hand the joy felt by those whose privilege it is to uncover a little about how the Universe works. (Sagan 1996, pp. xiv-xv)

In a good liberal education, science students, and hopefully other students as well, will learn about the philosophical dimensions of science, beginning with routine matters such as conceptual analysis, epistemology, values and so on. They will also learn about the metaphysical, especially ontological, dimensions of science, some of which have been discussed above. They should also be introduced to and hopefully make decisions about the constitution and applicability of the scientific outlook, habit of mind or the scientific temper. To entertain questions such as: Is a scientific outlook required for the solution of social and ideological problems? By reading about any number of courageous scientists beginning with Galileo and moving through Joseph Priestley and on to Andrei Sakharov (Sakharov 1968), students can be introduced to the issue of the social and cultural requirements for the pursuit of science, the issue that so animated the Enlightenment scientists, philosophers and social reformers.

---

[82] That there is no connection between advanced technology and advanced thinking was sadly demonstrated when numerous spectators to the Papua New Guinea witch burning described above captured the event on their mobile phone cameras and uploaded the burning onto the World Wide Web.

In particular students might think through and re-argue the Enlightenment tradition's claims that on purely epistemological grounds, science, and more generally the pursuit of truth in all human domains, requires legal protection of free speech, freedom of the press and support for diversity, unhindered scholarly publication and freedom of association. To entertain questions such as: Does the promotion and spread of science entail a liberal, secular, democratic, non-authoritarian state?

All of this makes science classes more intellectually engaging, it promotes 'minds-on' science learning, and it enables diverse subjects in a school curriculum (history, mathematics, technology, religion) to be related. The introduction of history and philosophy to science lessons enables students to better understand the science and the scientific methodology they are learning, to better appreciate the role of science in the formation of the modern world and contemporary worldviews and perhaps the knowledge and enthusiasm to support science and the spread of the 'scientific habit of mind'.

Undoubtedly such an education has an impact on, and contributes to, the world-views of students. So it is worth noting Frederick Copleston's caution:

> It must be recognized, I think, that the creation of world-views is none the less a pretty risky procedure. There is, for example, the risk of making unexamined or uncriticized presuppositions in a desire to get on with the painting of the picture. Again, there are the risks of over-hastily adopting desired conclusions, and also of allowing one's judgements to be determined by personal prejudices or psychological factors. (Copleston 1991, p. 71)

But science teachers are not so much creating worldviews but encouraging students to identify and then to begin to analyse and appraise aspects of worldviews. For educators, it is the student's inquiry and thinking that is important. A good science teacher can agree with Bertrand Russell who famously said in 1916 at the height of the Great War when he criticised the use of schools by both sides for nationalist indoctrination:

> Education would not aim at making them [students] belong to this party or that, but at enabling them to choose intelligently between the parties; it would aim at making them able to think, not at making them think what their teachers think. (Egner and Denonn 1961, pp. 401–402)

Michael R. Matthews is an honorary associate professor in the School of Education at the University of New South Wales. He has degrees in Geology, Psychology, Philosophy, History and Philosophy of Science, and Education. His Ph.D. in philosophy of education is from UNSW.

He is Foundation and continuing editor of the journal *Science & Education: Contributions from the History and Philosophy of Science*.

His books include *The Marxist Theory of Schooling: A Study of Epistemology and Education* (Humanities Press 1980); *Science Teaching: The Role of History and Philosophy of Science* (Routledge 1994); *Challenging New Zealand Science Education* (Dunmore Press 1995); and *Time for Science Education: How Teaching the History and Philosophy of Pendulum Motion can Improve Science Literacy* (Plenum Publishers 2000).

His edited books include *The Scientific Background to Modern Philosophy* (Hackett 1989); *History, Philosophy and Science Teaching: Selected Readings* (Teachers College Press 1991); *Constructivism in Science Education: A Philosophical Examination* (Kluwer Academic Publishers 1998); *Science Education and Culture* (Kluwer Academic Publishers 2001, with F. Bevilacqua and E. Giannetto); *The Pendulum: Scientific, Historical, Philosophical and Educational Perspectives* (Springer 2005, with A. Stinner and C. F. Gauld); *Science, Worldviews and Education* (Springer 2009); and the *Springer Handbook of Research in History, Philosophy and Science Teaching* (Springer 2013). In 2010 he was awarded the Joseph H. Hazen Education Prize of the History of Science Society (USA) in recognition of his contributions to the teaching of history of science.

Outside of the academy, he served two terms as an alderman on Sydney City Council (1980–1986).

Chapter 51
What Significance Does Christianity Have for Science Education?

Michael J. Reiss

51.1 Introduction

Worldwide, religion remains of importance to many people, including young people; a survey undertaken in 2011 in 24 countries found that 73 % of respondents under the age of 35 (94 % in primarily Muslim countries and 66 % in Christian majority countries) said that they had a religion/faith and that it was important to their lives (Ipsos MORI 2011).

Furthermore, to the bemusement of many science educators in school and elsewhere, and the delight of some, issues to do with religion seem increasingly to be of importance in school science lessons, science museums and some other educational settings. This chapter begins by examining the nature of religion in general and Christianity in particularly and then examines the nature of science before looking at possible ways in which religion in general and Christianity in particular might relate to science. The chapter then considers whether or not Christianity has implications for science education and, if it does, how teaching might take account of Christian belief.

To many science educators even raising the possibility that religion might be considered within science education raises suspicions that this is an attempt to find a way of getting religion into the science classroom for religious rather than scientific reasons. This is not the intention here. In terms of the nature of science, part of the argument is that considering religion can be, on occasions, useful simply for helping learners better understand why certain things come under the purview of science and others don't.

Another argument for considering religion within science education proceeds much as an argument for considering history in science education might. While

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_51,

science can be learnt and studied in a historical vacuum, there are a range of arguments for examining science in its historical contexts. For a start, this helps one understand better why certain sorts of science were pursued at certain times. Wars, for instance, have sometimes led to advances in chemistry, physics and information science (e.g. explosives, missile trajectories, code breaking), while certain botanical disciplines, such as systematics and taxonomy, have flourished during periods of colonisation. Much biology is studied in the hope that medical advances will ensue, so studies of anatomy have developed into studies of physiology and, more recently, genetics and molecular biology. Then there is the observation that for many learners understanding science in historical context can aid motivation. Science courses that take contexts and applications into account are now quite widespread (cf. the whole STS movement even if the jury is still out as to the consequences for the understanding of science concepts).

Similarly, while many students enjoy learning about the pure science of genetics and evolution, otherwise are motivated and come to understand the science better if they appreciate something of the diversity of religious beliefs held by such principal protagonists as Charles Darwin, Joseph Hooker, Thomas Huxley and Gregor Mendel and the religious views (including the diversity of religious views) of the cultures in which they lived and worked.

There are a number of places where religion and science interact. Consider, first, the question of 'authority' and the scriptures as a source of authority. To the great majority of religious believers, the scriptures of their religion (the Tanakh, the Christian bible, the Qur'an, the Vedas, including the Upanishads, the Guru Granth Sahib, the various collections in Buddhism) have an especial authority by very virtue of being scripture. This is completely different from the authority of science. Newton's *Principia* and Darwin's *On the Origin of Species* are wonderful books, but they do not have any permanence other than that which derives from their success in explaining observable phenomena of the material world and enabling people to see the material world through Newtonian/Darwinian eyes. Indeed, as is well known, Darwin knew almost nothing of the mechanism of inheritance despite the whole of his argument relying on inheritance, so parts of *The Origin* were completely out of date over 100 years ago.

Then consider the possibility of miracles, where the word is used not in its everyday sense (and the sense in which it is sometimes used in the Christian scriptures), namely, 'remarkable', 'completely unexpected' or 'wonderful' (as in the tabloid heading 'My miracle baby'), but in its narrower meaning of 'contrary to the laws of nature'. Scientists who do not accept the occurrence of miracles can react to this latter notion of miracles in one of the three ways: (i) miracles are impossible (because they are contrary to the laws of nature); (ii) miracles are outside of science (because they are contrary to the laws of nature) and (iii) miracles are very rare events that have not yet been incorporated within the body of science but will be (as rare meteorological events, e.g. eclipses, and mysterious creatures, e.g. farm animals with two heads or seven legs, have been).

This chapter addresses such issues. It focuses on Christianity because other chapters in this volume address others of the world's major religions. At the same time, without wishing to appear triumphalistic or colonial, there are some particular reasons why Christianity deserves consideration in its own right. For a start, and without negating the importance of science to all cultures, and the especial roles in its origins and development played in China and by Islam, Christianity played a major role in the origin of modern science. Historians appear broadly to agree on this although there is continuing debate about other influences and the relative contributions of each (Brooke 1991; Harrison 2001; Hooykaas 1972).

Then there is the fact that throughout the history of science, many scientists have been Christians and have seen their faith as supporting their science. In a sense this is a trivial point given that a large proportion of the population was Christian in the countries where modern science principally arose (i.e. Western Europe). Less trivial is the point that some of these scientists tackled certain scientific issues in ways that connected to their faith, though this is less the case nowadays when there is far more of a clear-cut separation between a scientist's beliefs and their science. A thorough history of science can only be developed if the significance of Christianity for certain scientists is acknowledged. Standard instances include Robert Boyle (e.g. Hunter 2009; MacIntosh 2006), Michael Faraday (e.g. Russell 2000) and Georges Lemaître (Farrell 2005).

The Christian faith represents a significant worldview in many countries, though substantially less so nowadays in Western Europe than in the past. It has helped to shape many modern institutions and provides a framework that exists in contrast to the materialism which is also widespread in many contemporary societies and classrooms. Gauch (2009) argues that 'the presuppositions and reasoning of science can and should be worldview independent, but empirical and public evidence from the sciences and humanities can support conclusions that are worldview distinctive' (p. 27).

Finally, there is the obvious point that there are a number of instances where science and Christianity intersect, whether in the classroom or wider public discourse. One clear instance is the creationism-evolution 'debate'; another is to do with such bioethical issues as the acceptability of genetic engineering, euthanasia, stem cell research and cloning; and another is to do with such philosophical issues as determinism. The importance of Christian theology and practice, noting that the situation is complicated/enriched by the fact that there is rarely a single Christian voice, for debates about determinism, evolution and bioethics are considered below.

51.2 The Nature of Religion

There are many religions, and it is difficult to answer the question 'What is the nature of religion?' in a way that satisfies the members of all religions. Nevertheless, the following, derived from Smart (1989) and Hinnells (1991), are generally characteristic of most religions (Reiss 2008a):

> Religions have a *practical and ritual dimension* that encompasses such elements as worship, preaching, prayer, yoga, meditation and other approaches to stilling the self.
>
> The *experiential and emotional dimension* of religions has at one pole the rare visions given to some of the crucial figures in a religion's history, such as that of Arjuna in the *Bhagavad Gita*, the revelation to Moses at the burning bush in *Exodus* and Saul on the road to Damascus in *Acts*. At the other pole are the experiences and emotions of many religious adherents, whether a once-in-a-lifetime discernment of the transcendent or a more frequent feeling of the presence of God either in corporate worship or in the stillness of one's heart.
>
> All religions hand down, whether orally or in writing, vital stories that comprise the *narrative or mythic dimension*, for example the story of the birth, life, death, resurrection and ascension of Jesus in the Christian scriptures. For some religious adherents such stories are believed literally, for others they are understood symbolically.
>
> The *doctrinal and philosophical dimension* arises, in part, from the narrative/mythic dimension as theologians within a religion work to integrate these stories into a more general view of the world. Thus the early Christian church came to its understanding of the doctrine of the Trinity by combining the central claim of the Jewish religion – that there is but one God – with its understanding of the life and teaching of Jesus Christ and the working of the Holy Spirit.
>
> If doctrine attempts to define the beliefs of a community of believers, the *ethical and legal dimension* regulates how believers act. So Sunni Islam has its Five Pillars, while Judaism has the Ten Commandments and other regulations in the Torah and Buddhism its Five Precepts.
>
> The *social and institutional dimension* of a religion relates to its corporate manifestation, for example the Sangha – the order of monks and nuns founded by the Buddha to carry on the teaching of the Dharma – in Buddhism, the umma' – the whole Muslim community – in Islam, and the Church – the communion of believers comprising the body of Christ – in Christianity.
>
> Finally, there is the *material dimension* to each religion, namely the fruits of religious belief as shown by places of worship (e.g. synagogues, temples and churches), religious artefacts (e.g. Eastern Orthodox icons and Hindu statues) and sites of special meaning (e.g. the river Ganges, Mount Fuji and Uluru (Ayers Rock)).

As will be discussed below, the relationship between science and religion has changed over the years (Al-Hayani 2005; Brooke 1991; Szerszynski 2005); indeed, the use of the singular, 'relationship', risks giving the impression that there is only one way in which the two relate. Nevertheless, there are two key issues: one is to do with understandings of reality and the other to do with evidence and authority. Although it is always desperately difficult to generalise (difficult in the sense that one lays oneself open to accusations that one hasn't considered every particular – and yet the alternative is to be submerged in a weight of detail that would surely suffocate all but the most devoted/obsessive of readers), most religions hold that reality consists of more than the objective world, and many religions give weight to personal and/or (depending on the religion) institutional authority in a way that science generally strives not to.

For example, there is a very large religious and theological literature on the world to come, i.e. life after death, (e.g. Hick 1976/1985). However, to labour the point, although some (notably Atkins 2011) have argued that science disproves the existence of life after death, it can be objected that science, strictly speaking, has little or nothing to say about this question because life after death exists or would exist outside of or beyond the realm to which science relates. Furthermore, many religious believers within a particular religion are likely to find the pronouncements on the question of life after death by even the most intelligent and spiritual of their present leaders (let alone reputable scientists) to be of less significant than the few recorded words of their religion's founder(s). In the case of Christianity, while the proportion of believers who take literally the resurrection promises of the New Testament may be less than in previous ages (though high-quality comparative quantitative data are unavailable), it remains the case that literal belief in an afterlife is widespread among believers.

Before moving on to the nature of science, it is worth, in this section on the nature of religion, briefly saying something specifically about the nature of Christianity. While there are many Christian denominations, they all treat the Jewish scriptures and the New Testament as jointly constituting their scriptures, though there are differences as to which books are included in the Christian 'Old Testament'. The core beliefs of Christianity are summed up in the books of the New Testament and subsequent formulations such as the Apostles' and Nicene Creeds. The most widely recited formulation is the Nicene Creed which, in its 1975 ecumenical version, reads:

> We believe in one God,
> the Father, the Almighty
> maker of heaven and earth,
> of all that is, seen and unseen.
> We believe in one Lord, Jesus Christ,
> the only Son of God,
> eternally begotten of the Father,
> God from God, Light from Light,
> true God from true God,
> begotten, not made,
> of one Being with the Father.
> Through him all things were made.
> For us and for our salvation
> he came down from heaven:
> by the power of the Holy Spirit
> he became incarnate from the Virgin Mary, and was made man.
> For our sake he was crucified under Pontius Pilate;
> he suffered death and was buried.
> On the third day he rose again
> in accordance with the Scriptures;
> he ascended into heaven
> and is seated at the right hand of the Father.
> He will come again in glory to judge the living and the dead,
> and his kingdom will have no end.
> We believe in the Holy Spirit, the Lord, the giver of Life,
> who proceeds from the Father and the Son.
> With the Father and the Son he is worshipped and glorified.
> He has spoken through the Prophets.
> We believe in one holy catholic and apostolic Church.
> We acknowledge one baptism for the forgiveness of sins.
> We look for the resurrection of the dead,
> and the life of the world to come. Amen. (Episcopal Church 1979)

It is evident that some of the issues addressed in the Nicene Creed are to do with science and some are not. However, even those that at first appear not to be (e.g. the Trinity) have been examined from a science and religion perspective (e.g. Polkinghorne 2004). Indeed, if we restrict ourselves to those features of Christianity that are central to the science-religion issue, these include a belief that the triune God who creates, sustains and redeems the world is non-capricious (i.e. there are laws of nature) and deeply concerned with the created order (Poole 1998).

51.3 The Nature of Science

The term 'nature of science' is understood in a number of ways, as discussed elsewhere in this volume, but at its heart is knowledge about how, and to a lesser extent why, science is undertaken. So the nature of science includes issues about the fields of scientific enquiry and the methods used in that enquiry as well as, to a certain extent, something about the purpose of science.

A key point about the fields of scientific enquiry is that these have shifted over time. In large measure this is simply because of developments in instrumentation. We can now study events that happen at very low temperatures, at distances, at speeds and at magnifications that simply were not possible even a few decades ago. What is still unclear is the extent to which certain matters currently outside of mainstream science will one day fall within the compass of science. Take dreams, for example. It may be that these will remain too subjective for science, but it may be that developments in the recording of brain activity will mean that we can obtain a sufficiently objective record of dreams for them to be amenable to rigorous scientific study.

But the scope of science has also shifted for reasons that are more to do with theorisation than with technical advances (Reiss 2013a). Consider beauty. Aesthetics for a long time was not considered a scientific field. But there is now, within psychology and evolutionary biology, growing scientific study of beauty and desire (e.g. Buss 2003). Indeed, a number of the social sciences are being nibbled away at by the natural sciences, and if one believes some scientists, almost the only valid knowledge is scientific knowledge (Atkins 2011).

Despite such movements in the fields of scientific enquiry and in the actual methods employed by scientists, the overarching methods of science (what a social scientist might term its methodology) have shifted far less, certainly for several hundreds of years, arguably for longer than that.

As is well known, Robert Merton characterised science as open-minded, universalist, disinterested and communal (Merton 1973). For Merton, science is a group activity; even though certain scientists work on their own, science, within its various subdisciplines, is largely about bringing together into a single account the contributions of many different scientists to produce an overall coherent model of one aspect of reality. In this sense, science is (or should be) impersonal. Allied to the notion of science being open-minded, disinterested and impersonal is the notion of scientific objectivity. The data collected and perused by scientists must be objective in the sense that they should be independent of those doing the collecting (cf. Daston and Galison 2007) – the idealised 'view from nowhere'. This is the main reason why the data obtained by psychotherapists are (at least at present) not really scientific: they depend too much on the specifics of the relationship between the therapist and the client. The data obtained by cognitive behavioural therapists, on the other hand, are more scientific (cf. Salkovskis 2002).

Karl Popper emphasised the falsifiability of scientific theories (Popper 1934/1972): unless one can imagine collecting data that would allow one to refute a theory, the theory isn't scientific. The same applies to scientific hypotheses. So, iconically, the hypothesis 'All swans are white' is scientific because we can imagine finding a bird that is manifestly a swan (in terms of its anatomy, physiology and behaviour) but is not white. Indeed, this is precisely what happened when early White explorers returned from Australia with tales of black swans.

Popper's ideas easily give rise to a view of science in which knowledge accumulates over time as new theories are proposed and new data collected to distinguish between conflicting theories. Much school experimentation in science is Popperian: we see a rainbow and hypothesise that white light is split up into light of different colours as it is refracted through a transparent medium (water droplets); we test this by attempting to refract white light through a glass prism; we find the same colours of the rainbow are produced, and our hypothesis is confirmed. Until some new evidence causes it to be falsified, we accept it (Reiss 2008a).

Thomas Kuhn made a number of seminal contributions, but he is most remembered nowadays for his argument that while the Popperian account of science holds well during periods of normal science when a single paradigm holds sway, such as the Ptolemaic model of the structure of the solar system (in which the Earth is at the centre) or the Newtonian understanding of motion and gravity, it breaks down when a scientific crisis occurs (Kuhn 1970). At the time of such a crisis, a scientific revolution happens during which a new paradigm, such as the Copernican model of the structure of the solar system or Einstein's theory of relativity, begins to replace (initially to coexist with) the previously accepted paradigm. The central point is that the change of allegiance from scientists believing in one paradigm to their believing in another cannot, Kuhn argues, be fully explained by the Popperian account of falsifiability.

A development of Kuhn's work was provided by Lakatos (1978) who argued that scientists work within research programmes. A research programme consists of a set of core beliefs surrounded by layers of less central beliefs. Scientists are willing to accept changes to these more peripheral beliefs so long as the core beliefs can be defended. So, in biology, we might see in contemporary genetics a core belief in the notion that development proceeds via a set of interactions between the actions of genes and the influences of the environment. At one point, it was thought that the passage from DNA to RNA was unidirectional. Now we know (reverse transcriptase, etc.) that this is not always the case. The core belief (that development proceeds via a set of interactions between the actions of genes and the influences of the environment) remains unchanged, but the less central belief (that the passage from DNA to RNA is unidirectional) is abandoned.

The above account of the nature of science portrays science as what John Ziman (2000) has termed 'academic science'. Ziman argues that such a portrayal was reasonably valid between about 1850 and 1950 in European and American universities but that since then we have entered a phase largely characterised by 'post-academic science'. Post-academic science is increasingly transdisciplinary and utilitarian, with a requirement to produce value for money. It is more influenced by politics, it is more industrialised and it is more bureaucratic. The effect of these changes is to make the boundaries around the domain of science a bit fuzzier. Of course, if one accepts the contributions of the social study of science (e.g. Yearley 2005), one finds that these boundaries become fuzzier still. The argument in this chapter does not *rely* on such a reading of science though someone who is persuaded by the 'Strong Programme' within the sociology of scientific knowledge (i.e. the notion that even valid scientific theories are amenable to sociological investigation of their truth claims) is much more likely to accept the worth of science educators considering the importance of religion as one of many factors that influence the way science is practised and scientific knowledge produced.

51.4 Understandings of Possible Relationships Between Science and Religion

It is clear that there can be a number of axes on which the science-religion issue can be examined. For example, the effects of the practical and ritual dimension are being investigated by scientific studies that examine such things as the efficacy of prayer and the neurological consequences of meditation (e.g. Lee and Newberg 2005); a number of analyses of religious faith, informed by contemporary understandings of evolutionary psychology, behavioural ecology and sociobiology, examine the possibility or conclude that religious faith can be explained by science (e.g. Dennett 2006; Hinde 1999; Reynolds and Tanner 1983); the narrative/mythic dimension of religion clearly connects (in ways that will be examined below) with scientific accounts of such matters as the origins of the cosmos and the evolution of life; the doctrinal and philosophical dimension can lead to understandings that may agree or disagree with standard scientific ones (e.g. about the status of the human embryo); and the ethical and legal dimension can lead to firm views about such matters as land ownership, usury and euthanasia.

Perhaps only the social and institutional and the material dimensions of religion are relatively distinct from the world of science (understand as the natural sciences rather than the social sciences more broadly), in that science has little if anything to say about such manifestations of religion – i.e. in Christianity, the Church and such things as religious artefacts.

There is now a very large literature on the relationship between science and religion (a major overview is provided by Clayton and Simpson 2006). Indeed, the journal *Zygon* specialises in this area, while *Science & Christian Belief* focuses on the relationship between science and Christianity. A frequent criticism by those who write in this area (e.g. Roszak 1994 and regular articles by Andrew Brown and Paul Vallely in the *Church Times*) is of what they see as simplistic analyses of the area by those, often renowned scientists, who write occasionally about it. Indeed, it is frequently argued that the clergy both in the past and nowadays are often far more sympathetic to a standard scientific view on such matters as evolution than might be supposed (e.g. Colburn and Henriques 2006).

A particularly thorough historical study of the relationship between science and religion is provided by John Hedley Brooke (1991). Brooke's aim is 'to reveal something of the complexity of the relationship between science and religion as they have interacted in the past' (p. 321). He concludes:

> Popular generalizations about that relationship, whether couched in terms of war or peace, simply do not stand up to serious investigation. There is no such thing as *the* relationship between science and religion. It is what different individuals and communities have made of it in a plethora of different contexts. Not only has the problematic interface between them shifted over time, but there is also a high degree of artificiality in abstracting the science and the religion of earlier centuries to see how they were related. (Brooke 1991, p. 321)

Perhaps the best known categorisation of the ways in which the relationship between science and religion can be understood was provided by Ian Barbour (1990). Barbour himself updated this book (Barbour 1997), and since 1990 there has been a considerable literature about the ways in which science and religion relate (e.g. Glennan 2009; Haught 1995; Plantinga 2010; Stenmark 2004); indeed, Mark Vernon argues that rather more agnosticism and less dogmatism in the science-religion field would be wise (Vernon 2008). Nevertheless, Barbour's (1990) typology continues to dominate the literature and so is employed here. Barbour, who focuses especially on epistemological assumptions of recent Western authors, identifies four main groupings.

First, there is the relationship of *conflict*; 'first' simply because it is the first in Barbour's list and first, perhaps, also in the minds of many people, whether or not they have a religious faith (cf. McGrath 2005). Barbour doesn't give a reason for the order of his listing, but at least two can be suggested: comprehensibility and familiarity. It is both easy and familiar (given Barbour's declared focus on recent Western authors) to see the relationship between science and religion as one of conflict. However, as one might expect from a professor of science, technology and society giving the Gifford lectures (the result of an 1885 bequest of £80,000 'for the establishment of a series of lectures dealing with the topic of natural religion' (Gifford lectures 2006)), Barbour sees limitations in this way of understanding the science-religion issue. As he memorably puts it:

> In a fight between a boa constrictor and a wart-hog, the victor, whichever it is, swallows the vanquished. In scientific materialism, science swallows religion. In biblical literalism, religion swallows science. The fight can be avoided if they occupy separate territories or if, as I will suggest, they each pursue more appropriate diets. (Barbour 1990, p. 4)

Barbour's second grouping is *independence* (e.g. Gould 1999). Science and religion may be seen as independent for two main reasons: because they use distinctive methods or because they function as different languages. In any event, the result is that each is seen as distinct from the other and as enjoying its own autonomy:

> Each has its own distinctive domain and its characteristic methods that can be justified on its own terms. Proponents of this view say there are two jurisdictions and each party must keep off the other's turf. Each must tend to its own business and not meddle in the affairs of the others. Each mode of inquiry is selective and has its limitations. (Barbour 1990, p. 10)

Barbour's third grouping moves beyond conflict and independence to *dialogue* (cf. Berry 1988; Polkinghorne 2005; Watts 1998; Williams 2001). As an example of dialogue, Barbour points out how our understanding of astronomy has forced us to ask why the initial conditions were present that allowed the universe to evolve. The point is not that the findings of science require a religious faith – that would be for the warthog of religion to swallow the boa constrictor of science. Rather the point is that scientific advances can give rise (no claim is made that they do for all people) to religious questions, so that a dialogue ensues.

Barbour's final grouping is one in which the relationship between science and religion is seen to be one of *integration* (cf. Peacocke 2001; Polkinghorne 1994). For example, in natural theology it is held that the existence of God can be deduced from aspects of nature rather than from revelation or religious experience (e.g. Ray 1691/2005). Natural theology has rather fallen out of favour (but see Polkinghorne 2006). A more modern version is process theology which rejects a view of the world in which purely natural events (characterised by an absence of divine activity) are interspersed with occasional gaps where God acts. Rather, for process theologians, every event is understood 'to be jointly the product of the entity's past, its own action, and the action of God' (Barbour 1990, p. 29). Furthermore, God is not the Unmoved Mover of Thomas Aquinas but instead acts reciprocally with the world.

I think it can be difficult for those who have never had a religious faith, or have only had one rather tenuously, to imagine what a life is like that is lived wholly within a religious ordering. For such a person, the relationship between science and their faith may be described as 'integrated' though this is to give an epistemological framing to the relationship, whereas what may be going on is that the person has little overt interest in the precise nature of the relationship between science and religion other than that there can clearly be no conflict between them.

Anthropologists provide good accounts of what it can be like to live a life where one's religious faith integrates with every aspect of one's life. One of my favourite such accounts is that of du Boulay (2009) who studied life in a Greek Orthodox Village in the late 1960s and early 1970s. Everything that happened in the village needs to be understood by reference to Greek Orthodoxy. To give just one instance, the annual liturgical and agricultural cycles intermeshed, so that after the harvest, the sowing of the seed for next year's harvest was closely related to the Christian calendar:

> The main sowing of the wheat is carried into November, and the Archangel Michael, celebrated on 8 November and seen on his icons with drawn sword, is a formidable figure associated with the darkening November days with the leaves being stripped from the trees and the smoke gusting in ashy draughts down the chimneys; but this is a month named after the preeminent agricultural task – 'The Sower' (*Σποριας*). And the Entry of the Mother of

> God into the Temple on 21 November, soon after the Christmas fast has begun, is also in the village given the character of the time as the ‘Mother of God Half-Way-Through-The-Sowing’ (*Παναγια Μισοσπειριτσα*). The task of the sowing of the wheat then continues into the time know as ‘Andrew’s’ (St Andrew, whose day is 30 November, but who has given his name to the following month of December), and can go on up to Christmas – and even beyond, if the weather has not been fit. (du Boulay 2009, p. 106)

Having examined possible relationships between science and religion, and given a flavour of the way in which religion can order a person’s understanding of and immersion in the world, I turn now to the issues of determinism and evolution to discuss at a more fine-grained level how Christianity and science can correlate.

51.5 Determinism

The ‘science-religion issue’ is often examined simply by recourse to certain cause célèbres – Galileo and Copernican heliocentrism, Darwin and evolution and arguments about the sanctity of life, for example. At school level, examinations of such particular instances of the relationship between science and religion, along with a more general consideration about how science and religion can relate, are perfectly appropriate. However, there are certain ‘higher-order’ questions that teachers and curriculum developers need to consider to decide whether they can be introduced meaningfully at school level. One such central question is about whether nature is deterministic and, if it/she is not, whether that has anything to do with divine action. Theologically speaking, this is part of the more general question as to how (for those who have a religious faith) God acts in nature (Dixon 2008).

The post-Newtonian advent in the early twentieth century of quantum theory and, later in the same century, of chaos theory has led many to wonder whether within either or both of these two frameworks might lie a space for divine action in a way that does not contradict the scientific worldview in the way that miracles seem to. For almost anyone who has not studied quantum physics to at least first-degree level, it is exceptionally difficult to understand what is going on that is relevant to the science-religion issue, but a core concept is that of determinism, which results from the issue of the relationship of measurement to reality (e.g. Bhaskar 1978; Osborn 2005).

As is well known, in 1927 Heisenberg argued that certain key physical variables that had previously been presumed to be independent (e.g. the position and momentum of an object) are linked. Measuring the one to a very high degree of precision necessarily means that the other cannot be so precisely determined. Thus far there is not a great deal that is of interest to the non-physicist – the issue appears to be one of epistemology. However,

> Heisenberg himself took a more radical view – he saw this limitation as a property of nature rather than an artefact of experimentalism. This radical interpretation of uncertainty as an ontological principle of indeterminism implies that quantum mechanics is inherently statistical – it deals with probabilities rather than well-defined classical trajectories. Such a view is clearly inimical to classical determinism. (Osborn 2005, p. 132)

Put somewhat loosely, a number of people have tried to find room for divine action in this indeterminacy. No consensus yet exists as to the validity of this search though, on balance, the current views seem to be that such a search is mistaken for reasons both of theology and of physics. A particularly helpful, though demanding, analysis of both the theology and the physics is provided by Saunders (2002). Beginning with the theology, Saunders draws on the widespread distinction between general and special forms of divine action. In the words of Michael Langford, general divine action is 'the government of the universe through the universal laws that control or influence nature, man, and history, without the need for specific or ad hoc acts of divine will' (Langford 1981, p. 11). On the other hand, special divine action is characterised by

> Those actions of God that pertain to a *particular* time and place in creation as distinct from another. This is a broad category and includes the traditional understanding of 'miracles', the notion of particular providence, responses to intercessionary prayer, God's personal actions, and some forms of religious experience. (Saunders 2002, p. 20)

Oversimplifying considerably, all religions are comfortable with the notion of general divine action, but they differ both among and within themselves considerably in their understanding of specific divine action. In particular, many leading theologians (but see Pannenberg 2006) are uncomfortable with the notion of specific divine action so defined for a number of reasons including the particular problems for the occurrence of suffering that it raises (if suffering can sometimes be averted miraculously, why isn't it always or, at least, much more often?) and the apparent shortcomings, including capriciousness, suggested by a divine being who relies on occasional exercises of supernatural activity to keep things moving along (cf. Kenny 1992).

Going onto the physics, Saunders is sceptical of attempts to locate the possibility of specific divine action in quantum or chaos theory. The argument here becomes even more technical and depends, in respect of quantum theory, on whether one accepts the standard (Copenhagen) interpretation of reality (in which Schrödinger's cat is either dead or alive before the box is opened) or the more radical interpretation (in which the cat is both dead and alive). In both cases, though, as well as in the case of chaos theory (sometimes termed 'complexity theory' on the grounds that it deals with systems that are deterministic but unpredictable because of their exquisite sensitivity to small changes in their initial conditions), Saunders rejects attempts to find opportunities for specific divine activity in the science.

51.6 Evolution

51.6.1 The Scientific Consensus Concerning Evolution

As with any large area of science, there are parts of what we might term 'front-line' evolution that are unclear, where scientists still actively work attempting to discern what is going on or has gone on in nature. But much of evolution is not like that. Evolution is a well-established body of knowledge that has built up over 150 years as a result of the activities of many thousands of scientists. The following are examples of statements about evolution that lack scientific controversy:

- All of today's life on Earth is the result of modification by descent from the simplest ancestors over a period of several thousand million years.
- Natural selection is a major driving force behind evolution.
- Evolution relies on those occasional instances of the inheritance of genetic information that help (rather than hinder) its possessor to be more likely to survive and reproduce.
- Most inheritance is vertical (from parents) though some is horizontal (e.g. as a result of viral infection carrying genetic material from one species to another).
- The evolutionary forces that gave rise to humans do not differ in kind from those that gave rise to any other species. (Reiss 2013b)

For those who accept such statements and the theory of evolution, there is much about the theory of evolution that is intellectually attractive. For a start, a single theory provides a way of explaining a tremendous range of observations: for example, why it is that there are no rabbits in the Precambrian, why there are many superficial parallels between marsupial and placental mammals, why monogamy is more common in birds than in fish and why sterility (e.g. in termites, bees, ants, wasps and naked mole rats) is more likely to arise in certain circumstances than in others. Indeed, I have argued elsewhere that evolutionary biology can help with some theological questions, including the problem of suffering (Reiss 2000).

51.6.2 Rejecting Evolution

The theory of evolution is not a single proposition that a person must either wholly accept or wholly reject. At one pole are materialists who, eschewing any sort of critical realist distinction between the empirical, the actual and the real (Bhaskar 1978), maintain that there is no possibility of anything transcendent lying behind what we see of evolution in the results of the historical record (fossils, geographical distributions, comparative anatomy and molecular biology) and today's natural environments and laboratories. At the other pole are the advocates of creationism, inspired by a literal reading of certain scriptures. But in between lie many others (Scott 1999) including those who hold that evolutionary history can be providential as human history is.

In addition, there are a whole set of nonreligious reasons why someone may actively reject aspects of the theory of evolution. After all, it may seem to defy common sense to suppose that life in all its complexity has evolved from non-life. And then there is the tremendous diversity of life we see around us. To many it hardly seems reasonable to presume that giant pandas, birds of paradise, spiders, orchids, flesh-eating bacteria and the editor of this book all share a common ancestor – yet that is what mainstream evolutionary theory holds.

It is, though, for religious reasons that many people reject evolution. Creationism exists in a number of different forms, but between about 10 % of adults in the

Nordic countries and Japan and 50 % of adults in Turkey (40 % in the USA) reject the theory of evolution and believe that the Earth came into existence as described by a literal (i.e. fundamentalist) reading of the early parts of the Bible or the Qur'an and that the most that evolution has done is to change species into closely related species (Lawes 2009; Miller et al. 2006). Christian fundamentalists generally hold that the Earth is nothing like as old as evolutionary biologists and geologists conclude – as young as 10,000 years or so for young Earth creationists. For Muslims, the age of the Earth is much less of an issue.

Allied to creationism is the theory of intelligent design. While many of those who advocate intelligent design have been involved in the creationism movement, to the extent that the US courts have argued that the country's First Amendment separation of religion and the State precludes its teaching in public schools (Moore 2007), intelligent design can claim to be a theory that simply critiques aspects of evolutionary biology rather than advocating or requiring religious faith. Those who promote intelligent design typically come from a conservative faith-based position (though there are atheists who accept intelligent design). However, in their arguments against evolution, they typically make no reference to the scriptures or a deity but argue that the intricacy of what we see in the natural world, including at a subcellular level, provides strong evidence for the existence of an intelligence behind this (e.g. Meyer 2009). An undirected process, such as natural selection, is held to be incapable of explaining all such intricacy.

51.6.3 Evolution in School Science

Few countries have produced explicit guidance as to how schools might deal with the issues of creationism or intelligent design in the science classroom. One country that has is England (Reiss 2011). In the summer of 2007, the then DCSF (Department of Children, Schools and Families) Guidance on Creationism and Intelligent Design received Ministerial approval and was published (DCSF 2007). The Guidance points out that the use of the word 'theory' in science (as in 'the theory of evolution') can mislead those not familiar with science as a subject discipline because it is different from the everyday meaning, when it is used to mean little more than an idea.

The DCSF Guidance goes on to state 'Creationism and intelligent design are sometimes claimed to be scientific theories. This is not the case as they have no underpinning scientific principles, or explanations, and are not accepted by the science community as a whole' (DCSF 2007) and then says:

> Creationism and intelligent design are not part of the science National Curriculum programmes of study and should not be taught as science. However, there is a real difference between teaching 'x' and teaching *about* 'x'. Any questions about creationism and intelligent design which arise in science lessons, for example as a result of media coverage, could provide the opportunity to explain or explore why they are not considered to be scientific theories and, in the right context, why evolution is considered to be a scientific theory. (DCSF 2007)

This is a key point and one that is independent of country, whether or not a country permits the teaching in schools of religion (as in the UK) or does not (as in France, Turkey and the USA). Many scientists, and some science educators, fear that consideration of creationism or intelligent design in a science classroom legitimises them. For example, the excellent book *Science, Evolution, and Creationism* published by the US National Academy of Sciences and Institute of Medicine asserts ‘The ideas offered by intelligent design creationists are not the products of scientific reasoning. Discussing these ideas in science classes would not be appropriate given their lack of scientific support’ (National Academy of Sciences and Institute of Medicine 2008, p. 52).

However, just because something lacks scientific support doesn’t seem a sufficient reason to omit it from a science lesson. This is a point that holds more widely than with respect to the teaching of evolution; for instance, when teaching about climate change, one might want to examine the argument that sunspot cycles are sufficient to explain all of global warming, even though this is no longer a reputable scientific position. Nancy Brickhouse and Will Letts (1998) have argued that one of the central problems in science education is that science is often taught ‘dogmatically’. With particular reference to creationism, they write:

> Should student beliefs about creationism be addressed in the science curriculum? Is the dictum stated in the California’s *Science Frameworks* (California Department of Education 1990) that any student who brings up the matter of creationism is to be referred to a family member of member of the clergy a reasonable policy? We think not. Although we do not believe that what people call ‘creationist science’ is good science (nor do scientists), to place a gag order on teachers about the subject entirely seems counterproductive. Particularly in parts of the country where there are significant numbers of conservative religious people, ignoring students’ views about creationism because they do not qualify as good science is insensitive at best. (Brickhouse and Letts 1998, p. 227)

51.6.4 Evolution in Science Museums

Education about evolution does not only take place in schools. It takes place through books, magazines, TV, the Internet, radio and science museums. Science museums have long had exhibits about evolution. Tony Bennett (2004) provides an historical analysis to look at how science museums have presented evolution. He attempts to discern the modes of power that lie behind the manifestations of particular forms of knowledge and concludes that

> In their assembly of objects in newly historicised relations of continuity and difference, evolutionary museums not only made new pasts visible; they also enrolled those pasts by mobilising objects – skulls, skeletons, pots, shards, fossils, stuffed birds and animals – for distinctive social and civic purposes. (Bennett 2004, p. 189)

In one sense this is hardly surprising – museums have to make selections about what to display and how to curate such displays, and these are clearly cultural decisions, whether one is referring to evolution or anything else. However, visitors to science museums can easily presume that they are being presented with objective fact. For example, the classic story about the evolution of the modern horse can be oversimplified to the point that the viewer concludes that evolution is linear and progressive.

Monique Scott too has produced a book about evolution in museums (Scott 2007) though her work, unlike Bennett's, is more to do with the present than with history. Using questionnaires and interviews, Scott gathered the views of nearly 500 visitors at the Natural History Museum in London, the Horniman Museum in London, the National Museum of Kenya in Nairobi and the American Museum of Natural History in New York. Perhaps her key finding is that many of the visitors interpreted the human evolution exhibitions as providing a linear narrative of progress from African prehistory to a European present. As she puts it:

> Despite the distinctive characters of each of the four museums considered here and the specific cultural differences among their audiences, it is clear that museums and their visitors traffic in common anthropological logic – namely the color-coded yardstick of evolutionary progress. In fact, visitors equipped with a weighty set of popular images – imagery derived from such things as *Condé Nast Traveler* magazines, *Planet of the Apes* films, and *National Geographic* images – occupy the nexus between the evolutionary folklore circulating outside the museum and that which has been generated within it. This collection of images often urges Western museum visitors to negotiate between the "people who stayed behind" and their own fully evolved selves (defined often by such culturally coded "evolutionary leaps" as clean-shaven-ness and white skin). (Scott 2007, p. 148)

So how might one hope that science museums would treat religion when putting together exhibitions about evolution? Museums have a number of advantages over classroom teachers; for one thing, they usually have longer to prepare their teaching. So we might hope that a science museum, while not giving the impression that the occurrence of evolution is scientifically controversial today, might convey something of the history of the theory of evolution. This would include the fact that evolution was once scientifically controversial and that religious believers have varied greatly as to how they have reacted to the theory of evolution. On the one hand we have today's creationists; on the other we have Charles Kingsley, the Anglican divine and friend of Charles Darwin, who read a prepublication copy of *On the Origin of Species* and wrote to Darwin:

> I have gradually learnt to see that it is just as noble a conception of Deity, to believe that he created primal forms capable of self development into all forms needful pro tempore & pro loco, as to believe that He required a fresh act of intervention to supply the lacunas w^{h}. he himself had made. (Kingsley 1859)

51.7 The Uses to Which Advances in Scientific Knowledge May Be Put

The tremendous growth in scientific knowledge means that we are faced with an ever-increasing number of ethical questions that our predecessors simply did not have to consider. Many of these are in the area of bioethics (e.g. Brierley et al. in press; Mepham 2008). How do we weigh human interests against those of the natural environment and laboratory animals? Is it acceptable to experiment on human embryos? And what role does religion have in answering such ethical questions about our use of scientific knowledge?

In a recent book titled *Dishonest to God: On keeping God out of politics*, Mary Warnock (2010), despite having a certain affection and sympathy for the Church of England, lists many examples where religious arguments have in her view inappropriately been used in parliamentary debates in attempts, some successful, some unsuccessful, to influence national legislation. She concludes:

> The danger of religion, any religion, lies in its claim to absolute immutable moral knowledge which, if justified, would indeed give its adherents a special place in instructing others how to behave, perhaps even a right to do so. (Warnock 2010, p. 165)

Our concern here is not so much with claims to knowledge as with how one makes practical decisions about scientific matters in a world with a multiplicity of values, religious and otherwise. And here religion has a place at the table (Reiss 2012). In just the same way as consequentialists have to learn to accept that many deontologists are not going to accept the consequentialist understanding of ethics as being decisive, and vice versa, so those of no religious persuasion need to accept that significant numbers of people have religious beliefs and hold that these beliefs help shape what is deemed morally right and morally wrong.

In this sense, those of no religious persuasion need to take the same sort of account of religious believers as those who eat meat need to take account of vegetarians. We would deem it unacceptable, nowadays, for the authorities in charge of a prison, a hospital or any other residential establishment to fail to provide vegetarian food on the grounds that vegetarianism is unnecessary, a minority lifestyle choice or a fad. In the same way, a secular society that respects its citizens needs to take account of religious views. Of course, precisely the converse holds too. A theocracy that respects its citizens needs to take account of the views of those who have no religious faith or belong to a minority faith.

I am well aware that to many with a religious faith, this may seem like ‘selling out’. To this objection I would respond as follows. First, it is as good as you are going to get nowadays in an increasing number of countries. Secondly, if a religious viewpoint has sufficient validity, it should be capable of holding its own in arguments with those who have no religious faith. For example, while Roman Catholic arguments about the unacceptability of contraception are very difficult to defend to non-Roman Catholics, more broad-based arguments about the sanctity of human life and therefore the unacceptability of euthanasia can receive a more sympathetic hearing among a secular audience so long as ‘the sanctity of human life’ is not seen as a trump card but is translated into religiously neutral language about respect and the protection of the vulnerable. Thirdly, my own reading of the Christian scriptures is that God’s nature is such that there is rarely an easily discerned voice from heaven. Usually, determination of what is morally right and morally wrong, while influenced by the reading of scripture and an understanding of the religious tradition to which one belongs, needs supplanting by broader reflection and study and should be informed, in the case of bioethics, by ongoing advances in the biosciences.

One objection to the line I have been advancing is that it is a relativistic one that depends on the specifics of history and geography. This is a common objection – not just in theology and bioethics but in other disciplines including science and aesthetics – and a standard response is to assert that to deny immutable knowledge is not necessarily to slide inexorably into relativism. One can occupy a middle ground. Indeed, as Parfit (2011) concludes, there are considerable commonalities between the main secular ethical frameworks (Kantian deontology, consequentialism and contractualism) once one gets down to specifics.

There will be some, who may or may not be atheists, who are not convinced that religion has any role to play in bioethics or any other issue to do with the use to which scientific knowledge is put. Religion, it might be maintained, rests on irrational belief in the supernatural and an excessive reliance on tradition, and while notions of respect may require us to tolerate such views, nothing should be done that might allow them to influence public policy. It is fine for people to have freedom of expression (e.g. freedom to attend worship) but that is entirely separate from granting religion a public role. If religion were to enjoy such privileges, we would have to extend them to other odd belief systems, such as those who believe they have been abducted by aliens (Clancy 2005) or those who hold that Elvis Presley is still alive (e.g. Brewer-Giorgio 1988, Elvis Is Alive 2012).

There are several reasons why this line of argument does not work. First, the proportion of the population, even in more secular countries, who have some religious beliefs, is considerably higher than the proportion of the population who believe in alien abductions or Elvis' longevity. Secondly, religious faith has been around for all of human time, whereas conspiracy theories and fads come and go. Thirdly, religious beliefs are often core to a person's being in a way that alien abduction (however upsetting) and Presley mania are but rarely. Fourthly, there is a close connection between many bioethical issues and religious faith which there isn't between bioethical issues and alien abduction or Elvis Presley. Of course, if the state were to set up a publicly funded museum about aliens, then there might well be a case for granting a voice to those who believe they have experienced such abductions (and this would almost certainly be good for business).

51.8 The Approach of Worldviews

Before going on to consider the pedagogical implications of all this, mention should be made of one approach to the science-religion issue that has become prominent within science education and is of considerable pedagogical value – namely, the concept of worldviews. The essence of a worldview, as the word itself implies, is that it is a way of conceiving and understanding the world that one inhabits (cf. Aerts et al. 1994). So, someone with a traditional Christian worldview is likely to believe that the world is fundamentally good but has become corrupted as a result of human sin. However, there is always the hope of redemption, and one of the tasks of Christians is to live their lives so as to help bring about the kingdom of God. On the other hand, someone with an atheistic worldview is likely to believe that the world is morally neutral and that there are no ultimate purposes in life beyond those that we decide for ourselves. Which of these two worldviews one finds the more convincing and conducive says much about oneself.

Creationism can profitably be seen not as a simple misconception that careful science teaching can correct, as careful science teaching might hope to persuade a student that an object continues at uniform velocity unless acted on by a net force, or that most of the mass of a plant comes from air as opposed to the soil. Rather, a student who believes in creationism can be seen as inhabiting a non-scientific worldview, a very different way of seeing the world compared to the scientific perspective. The pedagogical significance of this comes largely from the observation that one very rarely changes one's worldview as a result of one or two lessons, however well taught, whereas one may indeed replace a misconception with its scientifically validated alternative about such a brief teaching sequence (Reiss 2008b).

The probable reason for this difference in the difficulty of replacing worldviews and misconceptions is twofold. First, a student is likely to have far more of personal significance invested in a religious worldview than a scientific misconception. It is clear that the personal implications of abandoning a belief in a literal reading of the chronology of *Genesis*, including the 6 days of creation as 6 periods each of 24 h, are far greater than of discarding a presumption that plants gain most of their mass from the soil. Secondly, many scientific misconceptions are relatively discrete – one can discard one without this affecting much else of one's scientific understanding. Abandoning creationism entails accepting the notion of Deep Time, the relatedness of all life and the realisation that there is no *scala naturae*.

51.9 Pedagogical Implications

The question of the significance of religious issues for science education can be considered at the intended, the implemented and the attained curriculum levels (Robitaille and Dirks 1982). In a school setting there are therefore implications for curriculum developers, for classroom teachers and for learners. In this section I concentrate on teachers (whether in school science classrooms or informal settings) and learners.

Science teaching is demanding for teachers, particularly in a school setting. I have discussed elsewhere whether or not it is realistic to expect science teachers to deal with ethical issues in science lessons (Reiss 1999). Although there are examples of this happening successfully (Jones et al. 2010; Reiss 2008c), this is far from always being the case. It seems even more optimistic to expect science teachers to deal with religious issues, even when these are restricted to religious issues that relate to science. I therefore welcome the current guidelines in England about dealing with creationism in science lessons (DCSF 2007) which do not require but do allow science teachers to deal with the creationism and suggest that this principle be followed when dealing with religious issues in general in science classrooms.

The aim of including religion in science learning is not primarily to teach about religion but to enable richer and more effective ways to enable students to understand certain ideas within science and to help them appreciate better certain topics where science and religion interact. If science teachers, or other communicators of science, do deal with religious issues, or science issues that have religious connotations, I recommend that they be both true to science and respectful of their students and others, irrespective of such people's religious beliefs. Indeed, nothing pedagogically is to be gained by denigrating or ridiculing students.

The principle of respect for students has implications for assessment too. Well-designed examination material should be able to test student knowledge of science and its methods without expecting students to have to convert, or pretend that they have converted, to a materialistic set of beliefs. So, for example, while it is appropriate to ask students to explain how the standard neo-Darwinian theory of evolution attempts to account for today's biodiversity, it is not appropriate to ask students to explain how the geological sciences prove that the Earth is billions of years old.

Perhaps the most important implications of religion in general and Christianity in particular for the teaching of science come when teaching about the nature of science (Black et al. 2007). It can be a useful exercise with some students for science educators to get them to consider whether such topics as astrology, ghosts, paranormal phenomena and miracles fall within the scope of science or not. The aim is not to smuggle such topics into science but to get students more rigorously to think about what science is and how it proceeds. I remember one student of mine who undertook a survey among her peers to see whether, as predicted by astrology, their astrological birth sign was related to their personality, using a validated measure of personality. It wasn't. That student learnt something about science that was of value to her that I suspect she might not have learnt had I told her not to be silly and instead research something within mainstream science.

Skehan and Nelson (2000) point out that science educators generally do not do a good job of providing students with criteria to compare the strength of great scientific ideas. They emphasise the value of enabling students to develop skills of critical thinking when considering controversial topics such as evolution and provide a valuable list of eight criteria for comparing major scientific theories:

1. How many lines of independent evidence support the theory?
2. How many previously unconnected areas of knowledge did a theory tie together?
3. Does the theory make precise predictions?
4. How clear are the causal mechanisms?
5. Does the theory adequately explain the ultimate origin of the systems it describes and explains?
6. Is the theory scientifically controversial, or only publicly or politically controversial?
7. Is the theory fundamental to many practical benefits embraced by our economic system?
8. Is the theory widely understood and accepted by the general public?

This list differs considerably from the criteria discussed earlier (Sect. 51.3). Nevertheless, there would seem to be much of value in encouraging students to consider such questions (or others) when examining the validity of evolution or other major scientific theories.

Stolberg and Teece (2011) write about how to teach the science-religion issue but address their advice to specialist teachers of religion, not science, which provides a useful counterweight to the rest of this section. They point out that religious education teachers often assume that they should be neutral when teaching about controversial issues, yet this can be unrealistic and may not be the most effective way of teaching:

> Teachers may well feel that adopting a neutral stance – focusing on ‘the facts’, giving a ‘balanced’ picture – is most likely to be the ‘safest’ one to adopt. In practice, this is a very difficult strategy to achieve. The choice of facts you present (or withhold), the ‘expert’ opinions you share with your students and all the other educational judgments – in terms of the resources chosen and time devoted to the issue being explored – makes the effort of teaching religion and science issues in this way unrealistic. As with all controversial issues, however, your students need to be taught to examine critically the information they are given and the attitudes or values that have led to its production. So, rather than seeking to ‘not get involved’, you should be explicit about the aims and objectives of any exercise so that your students are aware of the circumstances in which they are being asked for their opinions and share the basis for their thinking. (p. 71)

51.9.1 Specific Issues to Do with Creationism

Part of the purpose of school science lessons is to introduce students to the main conclusions of science – and the theory of evolution is one of science’s main conclusions. For this reason, school biology and earth science lessons should present students with the scientific consensus about evolution, and parents should not have the right to withdraw their children from such lessons. At the same time, science teachers should be respectful of any students who do not accept the theory of evolution for religious (or any other) reasons.

Science teachers should not to get into theological discussions, for example, about the interpretation of scripture. They should stick to the science, and if they are fortunate enough to have one or more students who are articulate and able to present any of the various creationist arguments against the scientific evidence for evolution (e.g. that the theory of evolution contradicts the second law of thermodynamics, that radioactive dating techniques make unwarranted assumptions about the constancy of decay rates, that evolution from inorganic precursors is impossible in the same way that modern science disproved theories of spontaneous generation), they should use their contributions to get the rest of the group to think rigorously and critically about such arguments and the standard accounts of the evidence for evolution.

My own experience of teaching the theory of evolution for some 30 years to school students, undergraduate biologists, trainee science teachers, members of the general public and others is that people who do not accept the theory of evolution for religious reasons are most unlikely to change their views as a result of one or two lessons on the topic, and others have concluded similarly (e.g. Long 2011). However, that is no reason not to teach the theory of evolution to such people. One can gain a better understanding of something without necessarily accepting it. Furthermore, recent work suggests that careful and respectful teaching about evolution can indeed make students who initially reject evolution considerably more likely to accept at least some aspects of the theory of evolution (Winslow et al. 2011).

For sites of informal education, there are some issues that are the same for schools and some that are different. The principles of respect for students and others, irrespective of their religious beliefs, hold in the same way, but the principle of being true to science manifests itself somewhat differently depending on the nature of the site of informal education. If the site is one that identifies itself as being scientific, for example, a science or natural history museum or centre, then it can validly attempt to convince visitors that the standard scientific position is correct. Other informal education sites may have less of a science agenda. In any event, any museum or other site of informal learning should be able to prepare carefully and access resources in a way that may not be possible for a classroom teacher, so as to ensure that an exhibition, a display, a taught session or an outreach activity does deal with relevant religious issues.

Finally, there are an increasing number of creationist museums (e.g. http://creationmuseum.org/) and zoos (e.g. www.noahsarkzoofarm.co.uk/). Perhaps somewhat optimistically, I would ask those running such creationist places of learning to make one concession to evolution. I do not expect them to promote evolution, but it is reasonable to ask them to make it clear that the scientific consensus is that the theory of evolution and not creationism is the best available explanation for the history and diversity of life. It is perfectly acceptable for those running creationist institutions to critique evolution and to try to persuade those visiting such institutions that the standard evolutionary account is wrong. But just as science teachers with no religious faith should respect students who have creationist views, so creationists should not misrepresent creationism as being in the scientific mainstream. It is not.

Chapter 52
Rejecting Materialism: Responses to Modern Science in the Muslim Middle East

Taner Edis and Saouma BouJaoude

52.1 Islam, Science, and "Materialism"

Contemporary Islamic responses to science are similar to responses from within other world religions – they exhibit a degree of ambivalence. Supernatural agents no longer play any explanatory role in the natural sciences, which challenges religious perceptions of divine design in the universe (Edis 2002). At the same time, modern science is closely coupled with technological prowess, making science appear indispensable to Muslim populations seeking to avoid commercial and military subordination in postcolonial times. This puts pressure on religious thinkers to try to achieve harmony between science and Islam while guarding against the materialist influences they perceive in the conceptual frameworks of Western science.

Since Islam is a diverse religion, and since Muslims constantly dispute what is the best interpretation of their religious tradition, there are always various competing visions about how to attain harmony. Some general descriptions are nonetheless possible.

Most popular versions of Islam harbor some ideas about harmony between science and religion, even though these ideas tend to be very superficial. Muslim populations worldwide sustain some very popular pseudoscientific beliefs (Edis 2007; Guessoum 2008). More complex interpretations of religious doctrines are readily available in more intellectual circles, but the level of engagement with science in

more sophisticated theologies varies greatly. Most religious preoccupations, such as those about matters of social morality, have little to do with science, and in turn, most routine science does not touch on religion. But some scientific claims associated with the more ambitious theories of modern physics and biology invite friction with traditional beliefs about the supernatural governance of nature. Evolution in particular is a perennial source of conflict (Edis 2007).

Especially in the popular literature, "materialism" has become a common negative term expressing discomfort with modern ideas that emphasize impersonal, purposeless processes in explanations of phenomena. Historically, this is rooted in responses to mechanically inspired nineteenth-century materialist philosophy (e.g., Büchner 1884), together with later opposition to Marxist notions of materialism in the realm of social thought. Current developments of philosophical materialism, such as physicalism (Melnyk 2003), would naturally also be deemed unacceptable, due to their exclusion of supernatural agency and divine design. In popular writings, however, "materialism" is usually a generic term of abuse with little specificity. Nonetheless, as an umbrella term encompassing rejection of visible supernatural agency, opposition to "materialism" captures a central theme in Muslim concerns about modern science.

None of this is distinctively Muslim. Similar pictures can be drawn of Christian, Jewish, and even Hindu responses to theories such as evolution (Brown 2012). And when going beyond broad generalizations, it is very hard to identify a common, coherent Islamic philosophical framework through which Muslims tend to approach science. There is, perhaps, a distinctly Islamic preoccupation with questions about occasionalism and natural causality in Muslim thinking about science, reflecting the particular philosophical heritage of Islamic thought (Fakhry 2004; Leaman 2002). But such features of an Islamic philosophy of science are of minor importance. Both Islam and modern science are too varied for any common framework to dominate in Muslim thinking about science.

Instead, the distinctive aspects of present Muslim responses to science derive from the *history* of Muslim lands, especially the Middle Eastern heartlands of Islam. For Western Christendom, modern science, however revolutionary, still emerged as an organic development within its intellectual culture. When science caused religious discomfort, it did so as an endogenous heresy. For Muslim societies, modern science has been a Western import, significantly detached from their own intellectual tradition, including the highly developed medieval science of Islamicate societies. And for those Muslim thinkers most concerned about developing a religious response to modernity, modern science has often appeared as something to assimilate, to Islamize, and to guard against when it appears to challenge traditionally religious perceptions of nature (Edis 2007).

52.2 Medieval Islam and Modern Science

Natural science and doctrinally traditional forms of Islam have an uneasy relationship today. Muslim countries devote few resources to natural science, and the Muslim contribution to research in natural sciences such as physics is negligible

(Hoodbhoy 2007). Even in applied science and engineering, where the picture is not as dismal, Muslim countries suffer from relative backwardness. While Muslim populations have usually been enthusiastic about adopting modern technology, sustained creativity regarding new technologies still tends to characterize advanced Western and East Asian economies.

Muslims did not always have to play catch-up. Islamic empires famously were home to the best of medieval science. Though participation in serious intellectual life was inevitably confined to a small elite, Muslim scholars typically enjoyed better intellectual resources compared to their medieval European counterparts. Whether in medicine and public health, astronomy, optics, mathematics, or philosophy in the Greek tradition, Muslims were at the forefront of intellectual life. Historians of science continue to address the puzzle of why Europe became the site of the modern scientific revolution, rather than China or the lands of Islam (Huff 2003).

There are many myths about medieval Islamic science. Western observers used to describe Muslim scholarship as merely transmitting the heritage of Greek and Roman antiquity. This is not correct: Muslims further developed the ideas they inherited. Muslim science is often described as stagnating. Some Muslim reformers today add that this was due to the suppression of rationalist theologies, such as that of the Mutazila, and the influence of religious conservatives, such as al-Ghazali, who argued against philosophy (Hoodbhoy 1991). Yet those “foreign sciences” that were perceived as having practical utility were decoupled from the Greek philosophical tradition and continued to slowly develop even when philosophy faced a hostile climate.

Nevertheless, a large scientific and technological gap did open up between Europe and Muslim empires such as the Ottomans, Iran, and Mughal India. Europe made spectacular advances while Muslim conceptions of science remained closely anchored in the medieval tradition. With hindsight, it is easy to admire the accomplishments of medieval Muslim science. But this science operated within a premodern conceptual framework. Muslim medicine, for example, could boast interesting surgical techniques and impressive provisions for public health and hospital complexes. At the same time, the medical texts Muslims used were also full of bloodletting, humor theory, religious and magical practices, and no end of ideas that have a closer affinity to occult thinking than what became natural science as understood today. Furthermore, the medieval natural philosophy practiced in Islamicate societies, like its Catholic European counterpart, did not develop explanations within the sorts of theoretical framework comparable to, for example, early modern physics. Science remained an activity of collecting mostly isolated facts, and these facts were liberally mixed with what later scientists would come to call superstition. In this regard, modern science is radically different compared to its medieval precursors, in terms of explanatory power as well as its more immediately visible technological applications (Edis 2007). When Europeans, by historical accident, stumbled upon the new ways of thinking about nature that became modern science, Muslims would be left behind (Huff 2003).

Muslim intellectuals first became conscious of lagging in their knowledge of nature as a result of persistent military defeats of Muslim empires. The Ottoman Empire, which was nominally sovereign over today’s Turkey and most Arab countries up until the twentieth century, was closest to Europe. And in the seventeenth century dire reversals in the Ottoman-controlled Balkan territories forced Ottoman intellectuals to ask why the conquering armies of the faithful were suddenly so weak. Scholars called for intellectual and institutional renewal among Muslims. These calls gathered strength as it became clear that science-based technology and modern forms of social organization gave the Europeans their advantage. Similar experiences were to follow for Mughal India, Iran, and Indonesia – all but the most isolated Muslim countries. Muslims everywhere would face a similar challenge from the industrialized West, and Ottoman intellectuals would craft responses that would find echoes across the Muslim world.

52.3 Ottomans Respond to Modern Europe

Confronted with western European military and commercial superiority, Ottoman intellectuals became preoccupied with rescuing the Empire. Many insisted that if only Muslims would redouble their commitment to faith and proper observation of divine laws, Islam would be restored to its proper dominance. But most, including most religious scholars, came to recognize that technology was the key to European power and that Muslims would have to acquire and master the new forms of knowledge. How this was to be best accomplished, and especially how the religious nature of Muslim civilization could be protected, became matters of contention (İhsanoğlu 2004). This debate shaped intellectual life in the last century of the Ottoman Empire, spilled over into successor states such as the Republic of Turkey and Egypt, and continues vigorously to the present day. Indeed, many of the themes running through earlier Muslim ideas about renewal remain at the forefront of debates today.

In the seventeenth century, Ottoman intellectuals such as Katib Çelebi argued that Muslims needed to be more open to foreign scientific knowledge (Demir 2001, pp. 48–52; Lewis 1993, Chap. 16). Obviously, Western Europe could no longer be ignored; Muslims needed to learn as much as possible about European technical accomplishments. Ottoman officialdom would adapt, for example, sending representatives to European capitals rather than relying only on European diplomats stationed in Istanbul. By the early nineteenth century, as the Ottoman Empire's European territories continued to shrink, diplomats, travelers, and students became a significant conduit of information about Western ways. Translations of Western technological and scientific works became available, and westernized forms of education attracted the children of elites.

Together with Western Europe, however, Ottoman Muslims also looked toward their own history. Especially before the nineteenth century, almost all intellectuals were grounded in the classical tradition of religious scholarship. And for religious scholars, reforming Muslim attitudes toward knowledge made sense in the context of reviving the specifically Muslim "religious sciences." Even Katib Çelebi had expressed a perception that Muslims had become "imitators," relying too much on precedents set by earlier scholars. Assimilating the foreign sciences could be best accomplished if all the Muslim sciences were to become more vibrant. After all, the story went, in their glory days Muslims had enjoyed the best of the foreign sciences, anchored to a God-centered perception of nature, all mediated by a devout engagement with the sacred sources.

Achieving scientific progress in the context of a revival of religious scholarship remains a prominent theme in doctrinally conservative Muslim discourse today (Edis 2007). But the more general notion of revival resonates among more liberal parties to the debate as well. Liberals call for reviving rationalist currents of theology and accuse conservatives of preventing vital social and technological changes (e.g., Mernissi 1992). Most parties agree that recovering the intellectual practices that led to the golden age of medieval Muslim science is vital. Almost everyone overlooks the enormous differences between medieval and modern science.

Calls for revival aside, the immediate task faced in the crumbling Ottoman Empire was to transfer European technology and acquire modern organizational skills. Religious intellectuals felt a need to reconcile this dependence on Europe with the superiority due to Islam. İbrahim Müteferrika, a Hungarian convert to Islam responsible for the first Muslim-operated Ottoman printing press in 1727, stated that Europeans had advanced in rational science precisely because they needed to compensate for the inferiority of their religion. In social and religious matters, Islam was unquestionably superior (Black 2001, p. 268). Religious scholars typically argued that it was permissible to learn the technical knowledge possessed by infidels in order to use this knowledge against them in a military confrontation. More generally, scholars agreed that borrowing knowledge was necessary to defend Islam. However, this borrowing would have to take place in such a way as to guard against cultural contamination.

These remain major themes today. Conservative Muslims often temper their enthusiasm for technology with a conviction of religious superiority and highlight the need to protect the core values of Islamic civilization while modernizing. Indeed, even very traditional religious communities can sometimes adapt quickly to a highly technological environment, strengthening their commitment to orthodoxy in the process (Blank 2001). But more traditional religious commitments remain in tension with institutional structures that are aimed toward contributions to progress within a global scientific enterprise, rather than mainly transferring existing technology.

Just what this protected core of Islam should be is also, naturally, open to dispute. The modernization of Muslim countries over the last few centuries has brought large-scale social changes, including the erosion of the power and social position of the class of religious scholars. In the nineteenth century, this opened up possibilities for more modernist interpretations of Islam (Alperen 2003). Jamal al-Din al-Afghani in Ottoman lands, Sayyid Ahmad Khan in British India, and later Muhammad Abduh in Egypt advocated an interpretation of Islam that was more open to modern education and argued that Islam was in its essence a scientific religion. They downplayed the more miraculous and magical elements in popular piety, joining traditional Sunni orthodoxy in their suspicion of Sufi enthusiasm.

Muslim modernism, however, also harbors a conservative impulse. For example, while modernists downplayed overtly supernatural aspects of popular piety, they did not challenge traditional views of the sacred sources. Modernists produced an apologetic response to modernity rather than a coherent endorsement of modern values. In the twentieth century, with increased literacy in Muslim populations, religious movements that emphasized individual access to sacred sources, bypassing the mediation of traditional scholarship, became more popular. Often this implied a more literal reading of sacred texts and a fundamentalist flavor of populism. Modernist themes of moving beyond traditional forms of religious scholarship are today endorsed by fundamentalists who feel at home in a globalized economy (Roy 2004), as well as by more liberal-minded religious thinkers.

Most doctrinally conservative Muslim responses to Western encroachment have included an element of cultural defensiveness. Nevertheless, westernizers and secular-oriented thinkers have also taken part in the debate. In the Ottoman Empire, such intellectuals were more often rooted in the military and imperial administration rather than in traditional religious scholarship. The Ottoman military went through a wrenching westernization in the late eighteenth and early nineteenth centuries, and some military intellectuals began to think that a more comprehensive westernization of Ottoman society was unavoidable if the Empire was to avoid annihilation in the hands of European powers. A small minority of thinkers educated in a European style even expressed secular ideas. The more radical westernizers finally got a chance to implement their agenda in the 1920s, with the Turkish Revolution founding a new republic in the Anatolian heartland of the Ottoman Empire.

Secular westernizers proposed to solve the problem of adopting Western science by forcing religion to become a private affair. While personally remaining Muslims, modern Turks would become as Westerners in public life, joining the enterprise of creating modern knowledge on equal terms with Europeans (Kazdağlı 2001). Commitment to such a comprehensive ideal of secularization did not take root beyond a relatively small social elite, but due to its command of state power in Turkey and influence on the elites of many other Muslim countries, a secular outlook was a major party to Muslim debates over science and religion in the twentieth century. Even today, when Islamist politics dominate the public imagination in the Muslim Middle East, a secular westernizing view retains some influence due to its overrepresentation among elites and in those scientific institutions established in Muslim countries.

Today, the Muslim world is in a period of extensive religious experimentation. The desire to achieve a distinctly Muslim way of being modern has produced many competing ideas. So modernism, hopes for revival, westernization, or cultural defense are not the only themes that surface in current controversies over science and Islam. For example, Sufism, the mystical strand of Islam, has met with disapproval from both westernizers and conservative scholars and thus has been greatly disadvantaged during the modernization process. Recently, a kind of neo-Sufism has begun to appeal to modern professionals in an urban environment, influencing debates over miracles or spiritual realities accessed through mysticism. Occult notions, then, can find support from those who want to revive medieval perceptions of nature, those who defend survivals of such beliefs in existing religious orders, but also from neo-Sufi's who bring a westernized, New Age flavor to the arguments (Edis 2007; Raudvere and Stenberg 2009).

Even with this diversity of themes, however, it is possible to make some generalizations about the recent history of responses to Western science in the Ottoman Empire and its successor states. Both among religiously conservative intellectuals and much of the general public, enthusiasm for technology has been combined with an insistence that religious convictions should remain at the center of how Muslims perceive nature. This brings up the potential of friction with modern science, which has tended to disenchant the world. Moreover, this friction usually surfaces in the context of institutional and social conflicts between more religiously oriented and westernized segments of Muslim populations.

52.4 Against Materialism

Centuries of military disadvantage taught the Ottomans and their successors that their problems could not be solved by immediate technology transfer or by better techniques of organization. As long as Muslims were borrowers rather than creators of practical knowledge, they would always lag behind.

Most Muslim countries have been considered "underdeveloped" during the twentieth century. Today, countries such as Turkey have attained a middle-income status in part due to industrial manufacturing enterprises migrating away from Europe, but they remain in a peripheral position in the global economy, especially where the cutting edge of science and technology is concerned. Therefore technologically, Muslim-majority countries typically remain in a position of playing catch-up. This means that as with the past century, their educational and industrial policies continue to emphasize immediate applications and technology transfer over basic science. In Turkey and the Arab Middle East, the institutional infrastructure for basic science is poor, and engineering programs typically attract more talented students than natural sciences such as physics. Moreover, an emphasis on applied science has been easy to reconcile with demands for cultural defense. Both in technologically advanced Western countries and among Muslims, the culture of engineering is notoriously more politically and religiously conservative compared to natural science (Gambetta and Herzog 2007). Engineers and medical doctors who reject evolution are commonplace but a rarity among physicists and biologists. And in Muslim countries, engineers are well known to be heavily represented in the leadership of political Islamist movements. But relative success in adopting foreign technologies cannot solve the deeper problem: Muslim populations still lag in the creation of new knowledge, even when restricted to immediate practical knowledge.

This puts pressure on Muslims to master natural science, not just applied science and engineering. Religious responses to natural science, therefore, become important, particularly in areas where modern science appears to challenge traditional beliefs.

In the nineteenth century, most Muslim thinkers continued to take it for granted that Islam was religiously superior to the superficial Christianity of urban Western Europe. Some travelers and diplomats greatly admired Europe, adopting a “the West is the best” mentality. But many Muslim observers of Europe described lands that harnessed vast power through industrialization but were also moral disaster zones. Europeans cared about material things, were good at achieving worldly power and wealth for their elites, but were spiritually lacking. In the twentieth century, visible secularization in Europe would further bolster perceptions that Christian piety was inadequate compared to Muslim faith (Aydın 2000, pp. 43–50). In any case, the European example only intensified concerns that acquiring new knowledge should be done with care to avoid cultural contamination. Yet it was also clear that creating new knowledge required new intellectual habits and adopting those new ways of perceiving nature that were ushered in by the new natural sciences. Culture could not remain immune to change.

Ottoman perceptions of the natural science they imported were colored by the institutional struggle of European science to become independent of religion. Conflict with church authority was not a concern; even today, religious thinkers proudly declare that Islam has no ecclesiastical structure that can impede scientific inquiry (Aydın 2000, p. 86; Şahin 2001, pp. 177–182). But especially in the nineteenth century, materialist currents in European intellectual life influenced Muslim perceptions of science (Gümüşo lu 2012). Popular materialists such as Ludwig Büchner not only publicly argued against supernatural realities – unthinkable in a Muslim environment – they made it clear that their philosophy was inspired by scientific developments (Büchner 1884). Furthermore, materialism also had radical political implications, even before Marxism developed a significant following. When Darwinian evolution appeared on the intellectual scene, it immediately became part of the larger Western debate over science and the supernatural, rather than just a theory of interest to biologists.

European materialist literature aimed at a middle-class market also attracted attention from Ottoman elites in intellectual centers such as Istanbul and Egypt. Official censorship would not allow the full extent of materialist skepticism about the supernatural to become public, but large portions of books by materialist and anticlerical figures such as Ludwig Büchner, Ernst Haeckel, and Andrew Dickson White were translated and sold reasonably well. Darwinian evolution briefly became a matter of debate. Ottoman elites were in no position to contribute to scientific research, but many desired to learn about science, and in the late nineteenth century, popular science imported from Europe included a dose of materialism (Özervarlı 2003; Ziadat 1986, p. 23).

The direct influence of those Ottoman intellectuals who took a positive view of materialist ideas never extended beyond a small elite. Nevertheless, materialism took a symbolic role in debates over the role of religion and the power of the class of religious scholars in the changing empire. The handful of Ottoman materialists may have been a negligible extreme, but they were not the only ones who suspected Muslim lands were held back by religious obscurantism. And since materialism was a blatant example of infidelity, for conservatives the blasphemy materialists fell into could also serve as a warning against imitating Western ways blindly. Indeed, since conservative Muslims already held Europe in suspicion as a spiritually inferior civilization given to materialism in a crass sense, it seemed that a depraved denial of all that was godly was a logical endpoint of the Western approach to knowledge. Denouncing a symbolic "materialism" could serve as part of a warning against westernizing so far as to lose a Muslim identity. Even today, some Turkish conservatives remember the nineteenth century as a time when a materialist threat first surfaced and demanded a vigorous response from the faithful (Akyol 2009; Hanioğlu 2008; Gümüşoğlu 2012).

Early twentieth-century reform-minded scholars, such as Said Nursi in Turkey, developed apologetic responses to nineteenth-century materialism. Nursi attacked ideas such as natural causality and evolution, while at the same time endorsing science as a way of understanding God's creation. Today, a vaguely defined materialism remains a symbolic enemy, especially for many conservative Muslims – even though, especially after the waning of Marxism, explicitly materialist points of view do not have a significant presence in public debates. The path to reconciling science and religion still goes through defending against a threat of materialism.

52.5 Making Science Acceptable

Some Muslims have sometimes had moral objections to an application of science (Sardar 1984). This is, however, very different from rejecting a "fact" discovered by scientists. Indeed, conservative Muslims have typically been comfortable with science as a means of making an extensive catalogue of facts, presumably documenting the glories of God's creation.

Modern science potentially causes trouble, not because of any result produced in a laboratory but because it is *not* a catalogue of facts collected like stamps. Mature sciences such as physics and biology gain much of their power from the compelling conceptual frameworks they establish, explaining a very wide range of phenomena. Classical physics, later corrected and expanded into modern physics with relativity and quantum mechanics, are ambitious attempts to capture the fundamentals of how the world works. Darwinian evolution claims to present and explain a pattern of descent common to all of life. In such conceptual frameworks, supernatural agents are conspicuous by their absence. Moreover, important aspects of these frameworks are, at face value, hard to reconcile with traditional religious beliefs about how God must have a role in our understanding of nature. Quantum randomness challenges the notion that the universe is controlled by a divine purpose that is distinguishable from chance. Darwinian evolution does not just contradict Quranic stories about the special creation of Adam and Eve; it undercuts the common religious intuition that creativity must always be due to an overarching intelligence rather than a product of mindless processes (Edis 2002, 2006).

Western Christians have responded to such challenges not just by fundamentalist resistance but also by liberal reinterpretations of theology. But from a conservative

Muslim perspective, liberal theology can easily look like capitulation to materialism – another illustration of how Europeans have been unable to defend the core religious truths revealed in the Abrahamic faiths (Aydın 2000, p. 61). Moreover, science is not just a source of worry for intellectuals debating abstract matters. Most ordinary Muslims, even in technologically relatively modern environments, continue to understand their faith in a context where divine action directly and immediately shapes the world. Victims of an earthquake, for example, will usually interpret the earthquake as the will of God, very often as a divine punishment (Küçükcan and Köse 2000) – a view supported by Quranic stories about God punishing wayward peoples by earthquakes. As modern technology gives people more control over aspects of their lives, and state-mandated education includes a more scientific picture of nature, questions about science and religion take on a public significance beyond their merely intellectual interest.

The present Muslim debate over science and religion is significantly different compared to the debate taking place in advanced Western countries. Scientific institutions are weaker in Muslim lands. They are less able to assert their independence from cultural politics. Moreover, liberal theological options, which help grant science an independent sphere of operation, do not enjoy as strong a social presence. Indeed, observing the secularizing trajectory of Western societies, conservative Muslims are likely to be even warier about repeating the mistakes Christians have made.

Doctrinally conservative Muslims, then, often feel a need for an apologetic response to the ways modern science can engender skepticism about supernatural claims. Their literature on science and religion is broadly similar to Christian equivalents; after all, beyond a number of specific doctrinal matters, all Abrahamic faiths face similar challenges from the naturalistic tendencies within science. Like their Christian counterparts, conservative Muslims typically rhetorically endorse science and defend a perception of modern science in complete harmony with traditional beliefs. Where harmony is strained, however, making science acceptable requires some work. Especially in the popular apologetic literature, three approaches stand out: ignoring the challenge, co-opting science, and outright rejection.

Some questions that have become staples in the Western discussion over science and religion have little connection to the concerns of ordinary Muslims. Popular apologetics therefore tends to ignore them, and without public controversy, religious intellectuals devote little attention to such topics. Modern physics is rarely the subject of sustained reflection, with a few exceptions. Some thinkers try to validate the medieval Muslim philosophical position of occasionalism through quantum mechanics, though the typical result is a distortion of the physics. More often, quantum physics gets invoked in a neo-Sufi, even parapsychological context. This almost never rises above the level of popular pseudoscience (Edis 2007). A recent area of scientific development that has drawn the fire of Western opponents of materialism, such as the intelligent design movement, is cognitive neuroscience (e.g., Beauregard and O'Leary 2007). It is hard to find any distinctively Muslim response to the currently dominant materialist point of view in neuroscience.

Another common strategy, especially in popular apologetics, is to co-opt science, arguing that modern science supports traditional beliefs. For example, there is now an extensive literature that is very popular throughout the Muslim world, purporting to demonstrate how the Quran is full of miraculous anticipations of modern science and technology (e.g., Bucaille 1979; Nurbaki 1998). This parallels the way many conservative Protestants claim fulfilled prophesies as a way of providing concrete support for their belief that the Bible is the word of God. More sophisticated Muslim thinkers often have misgivings about this style of apologetics (Rehman 2003), but its popularity remains very strong.

Co-opting science extends to the way that some Muslims take a conciliatory attitude toward evolution, accepting an explicitly guided, non-Darwinian form of biological change. In this connection, there are occasional arguments that medieval Muslim scientists had already thought of the concept of evolution (Bayrakdar 1987). Much of the literature arguing that modern science supports traditional Islam is opportunistic. For example, while many conservative Muslims rely on various pseudobiological arguments to support traditional gender roles, some selectively quote from the popular sociobiological literature to that end while ignoring the evolutionary context of such arguments (Edis and Bix 2005).

Some scientific and scholarly ideas, however, appear to be both worthy of attention and too tainted with materialism to assimilate easily. One example is modern Quranic criticism, which is practiced almost exclusively outside of Muslim lands, and is nearly universally rejected by devout Muslims when they are aware of it. At least one European scholar has found it necessary to publish under a pseudonym to avoid repercussions (Luxenberg 2000). In natural science, the clearest example is Darwinian evolution.

Darwinian evolution – that is, a completely naturalistic understanding of common descent as driven by purposeless material processes such as variation and selection – has usually faced rejection from Muslim populations. Ideas about evolution first reached Ottoman intellectuals in the context of the European controversy about science versus revelation. And the first Ottoman defenders of Darwin came from among westernizers who were less interested in biology than evolution as an example of materialism triumphing over clerical obscurantism. Traditional religious scholars naturally reacted with condemnation. Interestingly, the prominent modernist Jamal al-Din al-Afghani also rejected evolution as an anti-religious philosophy that was absurd on the face of it. He only made concessions to a possibility of a non-Darwinian, guided version of evolution toward the end of his life (Keddie 1968, pp. 130–174; Bezirgan 1988).

As a result of the rejection of Darwin even by reformist Turks and Arabs keen to avoid the taint of materialism, the nineteenth-century Ottoman debate about evolution was stillborn. Most Middle Eastern Muslims, even many among educated elites, remained creationists by default. Indeed, until recently, Darwinian ideas usually did not have enough of a public presence to inspire an elaborate creationist pseudoscience as a reaction. As a result, conservative Muslim attitudes toward evolution today are often roughly comparable to those of more fundamentalist and Pentecostal Christians worldwide. Evolution is clearly unscriptural and obviously a materialist idea; therefore, it cannot be correct – nothing more need be said.

52.6 The Nur Movement

Muslim responses to materialist currents in science do not trickle down from academic theologians. They do not arise from traditional religious scholarship, which has little scope for analysis aside from condemning ideas that go against orthodox readings of the sacred sources. Muslim responses typically come from devout intellectuals facing immediate practical problems, and even more important, they achieve prominence if popular religious movements adopt them.

In this regard, the example of Said Nursi and the "Nur movement" he inspired is particularly important. Western scholarship on Islam has tended to be driven by political questions such as the potential for democracy in Muslim countries, and therefore figures such as the early modernists and later theorists of political Islam such as Sayyid Qutb and Abul A'la Maududi have drawn much attention. They all have writings that usefully represent aspects of modern Muslim thought on science, reason, and religion (Euben 1999). Nursi's movement, however, has been instrumental in shaping popular Turkish attitudes about science and religion today. It pioneered forms of popular apologetics that are now very common throughout the Muslim world. The Nur movement deserves more attention.

Nursi was trained as a traditional scholar in the Ottoman provinces and was most active in the first half of the twentieth century. Much of his thought repeats modernist themes, including an emphasis on reforming Muslim education, a positive view of technology, and a desire to combat harmful intellectual influences associated with nineteenth-century materialism. He argues that mystical illumination complements scientific investigation, that all useful arts and sciences emanate from the "names of God," and that the Quran anticipates modern technological possibilities (Abu Rabi' 2003).

None of these are remarkable ideas for Nursi's time and circumstances. But unlike many other reformist scholars, Nursi started a successful popular movement. He produced the *Epistles of Light*, revered by the Nur movement almost as a secondary scripture. After his death, Nur adherents continued to organize on the basis of studying the *Epistles*. The movement has been notable for its modernizing emphasis, capitalist mentality, and nontraditional forms of organization and religious authority structure. Social scientists have pointed to the Nur movement as an example of a very modern, pro-technology Islamic movement with a strong popular constituency. They have argued that it has been instrumental both in laying the groundwork for provincial economic development and in spearheading the success of modern Islamic forms of thinking in Turkey (Mardin 1989; Yavuz 2003).

The Nur movement is too large to be unified. Its many splinter groups today include the followers of Fethullah Gülen, one of the internationally best known Muslim leaders of recent times, plus others that enjoy considerable political influence in Turkey (Çalışlar and Çelik 2000). Yet a common denominator of Nur-inspired movements for decades has been a form of popular apologetics that places great emphasis on harmony between Islam and science. Most pseudoscience in Turkey, other than superficial Western-derived and media-driven fads such as astrology and UFOs, has the signature of the Nur movement.

In pre-Internet times, the Nur movement produced popular science magazines that regularly included articles on how Muslims should embrace technology and how the Quran miraculously anticipates modern developments, containing knowledge of astrophysics or embryology. They opposed evolution. The immediate social influence of the movement fluctuated according to changing political circumstances within Turkey, but over the long term, the Nur style of apologetics appealed beyond the study circles focused on the *Epistles of Light*. Today, some of the old popular science and religion magazines survive, but the Nur style of apologetics has acquired a much broader influence, becoming embedded in popular culture and spreading through new forms of media.

In today's Turkey, anyone with views on science and religion – for example, an academic theologian proposing a more liberal view concerning evolution – has to contend with the widespread influence of the Nur movement. The Nur version of harmony between science and Islam is entrenched not just in popular culture and popular pseudoscientific beliefs, but it also enjoys elite influence. Academic theologians and scientists who either have direct connections to the Nur movement or have absorbed its ethos are significant voices in the Turkish debate over science and religion (Şahin 2001; Tatlı 1992). Through such channels, opposition to evolution, for example, has a presence in the intellectual high culture as well as the mass media.

52.7 The Growth of Creationism in Turkey

Said Nursi was disappointed by the Turkish Revolution of the 1920s. The westernizers in control of the new Turkish Republic established official secularism, suppressing political expressions of Islam. Nursi spent time in prison. The intellectual influences upon political leaders such as Mustafa Kemal Atatürk tended to be secular, anticlerical, and even included then-current versions of materialism and positivism (Parla and Davison 2004). Science, not religion, was to light the path to a brighter future. Evolution entered the curriculum. Still, evolution remained a relatively small offense against religion in a state-controlled educational system that aimed to make religious sentiment a private matter rather than a reference for public policy.

Until the 1960s, like other Middle Eastern Muslim countries, Turkey presented a picture of grudging but gradual secularization. The Nur movement and similar religious conservative groups produced some creationist literature, but their market was limited. Anti-evolutionary activity stayed confined to the subculture of a strictly observant, self-consciously orthodox minority. It is harder to know what the bulk of the population thought of evolution in the textbooks, in the days before constant opinion polling. Most likely, evolution inspired passive resistance at most, when it drew attention at all.

In the 1970s, together with the rest of the Muslim world, a newer form of political Islam started to gain strength in Turkey. Evolution became a minor culture war item, a way for Islamists to demonstrate opposition to secularization without naming official secularism as a target. In parliament, an Islamist political party attacked the presence of evolution in education but produced only a minor media stir (Atay 2004, pp. 136–137).

Creationism came into its own in the aftermath of the conservative military dictatorship of 1980–1983. Religious conservatives, many with Nur movement connections, gained control of the Turkish Ministry of Education in the first quasi-civilian government. They were convinced that evolutionary ideas were morally corrosive, and yet they were very aware that science commanded significant cognitive authority. So they needed a way to show that evolution was a scientifically dubious idea, maybe even a fraud. They found the resources they needed in Protestant "scientific creationism." Adding an odd chapter to the history of Muslim intellectual borrowing from the West, religious conservatives invoked Christian creationists in a mirror image of the way secularists tend to rely on Western scientific authorities. While the Turkish creationists downplayed some important features of Protestant creationism such as a young earth and flood geology, they adopted the bulk of the anti-evolutionary debating points developed by their Christian counterparts. Indeed, the Ministry of Education had samples of "scientific creationist" literature officially translated and made available to high schools and teachers (Edis 1994).

Since this creationist breakthrough, Turkish secondary school textbooks have often contained anti-Darwinian or explicitly creationist material (Yalçınoğlu 2009). Islamists and conservatives favor a religious identity politics, so even though opposing evolution is not a leading item on political agendas, it tends to be a background commitment. Since 2002 a moderate Islamist party has held power. The Ministry of Education under its administration is perceived as sympathetic to creationism, due to incidents such as retaining creationist material in the curriculum in the face of academicians petitioning for the removal of unscientific material (Kotan 2006).

Islamist politics in Turkey relies on alliances between working class constituencies such as recent immigrants to large cities and a newly prosperous provincially based business class, often united by antagonism toward longer-established secular elites. Religious populists present political conflicts over religion as a clash between a debased, inauthentic secularism and the traditional piety of the common people. Nevertheless, the primary constituency for Turkish creationism is not traditionalists but modern believers, even though they are theologically conservative. It is precisely because they want to take their place in the modern world, where mastering technology is the key to success, that creationists fashion a pseudoscience that harmonizes science and their religious convictions.

Since 1997, the popular appeal of Turkish creationism has deepened. Indeed, the Turkish style of creationism has spread internationally, throughout other Muslim countries and the Muslim diaspora in Europe and North America. The central figure in this development is Harun Yahya, a pseudonym that serves as a brand name for a ubiquitous, well-funded, and media-intensive form of creationist propaganda (Edis 1999; Edis 2003; Riexinger 2008; Sayın and Kence 1999). There is not much new about the content of the Harun Yahya material: it consists of arguments that have no scientific substance and distortions of science often copied from Christian anti-evolution literature, presented with a conservative Muslim emphasis. The range and production quality of this material, however, is impressive. Creationism in the Turkish Ministry of Education resulted mainly in some translations and a few paragraphs expressing opposition to Darwinian evolution in some otherwise unremarkable textbooks. The Yahya operation is much better suited to a postmodern media environment. Large numbers of glossy books, magazines, videos, websites, public events, and television interviews make Yahya's simple, intuitively appealing creationism available to a large public. None of this material is marked out as being religious literature of interest only to a conservative Muslim subculture; from its presentation style to its use of everyday language, Harun Yahya material is designed to be marketed to ordinary, modern Muslims who need not be attracted to strictly observant varieties of Islam. Furthermore, Yahya material is artificially cheap and is often distributed free of cost. Clearly the Harun Yahya enterprise has considerable financial backing, though the source of these funds is not entirely clear.

Turkish scientists have tried to counter such popular creationism, but in the public arena, the creationists hold the upper hand. One reason for the weakness of the scientific position is that Turkish scientists not been able to present an organized response, in part due to other conflicts with the government due to neoliberal policies that would further weaken the position of basic science. In addition, there is also some opposition to evolution within Turkish academia, especially in newly established provincial universities. Even some biologists can go in search of an "alternative biology" more similar to intelligent design than Darwinian evolution (e.g., Yılmaz and Uzuno lu 1995). Moreover, scientists, especially in the more prestigious universities, represent a very westernized population. They have been most comfortable phrasing their opposition to creationism in the idiom of defending the secular nature of the Turkish state (Sayın and Kence 1999). Since republican secularism has been discredited in popular politics, this has been a strategic blunder.

Islamist rule may also have affected the structure of support for science in the Turkish state. In March of 2009, *Bilim ve Teknik*, the popular science and technology magazine published by the Scientific and Technological Research Council of Turkey, was supposed to have been released with a cover story about the two hundredth birthday of Darwin. A political appointee in upper management, an engineering Ph.D., intervened to change the cover story and delete the Darwinian material (Abbott 2009). This led to another round of the creation-evolution wars in the popular press. Religious columnists charged "Darwinists" and "materialists" with being the real censors, disallowing alternative scientific views favorable to creation from enjoying a proper hearing. Secularist writers interpreted the event as evidence of growing Islamist entrenchment in scientific institutions.

Building on its success in Turkey, the Harun Yahya brand of creationism has now gone global. Today, Yahya material is available in languages spoken by Muslim populations all over the world. Yahya books are prominently displayed in Islamic bookstores in London, appear in schools in Pakistan, and are promoted by speaking tours in Indonesia. As a publicity stunt, Yahya's publisher mailed copies of a volume of a typically lavishly produced encyclopedia called the *Atlas of Creation* to scientists and educators in Europe and North America, drawing media attention outside of Islamic circles (Yahya 2007). There is now a global variety of popular Islamic creationism that goes beyond long-standing but usually passive Muslim resistance to Darwinian ideas. Many modern Muslims are attracted to claims that evolution is scientifically false and that science, properly done, supports Quranic notions of special creation.

52.8 Accommodating Evolution

Strict creationism, whether based on outright rejection of science that contradicts conservative readings of the sacred sources or expressed in the form of a Harun Yahya-style pseudoscience, is not the only option available to Muslims. A minority consisting of theologically liberal and secular Muslims, for example, tends to accept evolution due to their general trust of modern education and science as a cognitive authority. Such acceptance of evolution need not imply more than a superficial knowledge either of biology or of the religious worries about evolution articulated by more conservative Muslims. Nevertheless, there is a constituency for efforts to interpret Islam in a way that is compatible with at least some minimal form of evolution.

The easiest option for harmonizing evolution and traditional beliefs is to downplay Darwinian explanations of the evolutionary process, affirming common descent while portraying biological evolution as a divinely guided progression toward higher forms of life (Ateş 1991). A particular concern is to interpret the Quran in such a way as to allow for a degree of evolution. Some theologians, for example, read 24:45 in the Quran, speaking of God creating all animals from water, as a statement that life emerged from the oceans, just as the scientific history of life on Earth has it. Verses that describe the special creation of Adam and Eve, however, need more strenuous attempts at reinterpretation. Very few Muslims will countenance the idea that the Quran is anything but the direct and unadulterated word of God. Therefore, while many Muslims think that considerable evolution under divine guidance may be applicable to nonhuman forms of life, devout believers typically consider humanity to be a separate creation.

Evolution can also become more acceptable if similar ideas can be located in a Muslim intellectual tradition. Some Turkish theologians have proposed reviving such ideas under a label of “evolutionary creation theory” (Altaytaş 2001; Bayrakdar 1987). This appears to be partly based on questionable readings of medieval philosophical reflections on the ancient Greek concept of the great chain of being. Still, in a cultural climate that privileges Islamic authenticity, such historical connections, even if forced, may help make guided evolution a more attractive view. In any case, efforts to compromise between Darwinian evolution and creationism are common. If the religious experimentation in the Muslim world today should lead to a liberalizing trend that can appeal to a broader base than a westernized elite, guided evolution will become an even more popular option.

Many influential Muslim intellectuals also avoid naive Quranic literalism and strict creationism while also expressing skepticism about the Darwinian, naturalistic form of evolution that is the established position in natural science. Some internationally known scholars defend such views. For example, Seyyed Hossein Nasr and Osman Bakar are well known for their outline and defense of a specifically Islamic philosophy of science. Both Bakar and Nasr allow for limited biological changes over time but deny that purely natural mechanisms can ever account for the creativity seen in the history of life. Like popular creationists, they describe evolutionary biology as a manifestation of materialist philosophy rather than a real science with a true empirical foundation. They go further, however, contrasting a Darwinian view of life with a God-centered perception of nature that hearkens back to classical Islamic conceptions of knowledge and creation. They aspire to restore the Islamic religious sciences to a position of preeminence and to have revelation provide the framework for all knowledge claims, including investigations of the natural world (Bakar 1987, 1999; Nasr 1989).

Proposals to "Islamize science" or otherwise reconstruct modern knowledge in a more Islamic fashion attract much attention in Muslim academic and intellectual circles (AbuSulayman 1989). Bakar and Nasr's views are similar, and they continue to resonate among Muslim thinkers concerned about science and Islam. In scientifically advanced countries, there is very little opposition to evolution in the academic and mainstream intellectual environments, and even the more sophisticated varieties of anti-Darwinian views tend to be muted. In contrast, the Muslim intellectual environment is much more hospitable to ideas hostile to Darwinian evolution. The view that the functional complexity exhibited by life must be due to intelligent design remains deeply embedded in Muslim intellectual culture (Edis 2004).

Therefore, it is not surprising that intelligent design, the latest version of anti-evolutionary thought developed in the United States, has attracted attention from Muslims inclined to be suspicious of evolution. In Turkey, where the public controversy over evolution has been most intense, the major books defending intelligent design have been translated and have been favorably reviewed in the Islamic press (Akyol 2005). The intelligent design literature sets scripture aside and concentrates on claiming that mindless processes such as variation and selection cannot create the information-rich structures seen in biology (Meyer 2009). This approach validates intuitions about divine design in the world common to all Abrahamic religions, including Islam.

Though Muslims have a wide variety of views on creation and evolution, the views of even politically liberal and modernist Muslims tend to gravitate toward explicit divine design. Opinion polls in Muslim countries show strong public sentiment against evolution (Hameed 2008; Miller et al. 2006). And even the non-negligible minority acceptance of evolution in such polls does not necessarily signify agreement with a naturalistic conception of evolution. Muslims who agree with common descent very often hold non-Darwinian views of evolution; it is, at present, impossible to use survey data to differentiate between acceptance of explicitly guided or progressive views of evolution and evolution as understood in mainstream science.

52.9 Evolution Education in the Middle East

Evolution becomes controversial especially in the context of education. Therefore, educational policy concerning evolution is a good indicator of official standpoints and their conflicts and alignments with popular social and political views concerning evolution. Given the wide variety of political contexts in which Middle Eastern science education policies take shape, a diverse array of outcomes can be expected. Examining evolution education provides an opportunity to see how some more general themes about Muslim responses to modern science, such as unease with apparently materialist aspects of science, play out in varying local circumstances.

Together with Turkey, the secondary biology curricula of Lebanon, Egypt, Iran, Saudi Arabia, and Israel have been relatively well investigated. Curricular studies, when combined with surveys indicating views on creation and evolution, give good snapshots of responses to controversial aspects of science at the level of students and educators. More detailed research on local histories is needed to reveal linkages to the broader ongoing debates among Muslims concerning science and religion.

Evolution education in Turkey is marked by changes imposed by different governments since the military coup of 1980, tending toward a more culturally conservative point of stability with the moderate Islamist government in power since 2002. The prominent presence of creationism for decades has clearly affected students and has led to a low level of acceptance of evolution among surveyed undergraduates (Peker et al. 2010). Research also suggests that state education policies have an important effect on the acceptance of evolution in Turkey. For example, a survey has shown that recently trained younger teachers reject evolution significantly more frequently than their older colleagues (Somel et al. 2007). The teachers' views then naturally affect their students. Turkey is a case study exhibiting a very successful anti-evolutionary movement that has found state support as well as a popular base, affecting both public opinion and educational policies (Yalçınoğlu 2009).

The teaching of evolution is treated differently in Egypt and Lebanon: while the theory of evolution is included as one complete unit in the Egyptian secondary level biology curriculum, it was eliminated from the official Lebanese curriculum because of pressures from religious authorities. However, many Lebanese students are still exposed to at least some ideas and concepts associated with the theory of evolution. Many schools in Lebanon implement international curricula such as the International Baccalaureate, the French Baccalaureate, and a variety of American curricula; many Lebanese schools adopt American or French textbooks. The secondary level Egyptian biology textbook required in all public and local private schools includes a unit entitled "Change in living organisms (evolution)" that is taught in Grade 10. As presented in the required textbook published by the Egyptian Ministry of Education (Duwaider et al. 2005–2006), the learning outcomes of the unit expect students to be able to define evolution and "improvement," differentiate evolution from "improvement," explain and critique Lamarck's theory, explain and critique Darwin's theory, explain the modern evolutionary synthesis, define the concept of hereditary balance, explain variability, define and give examples of natural selection, list different types of evidence in support of the theory of evolution, and understand that science is tentative. A close reading of the unit shows that the authors seem neutral – they present content matter and evidence in support of evolution without taking sides. The authors suggest, in the introduction to the unit on evolution, that there have always been different explanations of variability in living things and the appearance of life. They go on to explain the differences between special creation and evolution and state that the theory of evolution is accepted by most biologists, who use evolution to explain a wide range of biological phenomena.

Other Middle Eastern countries show considerable variation. Burton (2010, 2011) investigated the extent to which evolution is emphasized in the science curricula of Iran, Saudi Arabia, and Israel. Burton (2011) found that in Iran "science is not described as simply an outgrowth of Islam or subject to preconceived doctrines of any religion – rather it is affirmed as a separate valid field of knowledge, and one crucial to individual and social welfare" (p. 27). Consequently, according to Burton, the coverage of evolution does not seem to be a controversial topic, resulting in a thorough coverage of the topic at different grade levels. For example, in grade five, students are introduced to the history of the earth and life. This history is based on the work of geologists and other scientists with an emphasis on evidence in support of evolution. The same thing happens at the grade 8 and grade 12 levels where students are exposed to a thorough treatment of evolution and an assertion that almost all modern biologists have accepted Darwin's theory. The only topic that does not receive complete coverage in the Iranian textbooks is the most religiously controversial topic, human evolution.

In contrast to Iran, the science curriculum of Saudi Arabia asserts that science education is grounded in an Islamic view of the universe, humanity, and life and in a strong belief in the harmony between Islam and science (Burton 2011). As a result of the centrality of Islam in education, the Saudi science curriculum and textbooks provide ample evidence from the Quran in support of creation and emphasize the necessity of rejecting the theory of evolution because of its blasphemous and fraudulent nature (Burton 2010).

According to Burton (2010), the situation regarding the teaching of evolution in Israel seems to be in-between Iran and Saudi Arabia. While the publicly supported Israeli religious and secular schools share the same biology curriculum, religious schools are allowed to use educational materials produced by religious authorities that include references to creation, the Creator, and the special status of humans who are created in the image of God. The emphasis on creation in publicly supported religious schools appears to persist even after they study biology at the secondary school level.

Several studies have been conducted in Lebanon and Egypt to investigate students', teachers', and university faculty members' positions regarding evolution. In Lebanon, the positions of Muslims (Sunni, Shiite, and Druze) and Christians were investigated, while in Egypt Muslims (only Sunnis) and Christians were involved in the studies.

Dagher and BouJaoude (1997, 2005) explored how a number of biology majors attending a university in Beirut, Lebanon, accommodated the concept of evolution with their existing religious beliefs. Sixty-two university students enrolled in a required senior biology seminar responded to open-ended questions that addressed (a) their understanding of evolutionary theory, (b) their perception of conflict between this evolutionary science and religion, and (c) whether the concept of

Table 52.1 Students' personal positions toward the theory of evolution represented in relation to their religious affiliation

Position	Christian		Muslim		Total/position	
For evolution	82 %	(n = 14)	35 %	(n = 16)	48 %	(n = 30)
Against evolution	0 %	(n = 0)	47 %	(n = 21)	34 %	(n = 21)
Compromise	6 %	(n = 1)	18 %	(n = 8)	15 %	(n = 9)
Neutral	12 %	(n = 2)	0 %	(n = 0)	3 %	(n = 2)
Total/religion	100 %	(n = 17)	100 %	(n = 45)	100 %	(n = 62)

evolution clashed with their beliefs. Based on their responses, 15 students were selected for an in-depth exploration of their written responses. Students' answers clustered under one of four main positions: for evolution, against evolution, compromise, and neutral. As indicated in Table 52.1 above, more Christian than Muslim students were supportive of evolutionary ideas.

BouJaoude and Kamel (2009) found that Muslim and Christian secondary school students in Egypt and Lebanon had inadequate understandings of the nature of theories and of the scientific bases of evolution. Moreover, they found that there were significant differences between Lebanese Christian and Muslim students regarding their perceptions of the relationship between science and religion, with Muslims being in general more influenced by their religious beliefs than Christians. Also, while more Muslim than Christian Lebanese students rejected evolutionary science, these differences were not as pronounced in Egypt where Muslim and Christian students differed on only a few items on a survey that evaluated their conceptions of evolution.

BouJaoude and colleagues (2011b) investigated distinctions among the diversity of religious traditions represented by Lebanese and Egyptian Muslim high school students regarding their understanding and acceptance of biological evolution and how they relate the science to their religious beliefs. The researchers explored secondary students' conceptions of evolution among members of three Muslim sects – Sunni, Shiite, and Druze – in two cultural contexts, one in which the overwhelming majority of the population is Muslim (Egypt) and another in which there is a sizable Christian community (Lebanon). Data were collected via surveys that examined students' scientific and religious understandings of evolution among 162 Egyptian students (all Sunni Muslims; 63 % females and 37 % males) and 629 Lebanese students (38.5 % Sunni, 38 % Shiite, and 23.5 % Druze; 49 % females and 51 % males). Additional data were collected via semi-structured interviews with 30 Lebanese students to allow triangulation of data for accuracy and authenticity. Results indicate that many Egyptian and Lebanese Muslim students have misconceptions about evolution and the nature of science, which often lead to rejection of evolution. Also, Lebanese Sunni and Shiite students and Egyptian Sunni students tend to exhibit high levels of religiosity, and these students report that their religious beliefs influence their positions regarding evolution. Finally, Sunni and Shiite Lebanese students have religious beliefs, conceptions of evolution, and positions regarding evolution similar to those of Sunni Egyptian students.

BouJaoude and colleagues (2011a) investigated biology professors' and teachers' positions regarding biological evolution and evolution education in Lebanon.

Table 52.2 University professors' positions regarding evolution categorized by religious affiliation

	Muslim					
	Shiite	Sunni	Druze	Christian	Agnostic	Total
Accept	1			2	1	4
Selectively accept		2	1			3

Table 52.3 Teachers' positions regarding evolution categorized by religious affiliation

	Muslim				
	Shiite	Sunni	Druze	Christian	Total
Accept			5	4	9
Reject	3	1		1	5
Selectively accept	2	1			3
Neutral (noncommitted or confused)		2		1	3

Participants were 20 (13 private and 7 public) secondary school biology teachers (16 females) and seven university biology professors (two females and five males) teaching at a private, American-style university. Data came from 25 to 30 min, semi-structured interviews with the teachers and the professors. As shown in the tables above, university faculty members (Table 52.2) were divided between those who accept (4 out of 7) or who selectively accept (3 out of 7) the theory of evolution with more Muslims being selective in their acceptance. As for teachers (Table 52.3), the positions ranged from acceptance to total rejection with more Muslim teachers rejecting the theory than Christian teachers.

There is considerable variation in science education policies among Muslim countries and populations in the Middle East, reflecting a wide variety of local histories and religious influences on the politics of education. Nonetheless, there are some important commonalities. Those aspects of modern science that have a materialist association, especially biological evolution, meet with opposition at many levels. Therefore, even when evolution is taught in conservative Muslim environments, this usually takes place in a context where a creationist alternative is a prominent implicit presence. Iran is a partial exception, perhaps due to local Shia dominance allowing a degree of intellectual independence from Sunni resistance to evolution and the explicit Iranian state support for developing advanced biotechnological capabilities.

52.10 Separating Science and Religion?

The recent Turkish and Arab experiences with friction between science and religion partly derive from a common history as successor states to the Ottoman Empire, having undergone broadly similar historical experiences with Western colonial powers and facing a similar need to import science and technology from non-Muslim sources. In formulating religious intellectual responses to a perceived materialism in parts of modern science, and in developing highly successful varieties of opposition to evolution, Turkey has perhaps been at the cutting edge, due to proximity to Europe and the history of the Turkish experiment with secularism. But much of what can be said about Turkey applies to the Arab Middle East and beyond. For example, while Islamic creationism has acquired a Turkish flavor of late, this has not reduced its international appeal. Conservative Muslims worldwide, in South Asia as well as the Middle East, denounce materialism, sometimes using the stimulus of Harun Yahya to activate local objections to how modern science has removed divine purpose from its conceptual frameworks (Riexinger 2009).

Indeed, Harun Yahya creationism as an international phenomenon illustrates how, in the age of the Internet, doctrinally conservative Muslims concerned about materialist aspects of modern science rapidly interchange ideas and formulate responses that have global resonance. In some respects, the Harun Yahya corpus shows the marks of its Middle Eastern and specifically Turkish origin, as in its many books and pamphlets devoted to praise of Said Nursi and themes popularized by the Nur movement. And yet, especially the creationist Harun Yahya material, though it originates in Turkish, is immediately translated into English and languages of the Muslim diaspora as well as Muslim-majority countries. It is made available globally through well-designed websites and advertised and popularized throughout the Muslim world.

More serious Muslim thinkers about science and religion also have an international audience. Seyyed Hossein Nasr is not an obscure academic from Iran who now teaches in the United States – his views on achieving an Islamic philosophy of science are known and debated by interested Muslim intellectuals worldwide. Notions such as "Islamizing science" or using the anti-Enlightenment aspects of postmodern philosophy to defend Islamic traditions against science-based critiques (Aydın 2008) are, again, put to use and discussed globally. There are, naturally, local differences of emphasis, and local education policies are affected in various manners depending on diverse political circumstances. But the *intellectual* options available to Muslim thinkers today are everywhere alike. With the rise of a globalized Islam constructing a universal religious identity transcending local variations (Roy 2004), the discussions young Muslims enter into online concerning science and religion also sound similar themes. Indeed, populations that operate in a globalized economy, and most keenly feel the effects of technology on their lives, are the strongest constituency for today's efforts to harmonize modern science and traditional religion. They have the most at stake.

So a broad-brush description of conservative Muslim views of science and religion today should be appropriate. Muslim populations typically are positive toward technology. Though religiously informed criticisms of the uses of technology are not unknown (Sardar 1984), doctrinally conservative Muslim intellectuals – who usually take modern social conditions for granted – almost always support science rhetorically. But many also harbor distrust toward the present conceptual frameworks of science, which appear as "only theories" compared to the compelling facticity of the products of applied science. Therefore, conservative Muslims often find it easy to reject aspects of modern science that appear tainted with materialism or that otherwise challenge traditional beliefs.

Broad-brush descriptions must always overlook local variety and important details. But more important, even if it is true that modern science and popular forms of Islam have significant points of friction, the consequences for science and education are not immediately clear. After all, the United States also exhibits a strong degree of religious conservatism in its population, including a high and steady level of support for creationism. Scientists have plenty of occasions to complain about how Americans are scientifically illiterate, how they see science as a way to collect "facts" like stamps, and how they are enthusiastic about technology but often take an anti-intellectual attitude toward the conceptual frameworks of science. Some scientists even directly blame American religiosity for all this (Coyne 2012). And yet the United States supports world-class scientific and educational enterprises.

But the United States is also different from Muslim lands. In the United States, populist opposition to knowledge-based elites, such as that expressed by Christian creationism, is isolated from the intellectual high culture and has little effect on scientific institutions. The strength of liberal religious options also helps to protect science from religious populism, supporting a conventional wisdom according to which science and religion have separate spheres that do not interfere with one another.

In that case, perhaps a Muslim version of a separate spheres or "nonoverlapping magisteria" doctrine (Gould 1997) could help satisfy both desires for religious authenticity and scientific interests in describing how the natural world works. After all, there is no shortage of Muslim scientists who insist that their scientific commitments, including evolutionary biology, are perfectly compatible with their faith (Guessoum 2011). When Turkish academics publicly defend evolution, they usually express views similar to positions taken by American organizations such as the National Center for Science Education, endorsing liberal theological stances and advocating separate spheres (Aydın 2007). A few internationally known religious intellectuals, such as Abdolkarim Soroush, argue on a religious basis that science should be independent of religion (Soroush 2000).

The separation option is still possible. As the world of Islam continues to change rapidly, a strict separate spheres view may become more prominent in the future. But at present, this option is structurally weak and discredited by its associations with political secularism. In Turkey, defenders of evolution are disorganized and demoralized. And throughout the Muslim world, liberal theologians invite conservative reactions. Soroush, for example, was pressured to leave Iran; he now teaches in the United States.

Moreover, emphasizing the prospects for a separation of science and religion in Islam may lead to a distorted picture of specifically Muslim responses to science. The notion of separate spheres has been a successful device to keep the peace between science and religion in the post-Christian West. It may not be as applicable to a Muslim world where religiously conservative intellectuals are determined that they should not come to live in a post-Muslim environment. An insistence on separate spheres would be an imposition of a Western perspective onto Muslim concerns, when Muslims are trying to achieve a non-Western way of being modern. There is a strong tendency to see the present intellectual distance between science and religion as being a Western solution to a Western problem caused by factors inherent to Christianity (Aydın 2000; Şahin 2001). Very often Muslims gravitate toward the notion that since science and religion must coexist in harmony in an

Islamic context, perhaps as in the supposed golden age of medieval Muslim science (e.g., Al-Hassani 2012), there is no problem here to solve.

So conservative Muslim resistance to materialist conceptual frameworks in science deserves to be taken seriously. It is easy to observe that popular Muslim apologetics typically has very low intellectual quality. Recurrent worries about materialism can also seem odd. After all, Marxism has nearly vanished. There are some readers of Richard Dawkins translations, and among secular philosophers and scientists in Muslim lands, there are no doubt even outright physicalists. But all such materialists have negligible wider social influence. Nonetheless, there is also some real intellectual substance articulated in Muslim concerns about materialism.

The conventional wisdom among Western liberals both accepts and conceals conflicts between robust Abrahamic theisms and the naturalism that has come to characterize modern science. If divine purpose has no explanatory role in physics or biology or neuroscience, it becomes hard to see how to make sense of a claim of divine creation. Western liberals accept this difficulty but usually propose to overcome it by having supernatural belief retreat to a metaphysical realm. Religion handles ultimate meaning and purpose, while science investigates the details of how nature operates. This is an intellectually unstable position, since both religious and scientific thinkers usually have ambitions that cross over into each other's territory (Edis 2006). Moreover, Western liberals have inadvertently ended up giving science primacy over religion, in the sense that when a conflict has appeared, as over creation and evolution, it is always theology that has had to retreat and reinterpret. Many Muslims who are aware of the liberal Christian response to science cannot help but perceive it as a bowdlerization of revealed truths.

Conservative Muslim intellectuals affirm science as a form of worldly learning, but they often insist that science should be anchored in Islam. Inquiry should be free but only as long as it respects the boundaries set by faith. Muhammad Abduh, the Egyptian modernist, praised Islam as a religion of reason, saying Islam "did not impose any conditions on reason other than that of maintaining the faith" (Euben 1999, p. 106). This is a common sentiment, surfacing in legal reasoning as well as intellectual debates (Kamali 1997). To Western liberal eyes, it looks like free inquiry has a very important exception, since core Muslim beliefs are not open to question. But many Muslims would reject that framing of their views. By protecting Islamic beliefs from criticism, they see themselves not as carving out an intellectual exception but as protecting reason itself. Both in intellectual culture and at a popular level, Muslims very often think that some awareness of divine laws is constitutive of rationality itself (Rosen 2002). Critically examining religious beliefs invites doubt. And casting doubt on God or revelation can lead to nothing but irrationality and social disintegration.

So even with the religious experimentation taking place among Muslims today, it remains very uncertain whether Muslim views of science and religion will follow a trajectory toward a separate spheres style of accommodation. It is, for example, possible that Muslim populations will continue to gravitate toward a different equilibrium between supernatural beliefs and modern knowledge, one that emphasizes applied science while downplaying the conceptual frameworks of natural science. Whether this is sustainable will depend very much on future opportunities for technological creativity independent of developments in basic science.

Taner Edis is professor of physics at Truman State University, Kirksville, MO, USA. He was born and educated in Turkey, moving to the United States for graduate studies in 1987. While his background is in theoretical physics, he has also pursued interests in the history and philosophy of science, particularly concerning the conflicts between modern science and supernatural belief systems. His books include *The Ghost in the Universe: God in Light of Modern Science*, *Why Intelligent Design Fails: A Scientific Critique of the New Creationism* coedited with Matt Young, and *Science and Nonbelief.* Most recently, he has concentrated on examining the interactions of science, religion, and pseudoscience in an Islamic context. His book *An Illusion of Harmony: Science and Religion in Islam* and numerous articles, especially on Islamic creationism, contribute to understanding the role of science in modernizing Muslim cultures.

Saouma BouJaoude is professor of science education at the American University of Beirut (AUB). He graduated from the University of Cincinnati, Cincinnati, Ohio, USA in 1988 with a doctorate in Curriculum and Instruction with emphasis on science education. From 1988 to 1993 he was assistant professor of science education at Syracuse University, Syracuse, New York, USA. In 1993 he joined the American University of Beirut where he served as director of the Science and Math Education Center (SMEC) (1994–2003), as Chair of the Department of Education (2003–2009), and since 2009 as director of SMEC and the Center of Teaching and Learning. He has published in international journals such as the *Journal of Research in Science Teaching*, *Science Education*, *International Journal of Science Education, Journal of Science Teacher Education*, *The Science Teacher*, and *School Science Review*, among others. In addition, he has written chapters in edited books in English and Arabic and has been an active presenter at local, regional, and international education and science education conferences. He is member of several international science education research associations and has served as the International Coordinator and a member of the Executive Board of National Association for Research in Science Teaching. Presently he serves on the editorial boards a number of science education journals and is a reviewer for others. In 2009 he was appointed as a member of the Executive Committee of Supreme Education Council of the State Qatar.

Chapter 53
Indian Experiences with Science: Considerations for History, Philosophy, and Science Education

Sundar Sarukkai

The topic of science and science education in the Indian context encompasses many themes. This chapter will mainly focus on how the disciplines of the history and philosophy of science (HPS) can contribute to the debates in science education (SE) with specific reference to the Indian context. The extensive literature on the role of HPS in science education is comparatively recent. As Turner and Sullenger (1999, p. 10) point out, it is only in the nineties that there was a sudden proliferation of publications in this field. However, very few, if any, deal with the specific relationship between HPS and SE in the Indian context.

Why should this extension to the Indian context be of any interest to the community of science educators? Here are two answers: the first is that in the case of SE in India, it is primarily HPS which can help question the enduring claims that science is a Western enterprise and one that is unique to the West. By doing so, we bring in other cultural practices within the boundaries of science thereby extending the ownership of the essential characteristics of science to other non-Western cultures. Secondly, the Indian experience with science exhibits many stark differences from the European experience, and thus the lessons from a HPS that is responsive to these experiences will potentially offer new contributions to global SE. This chapter will illustrate how both these modes of intervention are possible. Invoking HPS is a powerful way to "localize" science and give a sense of ownership to scientists and science teachers. But in doing this, the HPS community itself is challenged for HPS traditionally has ignored the historical and philosophical contributions from the non-West.

The fundamental questions which frame the discussion here are the following: Does history and philosophy of science matter to science education? Do insights from Indian experiences with science matter to this debate?

There is a larger context in which these questions should be placed and that is the aims of science education. Does science education have the same aims as

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_53,

education? This cannot be – or at least is not seen to be – given that the larger aims of education include moral education and cultivation of human sensibilities. Science education seems to have become completely about the subject matter of science alone. It has been reduced to the teaching of the content of the various disciplines of science. Even history and philosophy of science are banished from science teaching. In this context, the real question that should be asked is this: Should science education be a handmaiden to the aims of science or should it have an autonomous agenda of its own, one that is more in tune with the aims of education in general?

This chapter makes the following argument. Even if restricted to the subject matter of science, it is possible to make the following observations. The decision of what subject matter to teach, the way to teach it, the background information on that content, and the many decisions of inclusion and exclusion of the content, and evaluation – all of these are based on certain presuppositions. There are hidden assumptions about the nature of science as well as the "invisible hand" of specific histories and philosophies of science in every science lesson.

To claim that HPS is not relevant in the content of science teaching is to ignore these hidden presuppositions. Thus, a call to include HPS in SE is only a call to make these hidden assumptions visible. Once this is done, the immediate relevance of the Indian (and other cultural) experiences to science teaching becomes obvious.

53.1 The Role of History and Philosophy of Science in Science Education

There have been many writers who have suggested the use of history and philosophy of science in science education.[1] This topic is central to science education for it confronts the basic questions of education: What does one teach in science and how does one teach science? It has also led to the question of whether nature of science (NOS) is relevant for the teaching of science, a theme which will be pursued later in this chapter. However, the impact of HPS on science education has been quite limited. In the Indian case, it is even more so. The reasons underlying this indifference illustrate the unique challenges of science and science education in India. Some of these reasons have to do with the very understanding of what constitutes science, the task of education in general and that of science education in particular, the complex histories of the idea of science, and its relationship to tradition and State. This and the following sections will address some of these issues with the fundamental objective being the following: Can the Indian experience with science from ancient times to the present add new insights and new themes to the debate on the role of HPS in science education?

Matthews (1989) argues for the importance of HPS in science teaching (ST). However, he also notes an enduring problem in establishing the relevance of HPS

---

[1] See Duschl (1985, 1994), Hodson (1988, 1991), and Matthews (1989, 2004).

for ST, namely, the "failure of science teaching to disturb ingrained beliefs" (ibid., p. 5). As he points out, it seems to be the case that students study science for their exams but use different belief systems for "everyday life." This is a "problem" that is very much a part of Indian school system. Moreover, the tendency to bifurcate the domain in which one practices science and the other in which practices contradictory to science are prevalent is not limited to students alone. In India, this is an integral part of scientific institutions also.

As far as the impact of philosophy of science on SE is concerned, it is arguably Kuhn who has had the greatest influence. Matthews (2004) discusses how Kuhn was ignored early on after the publication of his book, *Structure of Scientific Revolutions*, but in the post-seventies, the science educationists caught on to Kuhnian ideas. However, given the skewed understanding of the nature and practice of science, these ideas were most successfully used in the program of constructivism. The SE community seems to exhibit this constant tension of drawing on HPS but at the same time not being sufficiently trained to draw on it properly (ibid., p. 112). So it seems as if the community of science teachers either ignores HPS or jumps on to certain trends such as constructivism and relativism. One might think that perhaps history of science is better accepted as compared to philosophy of science. But, as Rodríguez and Niaz (2004) point out, science textbooks continue to ignore lessons from history of science. By analyzing the description of atomic structure in general physics textbooks published in the USA, they show how science textbooks continue to ignore the rich narratives of experiments available in the history of science on this topic.

Two of the more successful themes drawn from HPS relate to the NOS debate and a richer description of rationality, and their relationship to both science and education.[2] Although certain notions of rationality have come under attack, nevertheless there has been a sustained belief in the rationality of science as well as its importance in the idea of education. Siegel (1989) points out that critical thinking is the essence of education and through the idea of rationality he brings HPS and science education closer to each other. He considers critical thinking as the "educational correlate" of rationality (ibid., p. 21) and as an "educational ideal" (p. 27). Furthermore, he identifies "reason" as the common element of rationality: "a critical thinker is one who appreciates and accepts the importance and convicting force of reasons" (ibid., p. 21). The invocation of reason and rationality as important themes in the relationship between HPS and SE will be useful when we consider Indian philosophical traditions later on in the chapter.

The second theme – the debates on NOS – has been largely catalyzed by work in HPS, but there remains an open question as to whether NOS is relevant at all to science education. Turner and Sullenger (1999) point out how the divergent descriptions of NOS within science studies has had a negative impact in that it has led teachers to draw on this theme in a fragmented manner. There are many reasons why HPS does not make an appreciable dent among science teachers: for example, teachers resist them because they take away time from core teaching of science subjects (p. 13), science teachers themselves have little knowledge of or training in

---

[2] See Carey et al. (1989), Jenkins (1996), and Machamer (1988).

HPS, and because "teachers share many scientists' disdain for what they regard as soft add-ons" (p. 13). Science and technology studies (STS) are also not accepted by the community of science teachers because of the belief that discussions on science (through NOS) often end up as discussions on "law, economics, religion and power politics" (p. 16). This has led to teachers in many countries rejecting the role of HPS in ST. As these authors note, "Educational theory requires consideration of at least three factors: curricular content, instructional methods and approaches, and learning theory" (p. 17). They believe that HPS and STS have "emphasized" the first two but have ignored the third. In India too, there is continued indifference to HPS among science educationists. Although the National Curriculum Framework (2005) engages with the theme of nature of science and science education, there is little progress on the ground.

What is most surprising is that in the extensive global literature in this area, there is little that draws on other scientific traditions in order to pose the question about the nature of science. Did the Arabs, Indians, and Chinese do science the same way as the Europeans did? Did the Europeans have a unified idea of science at any time? Do the practices and notions of science in Asian and Arabic civilizations matter to the debate on NOS and science education? Does the HPS formulation of NOS continue to propagate the belief that "modern" science arose only in Europe since it draws only on a "Western" history and philosophy of science?

These questions become more urgent given some worthwhile historical challenges to the traditional view of science. The argument for the multicultural origins of science, a view that is still at the periphery of the mainstream history of science, necessitates changes that should be introduced in the nature of science debate. As far as philosophy of science is concerned, philosophical insights drawn from a consideration of Indian science and technology can illustrate how differing views of science and scientific methodology are articulated in other cultures.

Will science education get enriched by drawing on these diverse HPS traditions? Given the unique characteristics of the Indian society as well as its experiences with the notion of science, it should not surprise us to discover that a dialogue between HPS (one that is sensitive to these experiences) and SE leads to a new set of issues, some of which will be discussed below. If there is one particular issue that is at the heart of this dialogue, it is one on the definition of science. In a fundamental sense, unless we come to an agreement as to what constitutes science, it is not really possible to broaden the discussion on SE. It is precisely this question of demarcating science that is at the core of debates in non-Western cultures. Did these cultures "possess" science and technology before "modern science?" If so, how should these traditions be factored in SE? The sections that follow offer challenges to traditional views on science that locate it as part of a European tradition, following which their relevance for the NOS debates in SE is discussed. These arguments are placed within the larger context of defining science and the challenges of taking ownership of science, both of which have implications for science curriculum and pedagogy. Finally, the last two sections give an indication of some specific ways of "using" insights from Indian philosophical practices for SE.

53.2 The "Invisible Hand" of the Histories and Philosophies of Science in Science Texts

The most important rationale for taking HPS seriously in SE is that there is already a hidden domain of HPS in SE. There are many levels of the unarticulated presence of HPS in science texts. First of all, the content in a science text is already a product of a judgment of what constitutes science. For example, a textbook in physics presents certain subject matter as if it belongs unquestionably to the discipline of physics. On what basis is this judgment made? What content in physics, chemistry, and biology, for example, is chosen and on what basis? Why are certain subjects chosen as illustrations of science? A quick answer to these questions is that the scientific community decides what is science, what comes under physics, and so on. But this is to make science education secondary to the aims and ideology of the scientific community. If this is the case, then teachers function as mere conduits in a larger project of international science.

Consider a text in physics which contains Newton's laws of motion. Typically, there will be no historical or philosophical considerations which lead to the statement of these laws. Science texts, even today, present these laws as if they are ahistorical and appeared to Newton suddenly. There is no mention of a long history of motion, including interesting theories from Indian philosophies. Concepts that are used in the text including seminal ones such as mass, force, and energy, usually appear without any historical description. The fact that these concepts appear in other non-Western cultures is forgotten. In a science text, the choice of the content, the way the content is presented and ordered, and the choice of concepts and that of their definitions are all based on particular views of science, which themselves reflect particular histories and philosophies of science. For example, one such implicit assumption is that non-Western science is not really science.

Consider the following presuppositions that are at the core of science textbooks. Firstly, there is a standard history of science that is implicitly accepted. This history begins normally with Copernicus and goes on to Galileo and then Newton, with some mention of Aristotle and some "Greeks" thrown in. This history influences – greatly – the choice of the content of the text. And even within this story, there are many acts of omissions based on what story of science is chosen to be presented in the text. Similarly, the break between science and religion is an important part of this narrative. This is linked to the standard narrative that relates science to Western Enlightenment. The idea of the conflict with religion is often a selective rendering of a much more complex history of modern science's relationship with religion, as are the specific history of concepts that are presented in these texts.

There are larger themes which are also presupposed in these choices. For example, the philosophical assumptions of Platonism are an integral part of mathematics teaching. This worldview intrudes into the construction of the text in as many ways, including the structure of the problems, modes of evaluation, and the way mathematics is introduced. Mathematics is developed in a completely different manner in Indian and Chinese mathematics, but this material will not be found in textbooks. For example, the ways by which irrational numbers and negative numbers are conceived in Indian and Chinese mathematics illustrates alternate approaches to Platonism.[3]

Another invisible theme is the belief that European rationality characterizes science. There are many ways by which this idea is encoded into textbooks. One obvious manifestation of it lies in the almost complete absence of the mention of any non-western historical figure in the list of scientists and mathematicians mentioned in these texts. Along with this absence, there is an explicit emphasis on the figures of Western Enlightenment.

Yet another major theme is the belief that scientific content is universal and that science texts need not take into account the locale specificity of the students or the teacher. This also allows the propagation of these Eurocentric myths without second thought; this has led to generations of students in non-Western societies to believe that their cultures have had no contribution to the science of the modern world.

One may rationalize these choices by pointing to constraints of space in a textbook, access to material, and so on. However, it is the case that these constraints also influence what is taught *as* science. These constraints are also product in a textbook of specific choices which often reflect hidden presuppositions about science. All these choices reflect specific beliefs based on particular histories and philosophies of science and thus can be challenged on many counts as listed below.

First is the choice related to the material that is seen to constitute science. Should one choose to mention the rich domain of Indian metallurgy and technology in ancient times as well as later Chinese technologies? The extensive material on Indian mathematics, including Kerala mathematics, the complex and rich classification of botanical information in various indigenous traditions, and the vibrant practices of chemistry which rival similar practices in Europe of that time are all examples of science that are potential subject matter for science texts.[4] Anybody who is exposed to the multicultural histories of science will be able to appreciate the claim that the origins of science in Europe are indebted to the transmission of knowledge from different traditions including the Chinese, Arabic, Indian, and the Greek. To not integrate these histories into the content of science is to take a particular philosophical position about science and its subject matter.

Next, consider the history of fundamental concepts that are taught in texts. There is almost no recognition or acknowledgement that some of these concepts like mass, inertia, motion, energy, force, and causality have different formulations in non-Western cultures. Textbooks still talk of ideas like mass and force as if they are apples that dropped on Newton and other scientists from the tree of knowledge.

Moreover, the prevailing background of all discourse on science is based on some naive ideas of European rationality. Even today, scientists (and many science educationists) continue to believe that there is something special to this rationality and that alternative rationalities are not possible. Under tremendous pressure from extreme relativism, they might now acknowledge that perhaps other cultures

---

[3] See Dani (2010) and Mumford (2010).

[4] Details are given in the next sections that follow.

possessed some rationality but none of this has been factored into the basic texts in science. But, if European rationality is privileged, then the full story must also be noted. There is another use of rationality that should be taken into account in these claims: the notion of rationality was central to the European intellectual project as a way to distinguish European cultures from other cultures. Their claim to rationality was fundamental to the colonial project for through this category they could articulate their claim to being superior to other colonized cultures. In a powerful metaphor, they constructed themselves – because of this rationality – as adults and the colonized as children who needed the guidance of adults. So when the idea of rationality is repeatedly invoked, these two problematical characteristics are forgotten: one is the hegemonic work which rationality did and does, and the other is the existence of other equally important structures of rationality in other cultures. The examples of Indian logic and its mathematics are enough to indicate these possibilities; they will be discussed in greater detail in this chapter.

So the fundamental question is this: On what "rational" basis do science educationists make a choice when confronted with these new global histories and philosophies of science? If we look at how the Indian State confronted this issue, one can see how the ideology of universal, European science influenced and continues to influence science education in India.

53.3 Science and the State

History of education has as much influence on SE as does history of science. In India, students are taught science in a culture in which science is highly valorized. They tend to believe that they learn science because it is associated with virtues such as truth, knowledge, rationality, and power, virtues which are reinforced in the curricula. These virtues are those that are transmitted to the students by different agencies including the government, public space, peer groups, teachers, and parents. The strengths as well as the weaknesses inherent in SE are catalyzed by these different interest groups. Science educationists may find it useful to understand the context in which students are being taught science as well as the context of the educational methods to which they are subjected. In the Indian case, it is therefore necessary to consider the historical and ideological trajectory that sets into place educational practices in science. The most important influence on the institution of education is the colonial one, later followed by the independent nation.

The State (both pre and postindependence) was the primary patron of science and education. Sangwan (1990) analyzes some of the complexities in understanding the changing views on education in British India. He identifies three phases: in the first phase, the rulers did not change the system in India; in the second phase, they actually supported "oriental literature and science"; and in the third phase, they provided stronger support for science education. It is important to note that there was also a growing support among Indians for the Anglicization of education. As Sangwan notes, a group of influential Indians in Bengal "exhibited its revulsion" when the British supported Indian educational practices (particularly Sanskritic education) at the expense of "modern" education. But the British continued their support of "oriental education" in spite of protest from influential members of Indian society. Interestingly, the third phase, when European education was established, was also based on the belief that "modern" education would train Indians to support the activities and interests of the company rule, for example, to fulfill the demand for engineers and training of people to run the railways. Moreover, following the ideological interests of Macaulay, there was an overemphasis on teaching European literature and science, at the expense of indigenous science and knowledge systems. This was not conducive to science education since, as Sangwan notes, "what made things worse was their attempt to propagate English education rather than science education in India" (ibid., p. 89).[5]

There were also important changes introduced in the colonial era in the field of education. These changes, according to Kumar (2009), continue to influence educational practices even today. One such was the emphasis on textbooks and the introduction of a particular kind of textbook culture in Indian education. Kumar points out how textbook dominates curriculum and traces this attitude to the British colonial administration who saw education as a way to train Indians in "European attitudes" as well as "imparting to them the skills required for working in colonial administration." The insistence on textbook replaced traditional forms of education in which the teacher had freedom to choose what to teach. Kumar points out that in this colonial system, teachers also had to function as administrators. There were also punitive measures on teachers. Similar attitudes towards examinations and evaluative practices which were introduced by the British continue even today. For many educationists, these practices have been the bane of education in India today, particularly in science education.[6]

Postindependence, there was a calculated emphasis on science education. In so doing, the State was following colonial and modernist beliefs that science and rationality were external to Indian culture and that Indian society was characterized by irrationality and superstition.[7] Science education was to be the cure for this cultural "disease." The belief that science would be the vehicle for development meant that education in India would be skewed towards science education. Nothing defines the Indian State's engagement with science as well as the Constitution of India. At the dawn of the Indian independence, the Constitution was framed with the help of some of the most important intellectuals and freedom fighters at that time. Like most other Constitutions, the Indian Constitution is perhaps the most important public document in modern India. But unlike other Constitutions, this one has an intriguing clause listed in the constitutional duties of all citizens. One of

---

[5] See also Kumar (1980).

[6] See Kumar (1988). See also Dharampal (1983) for a brief discussion on education practices in eighteenth-century India.

[7] See Arnold (2000) for a discussion on the relation between modernity and science in India. Prakash (1996) discusses the support of the Indian elite to science as an exemplar of modernity. See also Habib (2004) for Islamic science in nineteenth-century India.

the constitutional duties of citizens is to cultivate scientific temper. Article 51A(h) of the Constitution of India states the following under Fundamental Duty: "To develop the scientific temper, humanism and the spirit of inquiry and reform."

To understand science education in India it is important to recognize the factors which made the authors of the Constitution to introduce this clause in the Constitution. First of all, this constitutional duty to "develop the scientific temper" reflects a fundamental aim of a new India, which was to reform its traditional societies and practices. Science becomes a way to reform a society which was seemingly suffused with superstition and irrational practices. Science, along with a particular view of the Western civilization, would liberate Indians from their past. Nehru's observation, as the first Prime Minister of free India, that industries would be the temples of the new India has often been quoted to point to a fundamental shift towards science and technology as the harbinger of a new society, one in which science would be used to better the economic state of the country. The government's support for the sciences immediately postindependence led to a large number of scientific institutes under the support of the government, including the atomic energy program under Homi Bhabha.

Since education was also primarily under the government, this view of science, as an agent of social change and development, as well as a reflection of a superior intellectual virtue special to the West, began to get propagated in schools and colleges. Even in the public sphere, science continues to be projected in these terms thereby adding to the social value of doing science. Since science was viewed as the agent to get rid of traditional beliefs, this led to the piquant situation of using science to erase any vestiges of ancient and medieval Indian intellectual traditions in the educational system, particularly in SE. This erasure is reflected in education at all levels in India leading to a chasm between postindependent India and precolonial India which remains to this day unbridged.

Alongside these ideological connotations of science, some influential Indian politicians too believed that national development meant promotion of science. The early models of development were all technology driven: thus the big dam projects, atomic energy program, the agricultural "revolution" through the use of technology, and so on. All these ideas of development clashed with traditional practices, particularly in the fields of agriculture and medicine. However, the State's commitment to a particular mode of development, one in tune with the rest of the developed world, meant a concomitant support to science and science education.

In spite of the early fervor of the leaders of the new nation, the public reception of science has been quite ambiguous. The claims that science education will eradicate social inequalities, remove caste system, and in general make people "rational" have remained just that. In fact, the greatest challenge to scientific temper in India comes from many of the scientists themselves, who while being good scientists are also committed religious believers. Such a dichotomy is well exemplified by the problematic example of offering prayers to machines.[8] Embodying the spirit of

---

[8] See Sarukkai (2008).

contradiction which seems to characterize an Indian way of thinking, scientists too easily wear contradictory roles of being a scientist as well as a religious person.[9] Many of them consult astrologers and visit religious institutions for family functions without that reducing their competence and standing as a scientist in their disciplines.

In the Indian scenario, the public space in which science gets articulated is a complex one. Interestingly, this public space also has religious elements within it. The relationship between religion and science in India is a complex one and historically challenges some standard history of science accounts of this relationship.[10] In the long history of science in India, it would be very difficult to actually find any cogently argued opposition to religion in doing and practicing science. Postindependent India, this opposition has been articulated by the Left as well as people science movements, but very often, this has been done with a certain amount of modernist understanding of science where science is an exemplar of rationality and religion that of superstition. Concomitant to this is the belief that ordinary citizens of the country were immersed in such superstition and it was the task of science (supported by the State) to "liberate" these citizens. Unfortunately, the scientists themselves were not up to the task demanded by these groups.

The popularity of science and technology education in India has largely been based on the easier availability of jobs from such education. However, the fact that science institutions, and science education in general, in India are excessively dependent on English means that there is a lack of democratic access to science education. This problem is compounded given the lack of good translations of science texts into other languages. These and other related factors contribute to the belief that science is not something "Indian"; they might also explain why the larger culture continues to ignore artificial expectations such as scientific temper, why the society does not buy into the story that science and religion have to be contradictory, and why there is an embarrassing lack of innovation in science and technology in India today.

Paradoxically, this is also a time when the government has increased its support to science education in an unprecedented manner, particularly in higher education. But almost all scientists and educationists point to certain well-established pedagogical practices as the bane of science education in the country. Rote learning continues to remain the dominant mode of learning in schools and many times in higher education as well. Critical thinking, including the capacity to critique, to build, and to innovate, is largely ignored in pedagogy, whether in science or other fields.

Ironically, the impact of science education on the larger public seems to be quite divorced from the cultivation of scientific temper. India, arguably more than in any other period postindependence, is in the throes of religious revivalism. There is a perceptible shift towards many traditional modes of learning, traditional practices of medicine, and also of some traditional social norms. Some feel that this is a reaction to the "imposition" of science and a corresponding rise in social problems related to

---

[9] A.K. Ramanujan's essay (1989) is often quoted in this context.

[10] See Kapila (2010).

modernity and technological development. Earlier views of science as liberating society from traditional practices, which gave way to the belief that science would be the harbinger of national development, has now changed to the belief that science is a pathway to jobs in the global market. Science education reflects this confusion at the highest level: What really is the goal of science as a national enterprise? An answer to this question is not under the purview of this chapter but an awareness of this issue is important for future State interventions in science education. With this larger background of science in India, the remaining sections will deal with the relationship between HPS and SE, and through the contours of this debate develop some India-specific themes that could be of interest to the global SE community.

53.4 Science Education and the Definition of Science

One of the problems in the understanding of science in India lies in an enduring cultural belief that modern science is a Western invention. Moreover, a sustained claim from European scholars that Asian cultures did not possess the requisites for being scientific (or equivalently, did not possess the capacity for being rational or theoretical) reinforced the outsider status of science in these societies. It is indeed surprising that scholars ranging from Locke to the German philosophers, Husserl and Gadamer, repeatedly question the availability of rationality and science to Asiatic cultures. This claim also becomes an integral part of the colonial discourse; thus for a few centuries, both within India and outside, there is a well-established tradition of scholarship that not only questions the existence of science in India but also questions the capacity of Indians to practice science.[11] Thus, it was no wonder that some science texts still continue to propagate these beliefs by emphasizing science as a Western "invention" and reinforcing this by primarily citing non-Indians as examples of scientists. One of the greatest challenges for science education in India is to convert the status of science from an outsider status to an insider one. While science teachers might see this issue as being irrelevant to the teaching of the content of science, in fact it is the exact opposite. If students do not take cultural ownership over science and if they do not think that they have a stake in the production of science, then it affects how they learn science and what they do with it. Learning has to have a sense of cultural confidence associated with it. Many scientists in India tend to believe that the lack of pioneering research (as exemplified by the lack of Nobel Prizes in the sciences or Fields Medal for scientists working in India postindependence), even after decades of massive support by the State to science in India, is an illustration of the lack of confidence and not taking ownership of science.

---

[11] See Gadamer (2001), Ganeri (2001) for the early European response to Indian logic; Adas (1989) and Alvares (1991) for the Western view on Indian science and technology; and Halbfass (1988) on the encounter of civilizations.

While there will be disagreements on this prognosis, it is nevertheless the case that science continues to inhabit the space between the inside and the outside in Indian society. This has serious ramifications on science teaching. For example, it is well known that scientists as role models influence young students. Science as a collective enterprise has recognized that creating legends out of scientists is a powerful way of attracting students to the field. Through the stories of these scientists, many popular notions of science, scientific method, and the idea of genius get communicated to the students and the larger public. The creation of the image of science in popular media is an important part of its success as a global enterprise. In this context, what happens to students who find few Indian models of great scientists? What is the lesson that is being communicated when all the scientists they encounter – the ones who have created new disciplines, new theories, and discovered new worlds of science – are predominantly non-Indian? This empirical fact coupled with the enduring hint that non-Western societies do not have an intrinsic capacity for being rational and scientific leads to a crisis of confidence in science learning. The often quoted comment from across all layers of society that a scientist is legitimized when she/he is first recognized in the West has become a cultural truism for other fields also.[12]

As much as research, this ambiguity about science has affected science teaching and learning, and this problem is primarily about the definition of science. Although over the past few decades there have been some seminal works on ancient and medieval Indian science (Adas 1989; Alvares 1991; Dharampal 2000), they are rarely incorporated into science textbooks. Part of the reason is the discomfort in viewing ancient or medieval discoveries and inventions as belonging to science. The problem of defining science is part of the larger theme of the nature of science. In India, this problem has two faces: one is the claim that some "disciplines" like astrology are also science, and the other is the scientificity of certain ancient and medieval practices and traditions. On both these counts, there is much denigration, particularly from the scientific community, and this is reflected in the general absence of any reference to Indian traditions of science within mainstream science.

One response has been to create a category called "indigenous science"; another is the category of "ancient science." Indigenous science has largely been reduced to innovations and modifications to "technologies" of the home and the community. It is largely artisanship and lacks some of the essential characteristics that define science – at least the definitions that constitute "mainstream" science. As innovations, they are largely experimental and technical, and do not exhibit any theoretical inclinations. This very category of "indigenous science" however illustrates an interesting way to appropriate the name of science into activities that have largely been excluded from science. This has also led to significant public movements on alternate technologies based on these indigenous and ancient technologies. However, the absorption of these movements into mainstream science education is still largely absent.

---

[12] A report in 1992 points out how around 80% of scientists in research institutes in India preferred to publish abroad and "hardly published" in India. See http://dspace.rri.res.in/bitstream/2289/3643/15/Chapter%208.pdf

But what really was the status of science and technology in ancient India? Should those practices be called science? Should they be called technology? And does all this matter to the problem of defining science, definitions that are relevant to teaching science? These questions are important for our understanding of science. Most science books begin with narratives of science in which Thales, Democritus, Socrates, Plato, and Aristotle are invoked as the fathers of science. Sometimes, they are even referred to as scientists. The absence of other cultural representatives in this story of science is inimical to the teaching of science, especially in those cultures which are excluded from a stake in the ownership of science and scientific rationality.

This is ironical, especially when we consider that the theoretical foundation of the sciences was integral to the philosophical traditions of the Hindus, Buddhists, and Jains in ancient India. All these traditions were fundamentally empirical in character and focused primarily on the nature of knowledge. Description of logic was an essential part of this analysis, and even logic was not immune to empirical inputs. The rich contribution of the Hindu, Buddhist, and Jaina philosophers illustrates their attempt to give a foundation for what we would call as scientific methodology today.[13] Alongside, there was a flourishing technological world which saw the world's first invention of steel, zinc, and alloys (such as the five-alloy process).[14] Indian mathematics not only gave the foundations of mathematics to the Arabs which then found its way into Europe, but the Kerala mathematicians also described the first modified heliocentric model (like the one proposed by Tycho Brahe) and the first conceptual ideas related to calculus much before they were known in Europe.[15] Another important marker of science was in the Indian medical systems such as Ayurveda, a practice that flourishes even today in India. These were all exemplars of science, but modern science education in India has largely ignored these ideas and practices of earlier science.

The British and European response to the discovery of these traditions was one of skepticism and derision. But confronted with the empirical evidence of these traditions, including a living tradition of the successful medical system called Ayurveda, they took recourse to the argument that such practices in India were primarily artisanal in nature. According to them, what made an approach scientific were the notions of theory and method, which presumably these earlier traditions in Asia did not possess.[16] Thus, these discoveries were seen to be "accidental," empirical, and not a product of a "method." Similar arguments were part of the European response to Indian philosophical systems, particularly the logical tradition that was part of almost all these systems.[17] It was important to deny the capacity for

---

[13] See Sarukkai (2005) for a discussion of how Indian logic shows conceptual similarities with methodologies that we would call as scientific methodology today.

[14] See Adas (1989) and Alvares (1991) for a detailed description of Indian technology.

[15] The text listing some of these results is available now with translation and with a symbolic rewriting of the text. See Sarma (2008).

[16] See Adas (1989) and Alvares (1991).

[17] See Matilal (1985), Mohanty (1992), and Sarukkai (2005) for a discussion on the nature of Indian logic and rationality.

logic to the Indians since rationality, a trait that defined the modern European mind, was a value that was used to hierarchize civilizations. European scholars took the view that Indian civilization did not develop logic and therefore did not have access to rationality.[18]

In understanding the relation between Indian culture and science education, we need to engage with the practice of science in ancient and medieval India.[19] This is not only to set right the asymmetry in invoking the ancient Greek or modern Europe in the context of science but also to begin to look at new features and characteristics of what could be called science. The only way these ideas and arguments can enter science education is through HPS. Adding the story of ancient and medieval scientific practices as part of a longer and multicultural history of science will have an immediate impact on the way students learn science. This approach should be of interest to science teachers in other countries as well. While science educators have discussed the importance and effectiveness of teaching scientific concepts through a historical trajectory, they have in general ignored the possibility of other histories of these concepts drawn from non-Western traditions. Almost all concepts such as mass, matter, energy, cause, effect, substance, chemical, and material are described in great detail in different cultures and are articulated in different ways.[20] When history of science draws only upon one historical narrative, it reinforces the myth that all seminal ideas in science (and even philosophy) occurred in the "West." But this is a limited reading of history of science itself. Thus, an encounter with the Indian context forces a change not only in science education (in terms of curriculum as well as pedagogy) but also in the mainstream history of science community. Through this intervention and broadening of their view of history of science, historians of science can actually make a stronger claim to the relevance of HPS to SE across the world.

53.5 Does Multicultural Origin of Science Matter?

In contemporary history of science, there is a strong claim to the multicultural origins of science (Bala 2006). There are some variations in this theme, but all of them agree that to claim modern science began in Europe is to ignore the many cultural influences that made this origin possible. The gist of this argument is that ideas from the Greek, Arabic, Chinese, and Indian cultures reached Europe in various ways – both in the form of texts and instruments. Europe afforded a geographical

---

[18] See Ganeri (2001) for the early European response to Indian logic.

[19] See Arnold (2000) for more on medieval India. He also points to rich development in science in the Mughul period, particularly in medicine.

[20] Indian metaphysics understands some of these concepts in quite different ways compared to the modern West. For example, the mind-body duality following Descartes is not found in these schools, since mind is seen to be a species of "matter." There are many interesting theories of causation in the various schools. The point is that some of this diversity may actually be useful for alternate understanding of scientific methodology and processes.

location where all these confluences could meet and develop, and it is in this milieu that modern science originated. There are deeper undercurrents to this claim – the possibility that knowledge had actually been transmitted to Europe but which had not been acknowledged. Examples of how Copernicus drew on the Maragha school of astronomy, how Kepler depended on Chinese observations, or how the possibility that the first ideas of calculus went from Kerala in India to Europe raise troubling issues about the beginnings of modern science and their true "origin." General principles that define science such as the amalgamation of the theoretical and the experimental, following Bacon and Galileo, are principles that inform earlier intellectual traditions in India and China. As Bala points out, "solar, lunar and planetary models of al-Shatir are mathematically identical to those proposed by Copernicus some 150 years later" (ibid., p. 83). Similarly, optical revolution in Europe was influenced to a significant extent by the work of al-Haytham (Alhazen). Bala further argues that mathematization of nature – a profoundly important moment in the origin of modern science – is indebted to the "meeting in Europe of Arabic philosophy and science with Chinese mechanical discoveries" (ibid., p. 122).

In the context of SE in India, the discussion on the multicultural origins of science, derived from history of science, will have a significant impact on the reception of science by students. There are two dimensions to this reception: one is the shared cultural and national histories of science available through multicultural histories of science, and the other is the availability of shared vocabularies and practices that might make the student more "culturally comfortable" or "culturally contiguous" to science that is taught today. In almost all the textbooks of science, the heliocentric model is associated with Copernicus. Where a little history of this model is available, it often begins with Tycho Brahe and ends with Galileo. The heliocentric model is an extremely important model of science – both for the history and origin of science and also for communicating the power of science because the claim that the Earth revolves around the sun is now such a cultural truism that it is part of commonsense now.

However, this is an incomplete version of history. There is sufficient literature to illustrate how the model of Tycho Brahe was described by the Kerala mathematicians quite some time before Brahe. The modified heliocentric model developed by these astronomers/mathematicians was described in texts that were known to the Jesuits in Kerala in the early sixteenth century.[21] Whether these ideas got transmitted across continents is not really the issue. What is however at stake is the placement of these seminal ideas within the capacity of other cultures. Does this mean that an Indian student will better understand and appreciate heliocentric motion once she is taught about the contribution of the Kerala mathematicians? There are no simple answers to this question, but this question needs to be considered for it is possible that awareness of a history of "their own" scientific theories might allow students

---

[21] See Bala (2006), Raju (2001), Ramasubramanian and Srinivas (2010), and Sarma (2008). See also Plofker (2009) for a detailed introduction to Indian mathematics.

to have a different stakeholdership towards that subject thereby influencing their learnability of science.

Teaching multicultural theories of the origin of science relates science and scientific ideas to subjects such as history and geography. It grounds science not only in the empirical world but also in a discursive world where it shares some common stories across disciplines. In the Indian context, one might say that the students face two kinds of alienation with respect to science: one is an experiential strangeness and the other is a cultural strangeness. An ironic illustration of this alienation lies in the history of technology. As mentioned earlier, there is a well-established scholarship now that describes the enormous technological advances of ancient Indian societies.[22] The first examples of metallurgy, including the invention of steel and zinc, were to be found in India. These processes actually found their way to England in the colonial era and catalyzed modern production of these metals. However, this rich and long history of metallurgy, chemistry, and other pioneering innovations in India and China are rarely even mentioned in science textbooks. Teaching science by drawing on multicultural origins of science is a good way to reduce the strangeness on both these counts. However, like in the case of HPS in SE, teachers have to first engage with these new histories.

Finally, we should note that introducing multicultural origins of science in SE is but one step in allowing multiple histories of science to enter the classroom and science texts. In the Indian case, there are such multiple histories available such as the subaltern histories and artisan histories. In all these alternate histories, there are some profound insights into the nature of the world and the universe, as well as important elements of the nature of enquiry, observation, and experimentation.

These arguments are but an extension of arguments in education that suggest that learning becomes easier when ideas are expressed closer to the contexts in which the children are immersed. For example, the attempt to teach abstract ideas through examples that are common to the cognitive experiences of the students is but one variation of the above arguments. What is being suggested here is that scientific ideas become more easily accepted and understood if a common history is exhibited. As a motivation, we only need to note the rich historical debates on the origin of science in Europe, a topic that has become so contentious that it inspires Dear (2005) to remark on the identity crisis confronting historians of science because of the difficulty in establishing strict boundaries that demarcate science from nonscience. The recognition of a stable subject matter for history of science has become difficult given that the "very category of "science" has become historicized – and hence very slippery" (ibid., p. 391). This observation, as well as the ones on the multicultural origins of science, should not be read as supporting the claim that "everything is a science." What it merely does is expand the space within HPS to interrogate the diverse forms of science[23] and take this into account in the larger debates in SE.

---

[22] See Adas (1989), Alvares (1991), and Dharampal (2000).

[23] We should remember that the diverse forms of science are already exhibited in the contemporary typology of science. Today, science includes quite different disciplines ranging from physics, chemistry, and biology to economics, library science, management science, and so on.

53.6 Nature of Science and Science Education: Lessons from Premodern Indian Science

The above discussion is related to a more commonly discussed theme in relation to HPS, namely, the NOS debate in SE. Turner and Sullenger (1999) offer a good overview of the sociology of the NOS debate within science education. But like other reviews in this field, there is no mention of the possibility of articulating new themes in NOS that are catalyzed by non-Western philosophical traditions.

One of the important ways to argue for the relevance of NOS is to show how awareness of the process of science (e.g., as a combination of the experimental, observational, and the conceptual) adds to the students' understanding of the concepts of science. Matthews (2001) describes how the study of pendulum in a class illustrates the importance of NOS to science education. Much of the impact of NOS has been discussed within the cognitive domain. However, a major influence of NOS on science learning also has to do with various psychological aspects of learning. A robust and complex theory of the nature of science demystifies the inherent ideology of a particular image of science. An outline of how the debate on NOS can be influenced through this engagement with Indian experiences follows; how these issues can directly affect SE is, at this moment, only speculative.[24]

As discussed in an earlier section, science and technology were well-established social practices in ancient and medieval India. All philosophical traditions were fundamentally concerned with the various means of acquiring knowledge. Hence, the study of epistemology was the fundamental concern for these philosophers (Matilal 1986). Thus, it should not be surprising that much of their work impinges on philosophy of science. In exploring the nature of knowledge, extensive work was done on the nature of perception, inference, language (testimony), and other related modes of learning. The Indian theories on inference make two important contributions of relevance to this chapter. One is the five-step process of inference in the early Nyāya tradition, which basically explains one's inference to another through a process of reasoning (Matilal 1999). Let us say that one infers fire on seeing smoke. The five-step process describes how we could effectively explain why we infer fire on seeing smoke. It begins by first noting the empirical event of seeing smoke, then invokes a universal reason (where there is smoke, there is fire), then uses a common example known to the speaker and hearer (such as smoke-fire complex in a kitchen), and finally concludes that the inference of fire is indeed correct. This five-step process at one stroke combines the rhetoric of communication, the process of inference, and also the process of cognition involved in the inference. It is also a system which has

---

[24] One of the sustained efforts in this direction in India is the series of conferences called epiSTEME organized by the Homi Bhabha Centre for Science Education, Mumbai. The publications of each of their conferences contribute significantly to this debate in India, although the difficulty of directly drawing on Indian intellectual traditions for science education remains.

striking parallels with the deductive-nomological model of scientific explanation (Sarukkai 2005).[25]

The second contribution to the study of inference comes from the Buddhists who offer a semiotic model of inference. They analyze the conditions that will enable one to know when a sign stands for a signified, such as smoke as a sign that stands for fire. This relation between sign and signified is also at the heart of instrumental observation in science. The way by which these Indian logicians analyze these inferences offers new ways of understanding the relation between semiotics and logic as well as between semiotics and science (a topic that has rich resonances in the interpretation of experimental results as well as in the use of mathematical writing in the sciences).[26]

There is an important lesson about NOS in these Indian approaches to inference. First of all, there is a completely different approach to the idea of "theory" in Indian thought. European scholars who encountered Indian logic found the combination of the formal and the empirical very troubling (Ganeri 2001). Similar arguments also legitimized the British appropriation of Indian technology by claiming that the Indians knew how to make steel, for example, but did not understand the theory behind it (Adas 1989; Alvares 1991). Do these alternate approaches have any implication for science and for science education today?

Any account of modern science has to engage with the idea of the theoretical. As is well known, what we call science today was referred to as natural philosophy at least till the seventeenth century. Natural philosophy was seen to be a speculative, theoretical act. The distinction of theorica/practica drawn from Greek thought was extremely influential in the way disciplines such as medicine, astronomy, and other "arts" were understood (Dear 2005, p. 393). Till the early seventeenth century, natural philosophy was immune to this distinction as it was seen to be mainly speculative philosophy with no practical applications. It was Bacon who constructed natural philosophy as a discipline which also had practical utility. Moreover, the influential distinction between mathematics and natural philosophy continued till the eighteenth century. These lead to the distinction between the categories of "pure" and "applied" in the nineteenth century which continues till today. This short historical interlude is merely to point out how such a tradition of understanding science does not occur in Indian thought. At the core of different Indian intellectual traditions there is a suspicion about such distinctions. There is no clear distinction between logic and epistemology, between metaphysics and epistemology, between ethics and epistemology, between formal and the empirical, and between mathematics and the sciences.[27] This approach to theory and practice in Indian thought is of great significance to science teaching of these subjects. For example, drawing on the unique nature of Indian mathematics – both in its empirical grounding and in its

---

[25] This model of scientific explanation suggested by Hempel and Oppenheimer argues that the explanandum is a deductive conclusion from a set of premises which consist of lawlike as well as empirical statements. This structure does a similar task as the Nyāya process.

[26] For a detailed analysis of these semiotic elements, see Sarukkai (2005). See also Sarukkai (2011).

[27] See Bhattacharya (1958) and Mohanty (2002).

textual and discursive practices – might actually help address some problems of science and mathematics education.

Ayurveda, the enduring medical tradition in India, is another classic example of the inherent mix of the theoretical and the empirical. In this case, there is also a strong component of the experimental and not merely the observational. Ayurveda is a classic example of a scientific tradition which exemplifies many of the virtues of modern scientific method including observation, theory, experimentation, and intervention. Yet it is rarely taught as such to students and in school science textbooks; it is rarely mentioned even though the so-called modern (allopathic) medicine is given as an exemplar of science. Ayurveda, as a scientific practice, involves some real observational biology. Its classification of plants is exhaustive and scientific in the modern sense of botany.

What then are the implications for science teaching if such contiguous, local traditions are taught as illustrations of the nature of science? Equally importantly, how will science education in the West learn to draw on these Indian scientific traditions in their own teaching of science? What is being suggested here is that HPS' contribution to the nature of science debate has been too Eurocentric. Drawing on another history of science from another culture – one in which the idea of "science" does not exhibit the standard fault lines of theory and practice, as well as the metaphysical baggage of this distinction – might actually contribute to the development of new ideas and practices in SE.

In the Indian context, whether in philosophy, art, or mathematics, the primary emphasis is on making the theoretical always answerable to the empirical. Thus, there is no idea of pure rationalism, pure mathematics, etc., which characterize some dominant traditions of Western thought. Now this has been interpreted by some European scholars, as pointed out in the earlier sections, to suggest that Indian culture has no understanding of theoretical rationality that is often associated with science. There has also been a long colonial project of interpreting Indian culture as being primarily religious and this along with the claim that modern science begins from a conflict with the Church has led to the claim that Indian culture had no links to modern scientific thought. This myth continues in spite of a large amount of literature on these aspects – both of Indian systems and on the nature of science. In particular, history, philosophy, and sociology of science have illustrated so well the complex relationships which science has with logic, religion, method, and so on (Sarukkai 2012). But the complete absence of these disciplines in science teaching means that certain traditional ideologies about science, such as those discussed in the earlier sections, continue to be propagated in science textbooks even today in India.

The implications of drawing on these "indigenous" modes of understanding the nature of science and mathematics are many. First of all, the metaphysical foundations of these disciplines are quite different in the Indian context when compared to the Greek and the modern "West." For example, Platonism seems to be unthematized in Indian thought. Mathematics and the sciences were always empirically grounded. Since their presuppositions are different, they create the possibility of a different method of teaching science. Secondly, when science is taught along this trajectory, students begin to understand science as a social process. Now, science is dominantly understood as a packaged knowledge system which seems to have been given to us miraculously – if not by gods, then by “great scientists.” In contrast, teaching science as a social and historical process, with its own special cultural moorings, may actually interest more students in science. Drawing on Indian logic gives us new methods of communicating the practice of reason and of thinking – arguably the two most important characteristics of learning. It also illustrates the importance of rhetorical communication in matters of reason such as using the nature of evidence and reason on which to base conclusions, details of which are given later in this chapter.

There is another important aspect of NOS from these Indian traditions, which can be briefly alluded to here. This has to do with the relationship between language and science. Almost all Indian philosophical traditions were deeply concerned with the nature of language and its relation to the world and human cognition. There is a constant attempt to create languages which capture truth and knowledge – Sanskrit itself is a very good example of a semi-technical language (Staal 1995). Later philosophers of the Nyāya tradition created a modified form of Sanskrit in order to remove the ambiguities present in ordinary Sanskrit (Bhattacharyya 1987). This engagement with language is wonderfully illustrated in the ways by which mathematics gets written in prose and poetic forms. Although a very important topic, the role of language in science[28] has not been sufficiently dealt with in the HPS literature. The richness of language use in science and science learning attests to the possibilities of drawing on these rich Indian philosophies of language.

Consider the teaching of mathematics. There is a long tradition of mathematics in India, one that includes the seminal text by Āryabhaṭa called the Āryabhaṭīya. What happens when a student is also given these historical descriptions of these alternate forms of doing and writing mathematics? Here are some speculative (but hopefully reasonable) outcomes: one, the student recognizes that there are different ways of doing and describing trigonometry – this automatically decreases the anxiety of doing something the right way or following the “right” method; two, she would recognize that such ideas were not really alien to the larger cultural world which she belonged to; and three, she might even recognize (with some help from the teacher) that mathematics has an interesting relationship with language, perhaps a language which she might be “culturally familiar” with. Such approaches might help in getting rid of the perennial and enduring fear of symbolism that seems to strike school children across the world.

53.7 Constructivism and Indian Philosophy

There is another characteristic of Indian philosophical traditions that may have a direct impact on SE. Indian philosophies have a unique way of describing the human interaction with the world. They, without significant exception, describe these

---

[28] See Sarukkai (2002).

interactions in terms of cognitive episodes.[29] Thus, perception is defined in terms of cognitive states that occur when somebody sees or perceives something. Inference is also defined in terms of cognitive states. So a description of a process is through a series of cognitive states. This mode of cognitive description for processes including that of logic is a good model for teaching subjects such as logic, mathematics, and science. The example discussed below will illustrate how this method of teaching science has metaphysical overlaps with constructivism while at the same time negating the excessive subjectivities which are potentially inherent in constructivism.

Consider a classic example of inference from Indian logic, the inference of fire on a hill from seeing smoke on the hill. Almost all schools of Indian philosophy considered inference as one of the valid means of knowing and so expended a great deal of effort in trying to describe the processes of valid inference. An example of valid inference would be the inference of fire from seeing smoke, but how can we be certain of this inference? Indian logic, pioneers of which include the Nyāya school and the Buddhists, described the inferential mechanism through a series of cognitive processes. For example, one such description followed by Nyāya is as follows: when a person sees smoke, there is a cognitive state corresponding to that perception. This state is followed by another state in which she remembers a universal rule – the principle or the reason for the inference – that where there is smoke there is fire. This cognitive state is followed by the next one which, through this rule, recognizes the smoke as standing for fire. This leads to a cognitive state which is the inferentially knowing state that there is fire in the hill.

Many Western scholars were puzzled at the cognitive descriptions of the logical process of inference and thus concluded that Indian logicians were committing the fallacy of psychologism.[30] This is a common mistake in responses to cognitive descriptions and is catalyzed by the belief that descriptions of the world should refer entirely to terms of the world and not to terms of personal experiences of the world. But what is intriguing is that the logical school, Nyāya, is a realist one. They do not in any way accept that the perception of smoke and the inference of fire are personal, subjective ones. They are committed to a realist metaphysics which acknowledges the "reality" of the smoke and fire. Yet, they are also committed to the reality of cognitive states, and the challenge in this philosophical approach is to retain the descriptive power of cognitive states and yet retain the possibility of a common reality accessible to the many cognitive subjects. It is this effort that really distinguishes and explains the unique nature of Indian philosophical discourses. As Mohanty points out, these philosophers do not end up with psychologism because "a cognition has a logical structure which allows for being exemplified in another numerically distinct episode belonging to another ego and/or another temporal location" (Mohanty 2010, p. 437).

Why would this matter to constructivism? While constructivism seems to be a popular movement in science education, there have also been strong critiques. For example, Matthews (2002) argues that although constructivism has been very

---

[29] See Matilal (1986) and Mohanty (1992, pp. 100–132 in particular).

[30] See Mohanty (1992) for a discussion on this theme.

popular in SE, there are nevertheless many points of disagreement and worry. He also notes that there are a variety of ways in which constructivism is invoked in SE, namely, constructivism as a theory of learning, teaching, education, cognition, personal knowledge, scientific knowledge, educational ethics and politics, and worldview (ibid., p. 124). In Matthews (2004, p. 107), he lists various claims of constructivism such as the lack of objective knowledge of reality and experience as the primary basis of scientific knowledge.

It seems to be the case that many of the conclusions of constructivism are grounded in the experiential mode and the cognitive primacy of learning, which situates knowledge/truth within the learner. Dominant analytical traditions in Western philosophy do not have the wherewithal to cope with this form of grounding. (There are other traditions which offer different approaches to "extracting" the objective from the subjective – Husserlian phenomenology is one such.) In Indian philosophy, this grounding in the cognitive states of the experience is a given for all processes related to knowledge of something real. But this does not reduce these descriptions to a naïve form of psychologism and individual subjectivities. That is, the mere fact of a cognitive description of the learning process, *in itself*, does not make the whole process subjective. In other words, there is really nothing in the metaphysics of constructivism (when viewed from the Nyāya perspective or the phenomenological perspective) that necessitates the shift to claims that all truth is within the learner and not "outside," that scientific knowledge and truth are all relative to each learner, and so on. The conclusion that constructivism is necessarily subjective is based on a flawed understanding of the nature of subjectivity as well as of the nature of cognitive states. The Indian logicians' analysis of inference shows how it is possible to hold onto a robust realism while at the same time accepting the primacy of individual cognitive processes of perceiving, inferring, and learning. Through this approach, there is a good possibility to marry constructivism with realism; this can be one example of "using" Indian philosophy for a contemporary debate in SE.

53.8 Rhetoric and Methods of Teaching

It would not be an exaggeration to say that rote education is seen as the bane of Indian education. Whether in newspaper reports or the last National Curriculum Framework, there are repeated references to the effect of rote learning and the prevalence of this mode in Indian schools and colleges. This mode of learning is particularly problematical for science education since rote education is often contrasted with critical and creative thinking, and problem-solving, which are the hallmarks of a "good" science education.

It is a mystery as to why the Indian educational system is saddled with such a strong component of rote learning. Like many other ancient cultures, there is a strong sense of orality in Indian culture.[31] Texts are memorized and recited. Even

---

[31] See Fuller (2001) for an interesting case study on orality.

when Sanskrit is taught today by traditionalists, the most important component of teaching that language lies in pronunciation. For a long time, texts were transmitted entirely through oral means, and this meant that the language as well as strategies of memorizing made it easier for oral transmission. It is interesting to note how even philosophy and mathematics texts were written in poetic form, thus making them amenable to an oral discourse. For some, this cultural practice of orality seems to have transformed into rote learning in contemporary education.

Although one might be tempted to ascribe the prevalence of rote learning to ancient cultural practices (such as language learning and oral transmission of texts – none of which necessarily implies rote learning), it is the educational policies and practices that are obviously a bigger culprit.[32] The most enduring reason for the continuation of this mode of learning is the examination system. Every year, one only has to see newspaper reports during exams and during admissions to read about the menace of "rote learning."[33] Even the government bodies and their representatives keep bemoaning this characteristic of Indian education. One of the most influential documents on education and education policies in India, the National Curriculum Framework 2005, notes the problem of rote learning and the means to curtail it. The National Curriculum Framework for Teacher Education 2009/2010, makes pointed references to the problem of rote education.[34] Many alternate private schools promote their system by claiming that they teach critical and creative thinking as against rote learning, which they claim is endemic to public education.

This entry into the discussion on rote learning is to offer a perspective from Indian philosophical and intellectual traditions on critical thinking. Critical, reflective thinking is often seen as the antidote to rote learning. The inculcation of these virtues is fundamentally the task of philosophy, and it is here that HPS becomes immediately relevant to SE. Philosophers over the ages have viewed philosophy as being concerned fundamentally with the nature and processes of thinking. It is impossible to engage with philosophy and not be involved in modes of reflection and thought. In the Indian context, there is an interesting practice related to critical thinking. All Indian philosophical traditions use "debate" as their fundamental rhetorical strategy. In these traditions, debate is classified into different types, and a student in these schools has to master these debating strategies. The influence of debate is so integral to Indian philosophies that even texts follow the form of a debate. Thus, a standard philosophical text will first describe the opponent's view and then counter it step by step. Almost all seminal philosophical texts follow this method.

Debate is an important rhetorical strategy. It is a great training for critical thinking and a powerful pedagogical tool. A good illustration of this can be found in the practices of Buddhist monastic training even today, where the students are trained not only in the theories of debate but also in the "performance" of debate. One can

---

[32] See Chitnis (1993) for an analysis of the changes needed in the Indian education system.

[33] See, for example, TOI http://articles.timesofindia.indiatimes.com/2011-06-19/education/29676322_1_high-scorers-evaluation-board-examination.

[34] See http://www.ncte-india.org/publicnotice/NCFTE_2010.pdf.

see these forms of “performative” debates between different schools in Buddhism in many monastic schools.

Debate is the founding principle of all Indian philosophical traditions (Matilal 1999). Logic in India arises out of debate. Every philosophical system classifies the various forms of debates; the intellectual battles between different schools were to be won on the court of debate. Interesting historical anecdotes about debates are prevalent in narratives about the different philosophical traditions. Debates were a common occurrence in the courts of kings, and there were well-established mechanisms for judging the winner of these debates. Debate was the forerunner not only of Indian logic but also of rhetoric and communication praxis.

As Matilal points out, the Buddhist canons of debate illustrated fundamental logical principles such as modus ponens and modus tollens. Debates themselves were classified into “good” and “bad” debates or “amicable” and “hostile.” Nyāya classifies debates into three types: one between a student and teacher, whereas the other two are primarily “hostile” in that their basic aim is about being victorious in the debate. The good or “honest” debate between a student and teacher is characterized by the following properties:

1. Establishment (of the thesis) and refutation (of the counter-thesis) should be based upon adequate evidence or means for knowledge *(pramāna)* as well as upon (proper) “hypothetical” or “indirect” reasoning *(tarka).*
2. The conclusion should not entail contradiction with any tenet or accepted doctrine *(siddhānta).*
3. Each side should use the well-known five steps of the demonstration of an argument explicitly.
4. They should clearly recognize a thesis to be defended and a counter thesis to be refuted. (Matilal 1999, p. 45).

All educational instruction followed these steps. These not only establish a communicative mode to discuss and analyze propositions, they are also essential to what we call as critical thinking today. Nyāya also has a classification of the other two kinds of “hostile” debates and lists in great detail the elements constituting these kinds of debates. Since victory (by any means) is the goal in these “hostile” debates, a debater can use the following strategies: quibbling, illegitimate rejoinders, and clinchers. Moreover, there is an extensive classification of the types of quibbling (3), illegitimate rejoinders (24), and clinchers (22) (ibid., p. 47). It is this complex system of argumentation that is at the heart of Indian rationality, and interestingly, it has pedagogy at its center. An illustration of these methods for students will enrich not only science education but also critical thinking and communicative processes in all aspects of education.

Although such practices have not become part of education in India, they can nevertheless be effectively used to teach critical thinking. The performative tradition of debates in Buddhist monasteries illustrates one way of incorporating the skill of critical thinking as part of educational practice. In schools today, such methods can easily be adapted. Here is one possible way to do this. The students will debate a particular hypothesis but will have to follow the rules of debate as enumerated in these philosophical traditions. For example, consider a simple thesis: all matter is made up of atoms. How will the students debate this question? What kind of rules of debate will they invoke? The rules of debate drawn from these Indian traditions of debate can be given to the students, and they can be asked to follow these rules in the course of the debate. For example, the Nyāya describe many kinds of checks, since for them, "debate was like a game of chess, in that the opponent and the proponent make their moves and at the end there is a clincher, when one side will be checkmated" (Matilal 1999, p. 81). They list "twenty-two types of defeat-situations," which are arguments which will show the opponent's arguments to be wrong. One such is abandoning the thesis in the course of argument; thus, if a student suddenly invokes the existence of space and time while debating the existence of atoms, she could be countered by saying that she has abandoned the thesis of the original debate. Some of the other clinchers against the opponent include "irrelevant speech," "incomprehensible speech," "adding unnecessary steps," and "repetition." (Examples of using jargon or dropping names of scientists to justify the thesis can fall under one of these categories.) Students trained in such manual of debates will be able to analyze what they hear and evaluate the faults of arguments based on specific categories. One can modify these rules for the present-day context. The bottom line is that such exercises in thinking and debating can enhance the skills of learning and thinking in a profound manner and there is much that the rational traditions of India and China, for example, can contribute to this project. Such an exercise will be of relevance to students across cultures.

53.9 Conclusion

This chapter explored new ways of engaging with HPS in the context of SE with a specific focus on Indian experiences of science and science education. One of the challenges to science education in India lies in the contestation about the very notion of science. Given that the Indian civilization (like other non-Western ones) had a long engagement with themes and practices of what seems like science, it is necessary to understand why science education in India is almost completely silent about engaging with these traditions. Thus, the sections on multicultural origins of science and the nature of science debate discuss the ramifications of understanding these practices as science and also the importance of including them in the curricula. One of the consequences of including them in the curricula is that students begin to develop a sense of ownership and confidence with respect to scientific thinking and practice. This step allows the possibility of broadening our understanding of science without also, at the same time, claiming that everything is science.

The two sections on constructivism and rhetoric are attempts to illustrate how one can draw on alternate philosophies that can contribute to some of the important contemporary debates in science education. By doing so, attention is also drawn to the exclusiveness of the global HPS community, which has steadfastly ignored the historical and philosophical contributions of the non-West. Hopefully, this chapter can partly loosen the intellectual strings of this community and through it that of the community of science educationists.

This chapter does not address issues related to learning scientific content and the philosophical issues associated with it. This is primarily because of the India centricity of this chapter. Much of the debate may seem unnecessarily focused on certain aspects of earlier science or on cultural implications of ignoring non-Western traditions. However, as argued in this chapter, it may not be desirable to so completely demarcate the learning of content from the learning of the concept and methodologies of science.

In drawing on the earlier intellectual traditions, some contemporary contributions have been kept out of the purview of this chapter. In particular, there is no engagement with two influential thinkers/educationists of contemporary India, Gandhi and Tagore. Both of them were deeply interested in education and both of them had deep insights into the nature of education. They are of particular interest because of their attempts to fundamentally integrate educational practices and ethics. Gandhi (1951, 1953) proposed his ideas of education as part of a new system called the *Nai Talim*. This schooling is radically different from mainstream, government-supported education system. It is important to realize that these approaches emphasized fundamental ethical principles as being integral to the education process, content, and pedagogy. These principles include social justice and nonviolence, the defining principles for Gandhi. Gandhi's views on education make ethical action integral to the process of learning; it is not possible to divorce the content of what we learn from the set of acts to which ethics is applicable. That is, the Gandhian challenge is to make the ethical an integral part of the cognitive. But the insights from Gandhi and Tagore are not specific to science education, and hence, this chapter concentrates on alternate engagements between HPS and SE.

Finally, is it important to take into account other HPS traditions in SE? The unequivocal answer to this question has to be in the affirmative. The major reason is that many of these beliefs about science which are at the foundation of curricula and teaching of science are just plainly mistaken. They represent a particular rhetoric of science, and this rhetoric is abundant in science texts. Those who claim that texts are only about content of science and nothing else are only echoing a particular rhetoric of science which is itself based on some specific history and philosophy of science. These particular views have been challenged enough in HPS literature. Ironically, the alternate formulations related to science are not just from non-Western cultures. There is absence of many small traditions within Europe itself, those which have not found their way into these science texts.

This is ironical given that HPS has generated enough material, especially in recent times. This is especially true of history of science which has been able to engage far more deeply with multicultural and global histories of science. They have also been able to disentangle the many small science traditions within Europe. However, the scientific community not only ignores these narratives but many times is also inimical towards them. The question that science educationists should ask is this: Can they afford to similarly ignore these contributions in teaching science? Should they be subservient to the dominant ideologies of the mainstream scientists? Most importantly, can SE be independent of the ideology of science propagated by the scientists, an ideology which is deeply encoded in the content of science in various ways?

The enduring question as to whether students will do better in science if they are taught the history and philosophy of science has to be addressed. Rather than take this position, it is more useful – at this juncture – to emphasize the importance of HPS to science teachers. The question that is relevant now is whether teachers will be able to teach science better if they are exposed to HPS. There are good reasons to believe that the answer to this question is an unqualified yes.

Acknowledgments I am grateful to Anu Joy who has deeply contributed to my understanding of science education. Comments and suggestions from the many anonymous reviewers of this chapter, as well as from Michael Matthews, were very useful and I thank them for taking the effort to read the text so carefully.

Chapter 54
Historical Interactions Between Judaism and Science and Their Influence on Science Teaching and Learning

Jeff Dodick and Raphael B. Shuchat

54.1 Introduction

To the eye of the layman, Jews and science seem to have a definite association. To support such claims, some point to the large number of Jews who have won Nobel prizes in the sciences and Fields Medals in mathematics (Efron 2007) and to the numerous scientists of Jewish origin teaching at US-based universities (Lipsett and Raab 1995). However, as Efron (2007, p. 2) rightly points out, statistics such as these are "crude" given that most practicing scientists of Jewish origin are not usually guided by the tenets of Judaism, so it is a misconception to argue that Judaism, in of itself, is the reason for these scientists' interest or even association with their respective fields. The question, therefore, is what does Judaism have to say about science?

In this chapter, we will examine the historical and philosophical meeting between Judaism and science and how it in turn has influenced the teaching and learning of science. In so doing, we will be asking the following questions: How has the relationship between science and Judaism developed over history? What are the philosophical approaches that have developed in Judaism for dealing with the challenges that science sometimes poses? What are the subjects of science that most specifically create such challenges for Judaism? And most important for this book chapter: How has this meeting between Judaism and science affected the teaching and learning of science?

The authors contributed equally to this manuscript.

In order to answers these questions, we will first provide a brief review of the historical interactions between Judaism and science, the goal being to examine the major trends that have developed through time. Based on these historical trends, we will define the major philosophical approaches (or models) that have developed within Judaism for dealing with the possible challenges posed by the domain of science. By understanding how Jewish thinkers have coped with these perceived challenges, it will be possible to analyze how this relationship has affected the modern science education system (specifically in Israel or in educational systems, outside of Israel, where Jews are the majority). The answers we provide to these questions may serve as a guide towards improving the quality of science education in Jewish school systems around the world.

54.2 Judaism and Science: A Historical Overview

To give a comprehensive analysis of the interactions of Judaism with science over the ages is beyond the scope of such a short chapter. Instead, as this chapter is found within a book on the role of history and philosophy of science in science teaching, we specifically define those interactions between Judaism and science that have relevance for science teaching. In this way, we will be better positioned to understand how Jewish teachers and students of science understand and even cope with potential conflicts between the two perspectives.

In order to understand the Jewish position on science, we will begin by defining what we mean by science for this chapter. In early Western-Greek culture, the philosopher was de facto the scientist: the physicist, the astronomer, and the medical doctor. Therefore, in order to gain a broad understanding of Judaism and science throughout the ages, we have to relate to three categories which characterize the scientific enterprise over the ages and their interface with Judaism: (1) technology, (2) exact sciences (most notably, astronomy and biology[1]), and (3) natural philosophy in antiquity. In the modern era, with the separation of science and philosophy, we have to relate as well to the fields of (4) cosmology and cosmogony (most notably, evolution). The first two categories represent the products

---

[1] In this historical discussion, we address, among other things, the simple question of the rejection or the acceptance of biology, in general, as a science in antiquity. In the twentieth century, the issue of biomedical ethics has developed tremendously and so have the discussions concerning medical ethics and Jewish law. Much has been written about, including organ transplants and the definition of death, fertility issues, machines for prolonging life and disconnecting terminal patients from them, and cloning. Steinberg (2003) wrote an *Encyclopaedia of Jewish Medical Ethics*; moreover, *Shaare Zedek Hospital* in Israel has a journal dealing with such issues titled, *Asiya*, and much discussion can be found in legal journals as well. However, there are two reasons why this issue is not part of this short chapter: First, the research is all done on the graduate level and by experts and does not find its way to the classroom at the high school or even undergraduate level. Secondly, this issue has nothing to do with acceptance of biology or medicine and how it effects education, but very specific ethical issues within that realm.

of human reason and the third and forth, human speculation and inquiry about life and the (formation of the) universe.

To understand any Biblical Jewish position, we must use the oral tradition, or as it is also known, the rabbinic tradition, to interpret the Masoretic text of the Bible; this rabbinic tradition commences with the Talmudic and Midrashic period (100 BCE–600 CE) and represents the classical period of Jewish literature.[2]

54.2.1 Technology

In the Book of Genesis, Noah, was so named by his father Lemekh to mean: "This one shall comfort us for our work and the toil of our hands because of the ground which the Lord has cursed" (Genesis 5, 29). The curse of the ground is mentioned twice before in Genesis: the first time as part of Adam's punishment for partaking of the Tree of Knowledge (Genesis 3, 19) and the second time when Cain kills Abel (Genesis 4, 11–12). The rabbinic understanding of the curse was that the land would not produce food so easily, so man would have to sweat and toil to produce something which is not just thorns and thistles. However, this curse is not insurmountable; it takes human initiative and cooperation to overcome it. The Midrash (Tanhuma Genesis, 11) writes that until Noah was born, one planted wheat and barley but harvested mostly thorns. After Noah was born, "They harvested that which they had planted; not only that, but until Noah they did the work by hand. [However, after] Noah was born he invented ploughs, scythes, and shovels and all their work tools" (Poupko, 1990).

---

[2] By necessity, we focus on primary sources of the Jewish literary tradition, such as the Bible (the Masoretic text), the Talmud (Preisler & Havlin, 1998) and the Midrash, and their interpretations. We do so because it is these source texts and their interpretations that have been used authoritatively by Jewish thinkers, and in addition it is these texts which have been used for coping with different scientific positions. In turn, this has affected the modern science education curricula in many Jewish school systems. The Talmud is the authoritative body of Jewish law and lore accumulated over a period of six centuries (c.100 BCE–c.500 CE) in both Israel and Babylonia. The Talmud has two components: the Mishnah (Kehati, 1991), the first written compendium of Judaism's Oral Law redacted by Rabbi Judah the Prince in 200 CE, and the Gemara, an in-depth discussion of the theoretical base of the laws of the Mishnah. In addition, the Gemara includes nonlegal discussions and interpretations of Biblical texts called Aggadah as well as stories with moral implications to human behavior. The Gemara written in Babylonia is the more popular corpus and is also referred to as the Babylonian Talmud. There was a parallel Gemara written in Palestine, and it is referred to as the Palestinian or the Jerusalem Talmud (Rozenboim 2010). If "Jerusalem Talmud" is not mentioned by name in the references in this chapter, then one can assume that the Babylonian Talmud is the version being referenced. Midrashim (pl.) are rabbinic interpretations of the Hebrew Bible consisting of homily and exegesis, on both its legal ramifications and its lore. Much of the Midrashic teachings are attributed to the Tannaim (rabbinical scholars of the period of the Mishnah who lived between 100 BCE and 200 CE). Individual Midrashic commentaries continued to be composed by rabbis after 200 CE until the Middle Ages. The Talmudic and Midrashic texts are seen as the classical period of Judaism in which the oral traditions and interpretations were put to text. This literature is referred to as classical rabbinic (or *Hazal* in Hebrew) literature. All denominations of Judaism are in a dialogue with this classical literature whether they see it as authoritative (as does Orthodox Judaism) or not (as does Reform Judaism).

For the rabbinic mind, human ingenuity and the technology it produced is not only a positive thing, but it is how humankind is expected to overcome “the curse of the ground.” Instead of taking a passive position of accepting a Divine punishment, the rabbinic literature saw this “curse of the ground” as something that humankind brought about through misguided human behavior and therefore had become an issue that had to be resolved. This is comparable with the Biblical story of Moses breaking the tablets of the law after which God told him to make new ones. The idea of fixing what you break is how the rabbis of the Talmudic period interpreted this story. The resultant technology was and is the human attempt to rectify the flaws of nature caused by their own wrong actions.

A second way of viewing technology (and science) is from a practical point of view: providing one with the practical means to have an occupation. The Talmud (Makkot, 8b) says that it is incumbent upon a father to teach his son an occupation. Thus, the rabbis learned from the verse “And you shall live by them” (Deuteronomy 30, 19) that one may take time away from Torah study to study an occupation (Jerusalem Talmud, Peah 1, 1).

This second approach is also reflected in the famous debate between Rabbi Ishmael and Rabbi Simeon Bar Yohai, in which Rabbi Ishmael said that one must take off time from Torah study for a livelihood, whereas Simeon Bar Yochai thought that one should strive to devote all one’s time to Torah (Talmud Brakhot, 36). The Talmud, however, preferred the view of Rabbi Ishmael finding it more practical and applicable. From the Biblical period until modern times, Jewish religious authority has largely remained positive towards the role of technology in society.[3]

54.2.2 Exact Sciences

The Talmud did not limit science’s role to the practical task of insuring one’s livelihood. Exact sciences, such as astronomy, were seen as bringing one to recognize the wonders of God’s world, as seen by the Talmudic statement:

> Rabbi Joshua Ben Pazi in the name of Bar Kapara said: anyone who can calculate the seasons and the astral [movements of the heavens] and does not, about him the verse says: ‘and the acts of God he does not behold and the works of His hands they did not see’ (Isaiah 5, 12). Rabbi Samuel Ben Nahmani said: How do I know that it is a mitzvah [a Divine commandment] for one to calculate seasons and astral [movements]? For it says: ‘For you shall keep and do [these commandments] for this is your wisdom and knowledge in the eyes of the nations (Deuteronomy 4, 6). Which wisdom is considered by the nations? This is the calculations of seasons and astral [movements] (Talmud Shabbat, 75a).

---

[3] In recent times, members of the ultra-Orthodox camp have raised concerns over the access that some computer technology gives to the media that is not in accord with their (Jewish) philosophy. As an example, some 40,000 ultra-Orthodox, US-based Jews attended a meeting at Citi Field (in New York, NY) to hear lectures about the dangers of the Internet (Grynbaum 2012). Similarly, in Israel, public calls are sometimes made to ban home computers in ultra-Orthodox communities due to their “spiritual dangers” (Ettinger 2007).

Rabbi Samuel Edeles (known as Maharsha), the sixteenth-century Biblical commentator, argued that this rabbinic statement is not speaking about calculating the Jewish calendar, since this is a calculation by the moon, but rather we are speaking here of the mathematical calculation of the movements of the heavenly bodies. Thus, Rabbi Josef Karo (2009) in his *Code of Jewish Law* (published 1565) allows one to look into an astrolabe on the Sabbath since Rabbi Karo understood that there is a rabbinic ordinance to study the heavens.

Both of these rabbis based their opinions on the rabbis of the Talmud who held scholars of astronomy in great esteem and had no problem admitting a mistake if proven wrong by non-Jewish scientists in this issue (Talmud Pesahim, 94b). In general the feeling was that there was wisdom to be gained from the scholars of the nations in this field, as the rabbinic dictum states: "If they tell you there is wisdom among the nations, believe them" (Midrash Rabbah Eikhah, 2, 17) (Freedman & Simon, 1939).

Aside from the high regard, the rabbis had for astronomy, the relation to the exact sciences was seen in quite a practical sense, similar to the attitudes towards technology. In the area of biology, we have a few sources for the study of zoology or botany in order to better understand the commandments. The Talmud states that Rav, the third-century head of the Talmudic academy in Sura, Babylonia, spent 18 years with shepherds in order to be able to differentiate between temporary and permanent wounds in animals. This he did to identify which animal qualified as a first born (sacrifice) for the Temple (Talmud Sanhedrin, 5b).

The students of Rabbi Ishmael dissected the dead body of a criminal to understand issues of purity and non-purity (Talmud Bekhorot, 45a). Again, the Talmud accepts the opinion of non-Jewish botanists when deciding an issue concerning the agricultural laws; its regard for the science of biology can be seen from the very fact that it allows one to go to a physician claiming that medicine is a legitimate science and furthermore claims that a doctor who does not charge for his skills is probably not worth seeing (Talmud Bava Kama, 85a).

54.2.3 Philosophy

In order to correctly understand the rabbinic attitude towards general knowledge, one (also) needs to understand the rabbinic attitude towards philosophy, especially Greek philosophy, which was the forerunner of scientific knowledge in the West; and in order to understand their attitude towards philosophy, it is important to introduce the subject with a brief discussion of the Talmud's attitude to Greek culture, as Greece was the birthplace of philosophy.

In this discussion we differentiate between two issues: Greek language on the one hand and Greek philosophy on the other. The Mishnah (Megilla 1, 9) states that Rabbi Gamliel permitted the translation of the Torah from Hebrew into Greek. In the Talmud, Bar Kapara added that speaking Greek was appropriate for a Jew since the beauty of Jephet (father of *Yavan* in Genesis 10,2 which is the Hebrew name for Greece) should be in "the tents of Shem" (i.e., the Jewish people) (Jerusalem Talmud Megilla, 1, 9).

Rabbi Simeon Ben Gamliel claimed that only Greek could capture the meaning of the Torah in translation (Jerusalem Talmud Megilla, 1, 9).

Despite the Talmud's positive attitude towards the Greek language (and the exact sciences) it saw the Greek use of verbal intimation negative light but was generally silent about Greek philosophy (See *Hokhma Yevanit* in Zevin (1963)). In the post-Talnudic period Greek philosophy was an issue debated for centuries among Jewish thinkers that set the tone for some of the modern Jewish attitudes towards philosophy and science.

Rabbi Hai Gaon of eighth-century Babylonia saw Greek philosophy as something which could sway one from the path of truth. Saadiah Gaon (882–942 CE), however, embraced the Islamic Philosophy of the Kalam,[4] which was strongly based on the Greek philosophical model, and was well versed in the sciences of his day. Isaac Israeli (855–955 CE) in Kairouan (modern Tunisia) also drew heavily on the philosophy and science of his day.

In Spain, the attitude of most rabbinic figures began with the acceptance of the value of Greek philosophy. Solomon Ibn Gabirol (1020–1057 CE) took a neoplatonic stance in his *Fons Vitae* (the Latin edition of what has been shown to be the original *Mekor Hayim – Source of life*) as well in his classic poem *Keter Malkhut* (*The Crown of the King*). Abraham Ibn Daud (1110–1180 CE) wrote an astronomical work and was the first to create a Jewish philosophical work based on the writings of Aristotle, titled *Emunah Ramah* (*The Sublime Faith*). Bahya Ibn Paquda, in the late eleventh century saw the study of Greek philosophy as an important tool for understanding nature and metaphysics incorporating these ideas in his *Duties of the Heart* (Ibn Paquda 1970). Abraham Bar-Hiyya (1070–1136 CE) embraced Aristotelian thinking openly in his *Higayon Henefesh* (*Meditation of the Soul*) and wrote works on astronomy, mathematics, and geometry (Bar-Hiyya 1968). Similarly, Abraham Ibn Ezra (1089–1164 CE) incorporated Aristotelian ideas and astronomy into his Torah commentary. He wrote a work entitled *Lukhot* (*Tables*) entailing astronomical tables and wrote a work on the astrolabe entitled *Keli Nehoshet* (*The Copper Instrument*) as well as *Yesod Mispar* (*Basic Numbers*) on arithmetic.

Maimonides (1135–1204 CE) was an avid believer in the importance of studying Greek philosophy and science and formulated in his *Commentary on the Mishnah*, the famous statement: "Accept truth from whoever offers it" (Maimon 1961). This echoes the (previously discussed) Talmudic respect for all knowledge, even that which originates outside the Jewish world. In addition to discussing issues of Greek philosophy and cosmology in his philosophic work, *Guide for the Perplexed* (Maimon 1956), Maimonides even incorporates ideas on cosmology into the first volume of his Halakhic[5] work, the *Mishneh Torah* (*Repetition of the Torah*) (Maimon 1987). Maimonides saw human reason and faith as inseparable. After all, if God created

---

[4] Kalam is an Islamic school of philosophy that seeks theological principles through dialectic; it flourished in what is today modern Iraq, from the eighth to tenth century CE (Wolfson 1976).

[5] Halakha is the collective body of Jewish religious law, including Biblical law and later Talmudic and rabbinic law, as well as customs and traditions. Judaism classically draws no distinction in its laws between religious and ostensibly nonreligious life. Hence, Halakha guides not only Jewish religious practices and beliefs but also numerous aspects of day-to-day life.

humankind with the faculty for reason, then it cannot be that this God-given gift is at odds with revelation. The faculty of human reason is the "image of God" through which He created us (*Guide for the Perplexed*, I, I). Therefore, we need to use this faculty to understand revelation correctly. The need for harmony between reason and revelation, he states clearly: "We always attempt to integrate Torah and reason, and therefore will always explain issues (of faith) from a natural point of view. Only that which is clearly described as a miracle (by the Bible) without any other possible explanation, will we grant it the name of miracle" (as cited by Shilat 1995). Therefore, in issues of science and philosophy, Maimonides goes to great lengths to demonstrate how the scientific thinking of his day is in total harmony with Jewish faith.

Even with the difficult issue of Aristotle's theory of the eternity of the universe, which appears totally opposed to the Biblical notion of creation, Maimonides defends the (Biblical) act of creation by using Aristotelian logic and arguments from nature (*Guide for the Perplexed* 2, 13–32). The place of logic is so important in Maimonides thinking that he argued that logical deductions from revelation are part of the original intention of the revelation (*Guide for the Perplexed* 3, introduction); therefore, revelation and reason can never contradict each other. Maimonides believed in the inseparability of revelation and reason (and its derivative, science). This is best demonstrated by his statement that "if he would have been convinced that science had proven that the earth was created differently than our understanding of the Biblical text, he would have had no problem reinterpreting Genesis 1, 1" (based on *Guide For the Perplexed* 2, 25 as cited by Sacks (2011, pp. 219–220)).

The philosopher Gersonides (1288–1344 CE) accepted the Aristotelian ideas as filtered through Islamic philosophy and was an avid student of the sciences himself writing on arithmetic, geometry, trigonometry, and astronomy (Touati and Goldstein 2007). He is said to have invented a marine navigational tool called Jacob's ladder (Stanford Encyclopedia of Philosophy, http://plato.stanford.edu/entries/gersonides).

Even Judah Halevi (1075–1141 CE) who claimed in his *Kuzari* that philosophy was limited in its ability to prove religious belief was still well-versed in philosophy and the sciences (Halevi 1998). In addition, the Raavad of Posquieres, in the twelfth century, who was a contemporary of, a commentator on, and fierce opponent of Maimonides, is still quite silent concerning Maimonides' embrace of philosophy. In addition, Nahmanides (1194–1270 CE) despite his leaning towards Kabbalah, defended the study of the sciences and Maimonides' *Guide to the Perplexed* in face of French rabbinic opposition (Shavel 1963).

In general, the entire Spanish era (900–1391 CE), prior to the inquisition was an age of acculturation in which rabbis openly embraced Western thought and culture while remaining faithful to their religious beliefs. It was also the most creative period of religious philosophy in which the three monotheistic religions, Judaism, Christianity, and Islam, stood side by side on the Iberian Peninsula. Despite any ongoing political struggle, the thinkers of all three religions openly borrowed ideas from each other in the common battle against problems arising from Aristotelian thinking.

Maimonides borrowed ideas from Al-Farabi and Avicenna. Gersonides borrowed openly from Averroes and Al-Farabi and Thomas Aquinas borrowed openly from Maimonides and Al-Farabi. In fact, the common front and common issues of the three religions were so vast that the Jewish philosopher Ibn Gabirol's book, *Mekor*

Hayim (*Source of Life*), translated into Latin, was mistakenly thought to be the product of an Arab-Christian scholastic philosopher by the name of Avicebron until the Hebrew original was discovered in 1846 by Solomon Munk.

In general, as Shuchat (2008) noted, Jewish philosophy evolved when two events occurred: (1) a meeting between Judaism and Western culture took place and (2) a period in which the Jewish community enjoyed at least minimal civil rights as a minority. This occurred during three time periods: (A) the Hellenistic period from about the second century BCE in Israel and Egypt until the end of the revolt against the Roman empire in 115 CE in Alexandria; (B) the Muslim period, from the eighth century until the expulsion of Jews from Spain in 1492; and (C) the modern period, from the emancipation of the late eighteenth century until today.

In these three periods Jews experienced both Western culture and felt accepted enough to ask themselves how their neighbors saw them and took interest in the surrounding culture and thought. In the interim periods, where the Jews of the Western world did not enjoy these rights, they usually limited their study to Jewish legal writings and Kabbalah.[6]

54.2.3.1 The Opposition to Philosophy

The controversy over Maimonides writings saw the growth of an anti-philosophical movement in Provence and Spain. The Maimonidean controversy began during Maimonides' lifetime but turned into an anti-rationalist debate only in its second stage (1230–1235 CE). Solomon B. Abraham of Montpellier, David B. Saul, and Rabbi Jonah Gerondi led the anti-philosophy movement in 1232 CE. Their argument seems to have been more that the Jewish philosophers were compromising on the observance of the law and allegorizing scripture and Biblical miracles, than an attack on philosophy per se. With the burning of Maimonides books by the church in 1232 CE, the shock brought Rabbi Jonah Gerondi to retract and the controversy ended (Ben Sasson et al. 2007).

The third stage of the controversy (1288–1290 CE) was short lived, but the fourth and final controversy (1300–1306 CE) seems to have erupted again due to renewed allegations that the rationalists gave allegorical interpretations of the Bible, were lax in observance of the law, and denied Biblical miracles.

Rabbi Moses Aba Mari Astruc of Lunel persuaded Rabbi Solomon Ben Adret (also known as Rashba) to join forces. The Rashba was willing only to ban the study of philosophy or the natural sciences before the age of 25 (Ben Adret 2000).

---

[6] Kabbalah (literally "receiving") is a discipline and school of thought discussing the mystical aspects of Judaism. It is a set of esoteric teachings meant to define the inner meaning of both the Bible and the traditional rabbinic literature (including Midrash and Talmud) as well as to explain the significance of Jewish religious observances in light of the inner soul and upper spiritual worlds. The term Kabbalah, meaning Jewish mysticism, is a term from the twelfth century CE and afterwards. However, Jewish mystical texts date back to at least the second temple period if not earlier. The best-known Kabbalistic work is the book of Zohar or more correctly Zoharic literature, which first appeared in Spain in the late thirteenth century (Dodick et al. 2010).

However, even Rashba, who opposed philosophy, neither had no problem with the study of Greek medicine (Reponsa part 1, letter 415) nor was he actually against studying the exact sciences.

It is possible that the political changes in Spain helped create the anti-rationalist movement. With the re-conquest of Spain by the Christians, Jews were suffering from the crusades and from the impact of martyrdom in their wake. The Maimonidean synthesis with Greek culture seemed less appealing and a move to mysticism was being felt. After the massive conversion of Jews to Christianity during the months of Spanish rioting against the Jewish communities in 1391, many Jewish scholars regarded the adherence to philosophic doctrine as a threat to the Jewish community; this included Hasdai Crescas (1340–1412 CE) who criticized Aristotelian physics in what was to be one of the first serious attacks on the system (Wolfson 1929).

After the Spanish expulsion, the interest in philosophy dwindled in the Jewish world. With the exception of scholars such as Joseph Solomon Delmedigo (1591–1655) in his book *Sefer Elim*; R. Moses Isserles (1520–1572) of Cracow and R. Abraham de Herrera (1570–1635), who combined philosophy and Kabbalah; R. Menasseh Ben Israel (1604–1657); R. Moses Zacuto (1625–1697), a kabbalist who was in contact with Spinoza; and R. Loew of Prague (1520–1609, known as the Maharal), Kabbalah took over from philosophy as the main intellectual interest.

David Nieto (1654–1728 CE), in his *Second Kuzari*, claimed that the rabbis of the Talmud were never against philosophy (Nieto 1993). In the eighteenth century, scholars like Rabbis Elijah Ben Solomon Zalman (1720–1797, better known as the Vilna Gaon), Jacob Emden, and Jonathan Eibeshitz still held the sciences in great respect. The Vilna Gaon was quoted as saying that for every amount that one lacks knowledge of the general sciences, he lacks one-hundred fold in the study of Torah (Baruch ben Jacob (1780) of Shklov, *Introduction to his translation of Euclid* in Hebrew). The Vilna Gaon even wrote his own treatise on algebra titled, *Ayil Meshulash* (*The Three Rams*), but concurrently he was rather cold towards philosophy (Shuchat 1996).

With the onset of the Jewish emancipation (from the later eighteenth to twentieth century) in Europe and Russia came the rise of the Jewish *haskalah* (*or enlightenment*) movement, which saw its goal to reintroduce secular education to the traditional Jewish masses. In Western Europe, the father of the Jewish *haskalah* movement was Moses Mendelssohn (1729–1786), a traditional and observant Jew well versed and acculturated in German intellectual society. Mendelssohn set out to portray Judaism as a religion of reason in his work *Jerusalem*, using religion and philosophical reasoning hand in hand as Maimonides did before him. The first period of the haskalah (in the late eighteenth century and the beginning of the nineteenth century) saw many religious Jews, especially in Eastern Europe, even rabbis, embracing the message of secular studies alongside Torah studies; however, with the secularization of the Russian and Eastern European haskalah movement, rabbinic leaders disassociated themselves with it and even became antagonistic to it.

Since then, ultra-Orthodox[7] Jewish thinkers tended to disassociate themselves from the study of secular knowledge, especially philosophy and the humanities, even if they had no overall opposition to the exact sciences. An example of such was the voluntary closing of the Volozhin Yeshiva (Seminary) in Lithuania after the government forced its students to include secular studies into its syllabus in the second half of the nineteenth century (Stampfer 2005).

In the Hassidic[8] (ultra-Orthodox) camp as well, there was a feeling of suspicion towards philosophy. However, even Rabbi Nahman Ben Simha of Breslov, the famous anti-rationalist Hassidic leader, who shunned philosophy (Ben Simha 1990) claimed that there was some good in all of the sciences (Likutei Mohran 18).

The revival of secular studies within Orthodoxy in Western Europe is attributed to Rabbi Samson Raphael Hirsch (1808–1888) who coined the term *Torah Im Derech Eretz* (or Torah *with secular knowledge*). Later in the twentieth century Rabbi A. I. Kook (first chief rabbi of prestate Israel) believed that all Torah scholars should have a basic knowledge of general culture and science. This has become the position of the modern-Orthodox stream in Judaism. However, within the ultra-Orthodox world, the exact sciences, i.e., physics, chemistry, and biology (excluding evolutionary biology), are tolerated but the humanities (including philosophy) are viewed with profound distrust.[9]

---

[7] In general, Orthodox Judaism is the approach to Judaism that adheres to the rabbinic interpretation and application of the laws and ethics of the Bible as found in the Talmudic literature. In the early nineteenth century, Orthodox Judaism divided into two different camps, the modern Orthodox and ultra-Orthodox which encompass a wide spectrum of beliefs. Nonetheless, Waxman (1998) details three major differences separating modern Orthodoxy and ultra-Orthodoxy. The first involves the ultra-Orthodox stance towards the larger society in general and the larger Jewish community, which is essentially an attitude of isolation, as opposed to the inclusive attitude of the modern Orthodox. The second is in reference to modernity, general scholarship and science, with the ultra-Orthodox being antagonistic and modern Orthodoxy being accommodating, if not always welcoming. Third, there is a basic difference between the two in their attitudes towards Zionism and active involvement in the rebirth and development of Israel, with the ultra-Orthodox being antagonistic and the modern Orthodox welcoming Zionism as a religious value. In this chapter we will use the English term ultra-Orthodox (even with its political connotations) as opposed to the Hebrew term, Haredi, as this is the more common term in English sources.

[8] Hasidism is a branch of ultra-Orthodox Judaism that promotes spirituality and joy through the internalization of Jewish mysticism as the fundamental aspect of the Jewish faith. It was founded in the eighteenth-century Eastern Europe by Rabbi Israel Baal Shem Tov (1698–1760) as a reaction against overly legalistic Judaism identified with Orthodox Jewry in Lithuania (sometimes called Mitnagdim (pl.) or "the opposition"). Today, the ultra-Orthodox community is comprised of both Hassidim and Mitnagdim.

[9] The ultra-Orthodox community saw support for their position in the opposition of the rabbis of the Middle Ages to philosophy. In the argument between the anti-rationalists and the Maimonidean school, for instance, they saw themselves as siding with the anti-rationalists against the Maimonidean embracing of philosophy and secular science.

54.2.4 Cosmology and Cosmogony (In the Modern Period)

54.2.4.1 Cosmology

Despite the seeming open-mindedness towards science in the nineteenth-century Western Europe, there was a greater ambivalence towards science in Eastern Europe indicated by the pain that the parting with the geocentric system of planets had on a few Jewish thinkers. The Vilna Gaon in the late eighteenth century still spoke of a Ptolemaic astronomical system in his commentary to the mystical *Sefer Yetzirah* (*Book of Creation*). Is this due to opposition to the new astronomy or just a lack of awareness? The Gaon studied philosophy and science from Hebrew texts; thus, it is possible that these texts were outdated and therefore could have had antiquated views of science. It is also possible that his ideas were just commentaries on the views in the *Sefer Yetzirah* which was written close to the Ptolemaic period.

Another scholar from Vilna, Rabbi Pinchas Elijah Horowitz (1765–1821 CE), in 1797 CE, published *Sefer Habrit* (*Book of the Covenant*), which acted as a Jewish encyclopedia of science. This volume needs special attention since it was extremely popular in the nineteenth and early twentieth century among Eastern Europe Jewish scholars, as evidenced by its more than 26 editions published between 1897 and 1925 CE in the original Hebrew as well as in Yiddish and Ladino (Robinson 1989).[10] An unusual aspect of this work was its attempt to create a synthesis between science and Kabbalah (Robinson 1989). In the chapters on astronomy Horowitz displays sympathy to the Copernican system but ultimately rejects it in favor of the geocentric position (Rosenbloom 1996).[11]

Rabbi Reuven Landau (as cited by Robinson 1983) of Romania wrote books on trigonometry (*Middah Berurah* or *Clear Measurement*) and astronomy (*Mahalakh ha-Kokavim* or *The Movement of the Planets*). In them, he tried to explain to the reader all the fundamentals of these fields, but he was also careful to integrate an explanation of how the Divine force permeates all of nature (Brown 2008). Despite his knowledge of the new cosmology, he raises objections to Copernicus' proofs and sides with the geocentric universe for spiritual reasons; if the Earth was not the center of creation, possibly humanity was not the center either. Landau, as with Horowitz's *Sefer Habrit* before him, adopts Tycho Brahe's system in which the sun and the moon revolve around the Earth but the other planets revolve around the sun. However, it should be mentioned that in the second edition of this book in 1818 CE, the publisher writes that it is possible for a believing Jew to adopt the Copernican view if he so chooses (Brown 2008).

---

[10] Solomon Schechter, the noted scholar of the Cairo Genizah in the early twentieth century, admits that in his youth in a village in Romania, he heard of America through Sefer Habrit (Robinson 1989).

[11] Nussbaum (2002, 2006) shows that in recent years, there has been a revival of geocentrism among some in the Orthodox community including rabbis and scientists; it is unknown how widespread this phenomenon is.

In Bialystok, Hayyim Selig Slonimski (1810–1904 CE) was a talmudist, a mathematician, and a popularizer of science for traditional Jews. Coming from the same mind-set of the Vilna Gaon and *Sefer Habrit* that secular knowledge is needed for the proper comprehension of Torah, he published his first volume on mathematics titled, *Mosdei Hokhma* (*Foundations of Wisdom*) in 1834 with rabbinic approbations (Robinson 1983). In 1838, he published a book on astronomy entitled *Toldot Ha-shamayim* (*The Heavenly Hosts*). He was one of the first to explain that the six days of creation are really six eons and therefore came closer to the ideas of the geology of the time than those relying on Biblically based calculations for the Earth's origins (Robinson 1983). In sum, Slominski looked for synthesis between science and rabbinic literature.

In Western Europe, however, Jewish thinkers seem to have been quicker to accept this new worldview. Raphael Halevi of Hanover (1685–1779 CE) a mathematician and philosopher, who had studied with Leibnitz, published two books in astronomy in 1756 CE. In his *Tekhunat Ha-Shamayim* (*Astronomy of the Heavens*), he openly embraces the Copernican system. It is of interest that Rabbi Landau read this work and quoted from it, without adopting this position (Brown 2008). Similarly, Joseph Ginsburg in his *Ittim La-Bina* (*Wisdom of our Days*) explained that one could accept the Copernican model and remain a faithful Jew. Dov Ber Rukenstein in his two-part series on astronomy entitled *Mesilot Ha-Meorot* (*Pathways of the Heavenly Bodies*) (as cited in Robinson 1983) talked of Copernicus' model as being accepted by all scientists of his day. Therefore, writing in the late nineteenth century, Rabbi Samson Raphael Hirsch could say:

> What Judaism does consider vitally important is the acceptance of the premise that all the hosts of heaven move only in accordance with the laws of the one, sole God. But whether we view these laws from the Ptolemaic or Copernican vantage point is a matter of total indifference to the purely moral objectives of Judaism. Judaism never made a credo of these or similar notions (Hirsch 1992, p. 263).

54.2.4.2 Cosmogony (Including Evolution)

In classical Jewish philosophy, Aristotelian physics and cosmology were seen as a challenge, rather than as an overt threat; thus, although being diametrically opposed to the book of Genesis, great effort was invested in order to reach a synthesis between the Aristotelian theory of the eternity of the universe and the Biblical creation narrative. In the twelfth century, Maimonides in his *Guide for the Perplexed* took great pains to explain how one can explain creation with the same Aristotelian hypothesis but with some alterations.

In the nineteenth century, rabbinic thinkers dealing with the new theories of cosmogony and particularly evolution acted in a similar same way. Orthodox Rabbi Israel Lipschutz of Danzig was a learned legalist who had a great interest in the science. Writing in the 1800s, before Darwin's *On The Origin of Species* was published, Lipschutz was familiar with the "evolutionary" theories of Lamarck. Rather than seeing the new theories as a threat to Biblical belief, he sees the idea of an ice age and the regeneration of life as a proof for the Jewish belief in the eventual resurrection of the dead. No criticism of the theory can be found in his writings, just a great enthusiasm that science is now proving the age old Kabbalistic theory that there were earlier worlds than ours (Shuchat 2005).

In the post-Darwinian world of the nineteenth century, there was still no major change. Jewish thinkers like Rabbis Elijah Benamozegh of Italy and Samson Raphael Hirsch of Germany, writing at the same time that the Church and the scientists of Europe were battling each other verbally, did not see evolution as a major threat to Jewish belief. For example, Rabbi Hirsch writes:

> Judaism is not frightened even by the hundred of thousands and millions of years which the geological theory of the earth's development bandies about so freely. Judaism would have nothing to fear from that theory even if it were based on something more than mere hypothesis, on the still unproven presumption that the forces we see at work in our world today are the same as those that were in existence, with the same degree of potency, when the world was first created. Our rabbis, the Sages of Judaism, discuss [Bereshit Rabbah 9, 2 and Mishna Hagigah 16a] the possibility that earlier worlds were brought into existence and subsequently destroyed by the Creator before He made our own earth in its present form and order. However, the rabbis never made the acceptance of this and similar possibilities an article of faith binding on all Jews. They were willing to live with any theory that did not reject the basic truth that every beginning is from God (Hirsch 1992, p. 265).

Rabbi Elijah Benamozegh (1862) saw the new scientific discoveries as proving the Midrashic and Kabbalistic notion of earlier worlds which God created before our own:

> In conclusion, this belief in earlier worlds is an ancient one in our nation and it stands as a proof for the divine nature of the Torah, which natural science now confirms. . . . And I finish [this discussion] with the dear words of the scholar in the Kuzari [1, 40] who said: 'If a believer in Torah had to admit to the existence of primordial matter of earlier worlds that predated us, this would not blemish our faith' (Benamozegh 1862).

In addition, Benamozegh saw the new theories of evolution as a proof of human potential and ultimately of the resurrection:

> I believe, as science teaches, that animal forms appeared on the earth and evolved into more perfect beings, either as Cuvier said, by revolutions and cataclysms, or by slow evolutionary processes, like the opinion of the modernist Lyell, or Darwin and others. More and more perfect species have developed, one after the other, over the course of millions of years on the face of the earth. The most perfect form is Man. But will nature stop here? This would indeed be strange. Present humankind, as Renan [French expert of Middle East ancient languages and civilizations] says, will evolve into another, more perfect human being. But Renan and the others stop here. They do not say that the order that reigns in the physical world has to reign in the moral one as well, and that there is no reason to believe that the 'I' that force which created the actual human, does not have to create the future human as well. They do not say that the 14 monads, the atoms, which are minuscule forces, are indestructible (as science teaches) for it is inevitable to believe that they will compose the future Man on a regenerated earth. All this is stated by Judaism, and is called the Resurrection (Benamozegh 1877, pp. 276–277).

Similarly, Rabbi A. I. Kook's writing in the early twentieth century also displayed an optimistic view of evolution claiming that it is closer to the Kabbalistic notion of creation than the philosophical idea of creation ex nihilo.[12] Despite this enthusiasm in his more philosophical writings, in his public letters, Rabbi Kook writes more cautiously. After explaining to a correspondent why the new theories of evolution do not contradict the Torah, he writes:

> We do not have to accept theories as certainties, no matter how widely accepted, for they are like blossoms that fade. Very soon science will be developed further and all of today's new theories will be derided and scorned and the well-respected wisdom of our day will seem small-minded Feldman (1986, p. 6).

Continuing this trend, Rabbi Isaac Halevi Herzog (the first chief rabbi of Israel), writing in the mid-twentieth century, displayed the discomfort that many later rabbinic figures were to have with the theory of evolution. This discomfort was caused not just by the challenge which this theory posed to Biblical exegesis but by the fact that it was considered to be one of the paradigms of modern secular scientific thought, which many of these rabbinic figures felt was in opposition to all organized religion (Robinson 2006).

Some rabbis of the second half of the twentieth century began, like their Christian contemporaries, to see the theory of evolution as a threat. As Orthodox Jews entered the arena of the sciences, many of them entered the battle against evolution, arguing from a scientific standpoint, rather than a Biblical or Talmudic point of view, and looked to those who opposed evolution as their comrades in arms (Cherry 2006). Rabbi Herzog's attempt to look for ways to harmonize the simple meaning of Genesis 1 with evolution without the multitude of rabbinic commentaries reflects this new attitude:

> How can the Torah chronology be scientifically defended, in view of the aeons which science postulates for the existence of man upon this earth? There is, of course, the well known Midrash, 'boneh olamotu-maharivan' [he built his worlds from annihilation] [Midrash Genesis Rabbah 3, 7; Ecclesiastes Rabbah 3:11], but this can only help if we assume that "maharivan" does not mean annihilation, so that we can assume that fossils of man asserted by science to be so many hundreds of thousands of years old are relics of a previous earth. Yet anthropology seems to assert upon internal evidence that the present man is already hundreds of thousands of years old! […] Of course, strictly literal interpretation of the Pentateuchal text is out of the question. But super literary interpretation should be resorted to only when reason absolutely rules the literary sense being utterly impossible… (as cited in Shuchat 2008–2009, p. 155).

Rabbinic scholars are not detached from the world around them. During periods of social turmoil, when the thinkers of the age begin to doubt the validity of the scientific order of the day, Jewish thinkers do so as well. The events of the Second World War proved both the supreme power of scientific technology as well as the threatening implications of the misuse of that power. The subconscious social impact of the atom bomb attacks on Japan and a war that used modern technology to claim millions of lives cannot be underestimated. Although faith in science

---

[12] The kabbalists had a different take on creationism seeing it more as an act of emanation rather than creation ex nihilo. They also differed on the question of the time that it took to create the universe (Shuchat 2009).

remained unscathed for the first decade and a half after the war, and the scientific community emerged from the war with enhanced prestige, these events planted the seed for the disillusionment with science, in general, and more specifically evolution that put it on the defensive in the 1960s and 1970s (Ben-David 1991).

The technological boom of the nineteenth and early twentieth centuries led to a belief in the omnipotence of science, and religious fundamentalist voices against the theory of evolution were stifled, out of respect for science; by the 1970s, however, attacks on science gained legitimacy, and the popular reaction to science was now a mixture of enthusiastic support and profound mistrust (Ben-David 1991).

In the Jewish world, a second element contributed to increased disdain for science. After the destruction of European Jewry, including all major institutions of Jewish learning and culture, some of the Orthodox rabbinic leadership did everything possible to hold on to what remained and held suspect any new way of thinking that might pose some type of threat to religious survival. These feelings of suspicion towards all new ways of thinking became more manifest in the seventies, as society as a whole became critical of science. As a result, the late twentieth century saw the Jewish attitude to science take on different voices. The theory of evolution, in particular, which was seen as one of the paradigms of modern, secular (scientific) thinking, became representative of how various elements in Judaism see religion and science. The syntheses of classical Jewish philosophy were therefore at times forgotten.

Approaches of Reform and Conservative Thinkers Towards Evolution in the Twentieth Century

The historical picture for Judaism in the nineteenth and twentieth centuries becomes even more complex with the rise of non-Orthodox movements in Europe, which eventually made their way to North America in the late nineteenth century. The non-Orthodox rabbis of the early twentieth century were very committed to finding a way to synthesize between science and Judaism, specifically the modern theory of evolution. The theological debates, which arose in light of the Scopes trial in 1925 over the legality of teaching evolution in public schools in Tennessee (Numbers 1998), generated a discussion among leading Reform rabbis in the United States of how to treat this sensitive issue.

The view of Reform rabbis of the 1920s was identical to their predecessors, Rabbis Kaufmann Kohler and Emil Hirsch of the late nineteenth century, in their belief that fundamentalists had erred in understanding the first verses of Genesis, literally, and in assuming that evolution denied a creator (Swelitz 2006). They argued that Genesis is not a textbook for science and literal interpretations of it were not acceptable. Reform rabbis went as far as claiming that progressive change and design were an inherent part of evolution and therefore provided a case for God as a creator (Swelitz 2006). In the 1930s, Rabbis Cohon, Brickner, and Felix Levy saw the new physics as supporting the view of intelligent design making the evolution of life possible (Swelitz 2006).

Conservative rabbis in the 1920s and 1930s like Levinthal and Finkelstein took the same position as the Reform on this issue (Swelitz 2006). Rabbi Mordecai Kaplan was somewhat of an anomaly at this point adopting a naturalist approach to God that disregarded the theological arguments leading from evolution to God.

In the postwar era of the 1950s and 1960s, Reform Rabbi Emil Fackenheim, Rabbi Abraham Joshua Heschel of the Jewish Theological Seminary, and theological scholar Will Herberg believed that an excessive reliance on science and reason had distorted the proper understanding of Judaism (Swelitz 2006). No evolutionary argument can explain a personal God. It is necessary to demarcate the boundaries between science and religion, they argued.

By the end of the 1960s, evolution was generally ignored by most among the Conservative and Reform, except in the writings of Reform Rabbi W. Gunther Plaut. This position, separating science from religion, was challenged by Reform Rabbis Levi Olan and Roland Gittelsohn and Conservative Rabbi Robert Gordis, who defended the centrality of reason and science in Jewish theology. Gittelsohn was personally interested in evolutionary biology and advocated what he called "religious naturalism" invoking the new science to aid one in proving the existence of God (Swelitz 2006). Gordis shared Milton Steinberg's belief that religion has to provide a philosophy of life which includes the conclusions of science.

In the 1980s there was a renewed interest in evolution, with the attempt by creationists in the United States to gain equal time in public schools for teaching Biblical creation. However this time, Reform rabbis, like William Leffler and Jack Luxemburg, maintained the need to emphasize the limitations of science in proving or disproving God (Swelitz 2006). This apparent divorce of science from religion in the 1980s was followed by evolution reentering Jewish theology with the renewed interest in Kabbalah. The idea of cosmic evolution was adopted by Reform Rabbi Lawrence Kushner as well as Rabbi Zalman Schachter-Shalomi of the Jewish Revival Movement and Prof. Arthur Green.

Approaches of Ultra and Modern-Orthodox Thinkers Towards Evolution in the Twentieth Century

Turning to the postwar Orthodox world of North America, we see that the situation was different. It was mentioned previously that Rabbi Herzog was hesitant in utilizing the rabbinic notion of earlier worlds and preferred to see if there were scientists who held other views. The second half of the twentieth century saw Orthodox responses to evolution, which were much different than those of the late nineteenth and early twentieth centuries. The ultra-Orthodox saw evolution as representing a secular alternative to the religious weltanschauung and therefore saw it as stepping over its legitimate boundaries. Rabbi Moses Feinstein claimed that

> Textbooks of secular studies that contain matters of heresy with respect to the creation of the world… are forbidden to be taught…If it is not possible to obtain other books, it is necessary to tear out those pages from the textbook (Feinstein 1982).

More modern-Orthodox thinkers looked for inroads to recreate the syntheses of earlier days. Like his predecessor Rabbi Herzog, Rabbi Aaron Lichtenstein wrote in the late twentieth century:

> Confronted by evident contradiction [between Torah and science] one would… initially strive to ascertain whether it is apparent or real… whether indeed the methodology of madda [science] does inevitable lead to a given conclusion, and … whether… Torah can be interpreted… so as to avert a collision (Robinson 2006, p. 78).

An interesting phenomenon that developed in the second half of the twentieth century, with the entry of Orthodox Jews into Western universities, was the place of the Orthodox Jewish scientist. In 1948, some of these scientists founded a group they called the *Association of Orthodox Jewish Scientists* (AOJS). One of its aims was to resolve "apparent challenges of scientific theory to Orthodox Judaism" (Robinson 2006, p. 79), and evolution, specifically, was an important issue that they needed to deal with.

In the late twentieth century, three Orthodox Jewish physicists can be seen as representing three different approaches to evolution: Prof. Hermann Branover, Prof. Nathan Aviezer, and Prof. Gerald Schroeder. The American-trained Prof. Aviezer (1990) of Bar-Ilan University in Israel, in his work *In the Beginning*, took a nonliteral attitude to the 6 days of creation, seeing them as epochs rather than days of 24 h, but then continues to read into the literal text a novel interpretation in which he claims that the main elements of the Biblical story harmonize with all the main elements of modern scientific cosmogony (Cherry 2006). Aviezer also takes a non-chronological reading of the creation story in which he sees the 6 days of creation as representing two stages: days 1–4 which represent the formation of the structure of the universe and days 5–6 which represent the inhabitants of the universe which begin while the universe is being formed.

The second approach is from another American-trained physicist from Israel, Gerald Schroeder. Schroeder (1998) accepts, as does Aviezer (2002), the evolutionary timetable; however, in a novel literary hermeneutic, he claims that the 6 days of creation were 6 days of 24 h, but claims that according to Einstein's theory of relativity and time dilation, from the perspective of the forward rushing cosmos ("God's perspective"), 6 days is equivalent to 15 billion years looking backwards.

A third perspective is that of Russian-educated Prof. Hermann Branover of Israel. Associating himself with the ultra-Orthodox Hassidic community of Lubavitch, he holds a literalist view of the creation story. He uses alternative scientific views to argue against scientific evolution.

Ultra-orthodox groups such as the Israeli outreach organization "Arachim" feel more comfortable with these more aggressive fundamentalist anti-evolution positions. The open attacks of these fundamentalists against scientific thinking have gone so far as to find among them those who now are even questioning again Copernican heliocentricity in the twenty-first century. Moderate elements in the ultra-Orthodox world, such as the Aish Hatorah outreach organization, see Schroeder's position as saving both creationism and science, whereas modern-Orthodox Jews feel comfortable with Aviezer's ideas or just accept a nonliteral interpretation of the creation story (Sacks 2011).

Evolution aside, mainstream Orthodox Jewish rabbinic thinkers tend to adopt a generally positive attitude to science. This view of the legitimacy of science to overcome the Biblical curse of the ground mentioned earlier or to heal the sick is the age-old Jewish view which sees the idea of scientific progress as a way of mending the world when used for the good.

54.3 Historical Summary

This brief historical overview shows a somewhat complicated relationship between Judaism and science, but certain tendencies can be deduced from it. As we have seen, from earliest times, technology was seen positively as something that can help mankind overcome the difficulties of life. The Talmud praises the study of astronomy and sees biology and medicine as legitimate fields of study. The Jewish rationalists of the middle ages, especially in Spain, were particularly open to general studies and well versed in the sciences, medicine, and philosophy of their day.

The debate over philosophy in the post-Maimonidean era seems to have been more of an attack against lax observance, as well as the non-Orthodox ideas of the rationalists, than a ban on science per se. Philosophy was often seen as the culprit which brought in foreign ideas to Judaism. This same style of controversy can be seen in the middle to late nineteenth century Eastern Europe between the secular exponents of the Haskalah (or enlightenment) and their rabbinic counterparts.

The late nineteenth century saw the rise of Darwinian evolution and its entrance into Jewish thinking. Early thinkers until the First World War had an open and even accepting attitude, but in the post Second World War period, suspicion arose and the fear of foreign elements challenging Jewish faith renewed the debate over the relationship of science and Judaism. Most modern orthodox, as well as well as almost all Conservative and Reform thinkers, showed an attitude of acceptance; in contrast, the postwar ultra-Orthodox camp, suspicious of most modern concepts, showed antagonism to these ideas, even if they did not oppose the study of the sciences for the need of a livelihood or to practice medicine. Jewish educators abroad and in the educational system of the State of Israel struggle to this day to accommodate these different philosophical approaches, as we will see in the next sections of this chapter.

54.4 Philosophical Approaches Towards the Interaction Between Science and Judaism

Our brief historical survey confirms what Efron (2007) previously noted about the attitudes of Jewish thinkers towards science, in that historically it was "never subject to consensus." Certainly, we have seen that there were specific periods and regions where (rabbinical) authorities were worried about how secular science might affect Jewish piety and so strongly opposed contact with secular learning, including science, or specific scientific disciplines. At the same time, Judaism has often looked positively upon science, and its precursor, the study of nature and astronomy in antiquity, not just in its applied form where it benefits man's ability to derive a living or protect one's health but also in order to gain a better understanding of the natural world.

Moreover, Efron (2007) suggests that Judaism has avoided many of the science-religion clashes that have occurred among the Christians. In part, this was due to the fact that Jews never developed institutions with the coercive power to declare an idea or a book to be an anathema.[13] More importantly, in his view, the long exegetical tradition within Judaism of reading and interpreting texts meant that Jews by their nature did not sanctify the ideal of consensus. In fact, Jewish exegetes actively sought to multiply interpretations to arrive at deeper understandings of a text. Indeed, we can see this tradition of multiple interpretations operating in our brief historical review in the previous section of this chapter.

Thus, even if there might have been a mainstream trend during any period of Jewish history concerning how Judaism saw science, or any of its disciplines, from a practical viewpoint, rather than looking for consensus, it is better to discuss a spectrum of philosophical approaches that were developed to classify the (multiple) positions of Judaism towards science. In this section, we will discuss these approaches in order to create a set of definitions that can be applied to our discussion about Judaism and its interaction with science education.

Much of the work dealing with the philosophical interaction between religion and science has focused on Christian perspectives. The four most comprehensive works on this interaction include the books of Barbour (1997), Brooke (1998), Haught (1995), and McGrath (1999).

Among sources dealing with Judaism's interaction with science, there are two comprehensive works: Lamm's (2010) *Torah Umadda* and Rosenberg's (1988) *Science and Religion in the New Jewish Philosophy* (published in Hebrew). Both works are important but emphasize different approaches. Lamm's (2010) work is somewhat broader in that it deals with how Jewish thought has dealt with worldly knowledge, in general, rather than just science, which is Rosenberg's focus. From a practical perspective, Rosenberg's (1988) work has been used in a number of science education studies to classify the positions held by religiously Jewish teachers (Dodick et al. 2010) and students (Allouch 2010) in Israeli schools, and so we will examine his approaches here, as a precursor to our discussion of science education; nonetheless, whenever possible, we will integrate Lamm's (2010) discussion.

In structure, Rosenberg's (1988) approaches are somewhat similar to those mentioned in Barbour (1997) albeit the number of categories he developed was larger. Moreover, both Rosenberg (1988) and Lamm (2010) develop a set of approaches or models based on Jewish thinkers and their interpretation of classical

---

[13] One of the most famous historical examples of the use of coercive power in the Christian world was the Church's imprisonment of Galileo as a heretic in 1613 for his support of the heliocentric theory. Bronowski (1973, p. 218) argues that "the effect of the trial and the imprisonment was to put a total stop to the scientific tradition in the Mediterranean."

Jewish texts (such as the Talmud and Midrash) which contrasts with Barbour's approach in which he delineates a set of historical-based Christian attitudes towards science. Thus, Lamm (2010) and Rosenberg (1988) provide us with greater insight than Barbour (1997) when we examined science education and its interaction with Judaism. In his book, Rosenberg (1988) talks about four main approaches.

54.4.1 Limiting Approach

This approach opposes any attempt at integrating secular knowledge with Jewish thought. From this point of view, such a mixture creates the chance that heresy may infect the student of Torah; therefore, from a practical perspective, there was no room in the curriculum of a Torah student for such lesser knowledge (Lamm 2010). When faced with a scientific approach to problematic issues such as creation, those adopting this approach reject the scientific approach, as it challenges the primacy of the Bible's literal meaning. An example of this approach can be found in the writings of the late Rabbi Menachem Schneerson the former leader of the Lubavitch Hassidic movement in his commentary concerning geologic time and evolution:

> In view of the unknown conditions which existed in prehistoric times (atmospheric pressures, radioactivity) conditions which could have caused reactions of an entirely different nature and tempo from those known under present-day processes of nature, one cannot exclude the possibility that dinosaurs existed 5,722 years ago, and became fossilized under terrific natural cataclysms in the course of a few years rather than millions of years (Schneerson 1972).

In philosophical terms, Rabbi Schneerson (1972) was rejecting the principle of uniformity which states that the laws of nature remain unvarying throughout time. This approach to secular learning, in general, and science specifically is most common among the ultra-Orthodox. Such explanations also *seem* to match most closely with a Christian fundamentalist view of religion and its relationship to science, most notably those issues connected to creation and evolution.[14]

54.4.2 Explanatory Approach

In this approach, Biblical texts are not understood literally, but rather are explained so that religion and science can be brought closer together. Contradictions are

---

[14] Regarding evolution, Robinson (2006) argues that care should be taken in blindly comparing ultra-Orthodox attitudes to fundamentalist Christians too closely. The ultra-Orthodox are united in their opposition to Christian creationism as it is based on the King James Bible and not on traditional Jewish texts, which incorporate the cumulative perspectives obtained from (a large number of) traditional Torah commentaries and interpretations. In fact, Robinson (2006) could only find one source written from an ultra-Orthodox perspective whose author identifies as a creationist. Thus, at least in philosophy, if not deed, the ultra-Orthodox do differ from fundamentalist Christians.

viewed as a misunderstanding of the Bible and simply require proper interpretation. For example, with regard to the Earth's age, some Jewish Biblical commentators explain that the days of creation went far beyond a 24-h period of time, or as Rabbi Abbahu states in the Midrash that "God created [many] worlds and destroyed them until he created this one" (Rabba Bereshit, 3, Sect. 7). Thus, according to this interpretation, there were cycles of destruction and creation culminating in this world, such that the age of this world far exceeds the 6-day period of creation.

Among the most important exponents of the explanatory approach was Maimonides. More than that, his attitude to secular studies, in general, was not just that it was permissible but that there was an "obligation to pursue them as an act of mitzvah" (i.e., religious command) (Lamm 2010, p. 67).

54.4.3 Parallel Approach

This approach sees contradictions between science and religion as being derived from not clearly separating between the domains, as the former deals with rational explanations of nature, while the latter focuses on religious belief which illuminates human purpose, meanings, and values. Each domain has value for human experience, but they should not be integrated. Scientist and philosopher Yeshayahu Leibowitz is a noted exponent of this approach:

> There is no mutual dependency between scientific knowledge and decisions about [religious] values. What can the immense achievement of science contribute to these decisions on values? Science cannot contribute anything because concerning the problem addressed by these decisions, such as to be a believer, not only does science have nothing to contribute, but these questions cannot even be posed because these concepts do not appear in the lexicon of science (Leibowitz 1985, p. 35).

Historically, one of the more important exponents of the parallel approach in the Jewish world of education is Rabbi Samson Raphael Hirsch's Torah Im Derech Eretz ("Torah with secular knowledge") (Lamm 2010) whom we discussed previously. This approach also represents, as we have seen, the position of Reform Rabbi Emil Fackenheim, Rabbi Abraham Joshua Heschel of the Jewish Theological Seminary, and the theological scholar Will Herberg. Philosophically, the parallel approach is also equivalent to scientist Stephen J. Gould's (1997, 1998, 1999) principle of "respectful noninterference" between the worlds of science and religion or *NOMA* (Nonoverlapping Magisteria).

54.4.4 Complementary Approach

This approach suggests that science complements religion, creating a synthesis of the sacred and secular. Supporters of this approach see a strong (though not necessarily literal) fit between scientific discoveries and what is described in the Bible (Lamm 2010). This approach is personified by Rabbi A. I. Kook who viewed the theory of evolution as a model for spiritual growth; thus, he did not see it posing a threat to religion:

> The theory of evolution that is presently gaining acceptance in the world has a greater affinity with the secret teachings of the Kabbalah better than all other philosophies. Evolution which proceeds on a course of improvement offers us the basis for optimism in the world. How can we despair when we realize that everything evolves and immediately improves? In probing the inner meaning of evolution toward an improved state, we find here an explanation of the divine concepts with absolute clarity. Evolution sheds a light on all the ways of God (Kook 1938, p. 555).

54.4.5 Conflict Approach

This approach was not found in Rosenberg (1988), but it emerged as a consequence of interviews that were held by Dodick et al. (2010) with religiously observant Jewish teachers (in the Israeli high school system) and scientists (in the Israeli university system); it was therefore added to the taxonomy used by Dodick et al. (2010) to classify the philosophical approaches of religiously oriented, Jewish teachers and scientists. Conflict emphasizes the understanding that there sometimes exists a contradiction between science and religion because of the overlap between the two domains such as occurs with evolution. Such conflict largely arises because of the open, unanswerable questions that occur due to this overlap. Nonetheless, although some are affected by this conflict, they are willing to live with the situation and do not reject science as is the case with the limiting approach.

54.5 Judaism and Its Interaction with Science Education

In discussing Judaism and its interaction with science education, it should be understood that prior to the emancipation period in Europe, Jewish contact with general secular learning and science learning, specifically, was largely limited to those rabbis who approved of and conducted such learning (Efron 2007). Thus, it is impossible to talk of the interaction between Judaism and science education on a large scale before that time period. Even post-emancipation, there is no published research dealing with science education until we enter the twentieth century. Therefore, we will confine our discussion to recent times because all of the education research that has been conducted on this topic has been done in the last 20 years or so.

Unfortunately, there are only a small number of studies dealing with the interaction between Judaism and science education, especially when compared to the larger number of studies from a Christian perspective. This is due to a number of interrelated factors. Most science education studies dealing with the interaction between science and religion emanate from Western countries, where the dominant religious background (measured by population) is Christian. Therefore, by default, such studies are strongly flavored by a Christian perspective because the majority of school-age students come from a Christian background.

Hence, if we are to understand how Jewish attitudes towards science influence science education, we need to discuss the situation where Jews represent the majority and thus influence the school system. If we are talking geographically, we must focus on Israel, the only country with a Jewish majority. If we are talking systemically, we can also include the extensive private Jewish school systems that have developed in Western countries, most notably in the United States, which contains the world's second-largest Jewish population after Israel (DellaPergola 2010).[15]

Historically, for those groups of Jews who were not opposed to the integration of secular knowledge into the Jewish domain, the scientific issues that are most challenging to Judaism emanate from subjects touching upon Biblical creation including cosmology, geologic time, and most notably evolution. Not coincidentally, these issues have also had the greatest impact on the interaction between Judaism and science education, and it will be a discussion of these conflicts that will dominate this chapter.

However, before analyzing this conflict, we must discuss Jewish school systems, both within and without Israel, because their structure affects how controversy is dealt with. Indeed, school systems that serve the Jewish public are guided by a specific religious philosophy and in turn this philosophy guides the school system's interaction with secular subjects such as science, so it is important that we discuss their basic structures.

In Israel, the school system is divided between Hebrew and Arabic speakers. The two largest divisions among the Hebrew-speaking system are the Secular State and National Religious systems, respectively (Dodick et al. 2010). The Secular State system teaches a population of primarily secular and traditional students with many of its teachers coming from secular backgrounds. Its matriculation system is designed so that students have the possibility for continuing to higher academic studies. The only component of "religion" in this system is that the Bible is one of the core subjects (and is taught as part of the cultural background of Israel, and not from a religious perspective).

In contrast, the National Religious school system's philosophy is to integrate secular and (Orthodox-based) religious studies, making it possible for its students to pursue both secular studies at a university and religious studies at a Jewish seminary.[16] Many of the teachers are religious in orientation and have a professional background from a university, college, or seminary, depending on the subjects they teach.

A third system of schools in Israel, termed independent, focuses exclusively on the ultra-Orthodox population. For male students, the focus is on religious studies with little to no secular studies, including science learning; the ultimate goal is to prepare them for higher religious studies in a *Kollel*.[17] There is more flexibility in

---

[15] Of the approximately 13.5 million Jews in the world in 2010, Israel's Jewish population accounted for 42.5 %, and the United States' Jewish population accounted for 40 % of the total (DellaPergola 2010).

[16] Philosophically, Israeli-based National Religious schools are most similar to modern-Orthodox day schools outside of Israel.

[17] A Kollel is a Yeshiva learning program for married men.

the education of the female population who study secular subjects, including some subjects in science, out of a practical need to secure their families' financial futures. However, studies in the female ultra-Orthodox system do not usually lead to higher academic learning.

Outside Israel, concerns about inculcating youth in the practices and religious literature of Judaism spurred on the development of private "day" schools as well as afternoon schools, among the various denominations of Judaism in many Western countries. Day schools offer a "dual" curriculum, offering a secular program including science and math, as well as course offerings in traditional Jewish subjects such as the Bible, Hebrew, and Jewish history. With the exception of ultra-Orthodox schools, secular subjects share equal time with religious subjects including science (as part of a longer school day). This means that the majority of graduates from (k-12) Jewish-based schools are well displaced to tackle higher education, if they so desire. Afternoon schools offer various Jewish subjects and are attended by students who attend secular schools during the day.

In the case of the ultra-Orthodox within Israel (as well as sometimes outside of it) secular learning is (largely) omitted for its male population because religious subjects take priority; all the more so, scientific issues of creation are not taught because they challenge the belief in God's creation. In simple terms, they have strongly adopted a limiting philosophical approach. In the exact opposite way, scientific issues of creation pose much less difficulty to the liberal branches of Judaism, including the Conservative and Reform movements[18]; thus, they are taught as a usual part of the science curriculum.

However, the situation is different within modern-Orthodox schools. Although most are committed to a *Torah Umadda* (*Torah and Science*) philosophy, which believes in the integration of religion and secular learning, creation issues can test that resolve, creating conflict, so this group will be a prominent feature of our discussion.[19]

We begin this discussion by examining both the philosophical approaches of the schools and the teachers that work within these schools. We start here, because the roots of students' approaches to the conflict between science and religion are

---

[18] As we have seen, Swelitz (2006) extensively explored the historical responses of Conservative and Reform rabbis towards evolution. Using Rosenberg's (1988) system, their responses can be classified as falling within the parallel, explanatory, and complementary approaches. They do not adopt a limiting approach, in contrast to some among the Orthodox. Looking at the Conservative movement today, although they appear to have no official position, many of their Rabbis have adopted the idea of theistic evolution. Rabbi David Fine, who has authorized official responsa for the Conservative movement's committee on *Jewish Law and Standards*, expressed this idea as the following: "Did God create the world, or not? Is it God's handiwork? Many of the people who accept evolution, even many scientists, believe in what is called 'theistic evolution,' that is, that behind the billions of years of cosmic and biological evolution, there is room for belief in a creator, God, who set everything into motion, and who stands outside the universe as the cause and reason for life" (http://www.jewishvirtuallibrary.org/jsource/Judaism/jewsevolution.html).

[19] It will also be seen that almost all of the empirical studies that examine the relationship between Judaism and science education focus on the modern Orthodox, so this is another reason for this focus.

strongly shaped by how they understand science, its nature, and its relationship to religion and it is the schools and their teachers that most strongly shape this understanding. It might also be added that school choice both reflects and is influenced by informal sources – parents and religious authority.

Outside of Israel, Selya (2006) has completed the only major study concerning modern-Orthodox day high schools and their perspectives towards evolution. Surveying 12 such schools in the United States and Canada, she discovered four approaches for teaching evolution (that largely match the philosophical approaches of Rosenberg 1988). These approaches include curricula where evolution is taught in class without a religious discussion, whatsoever (parallel approach). In other schools, teachers teach evolution with the aid of a religious teacher or rabbi who interprets the creation story either in a nonliteral way (explanatory) or from an intelligent design perspective (limiting/complementary). A third perspective is assigning students' readings on evolution without discussing them in the class (sometimes because it was part of the mandated final year examinations) (parallel approach). Finally, evolution was not taught at all (limiting approach).

There were no instances of substituting a creation-science curriculum to replace the standard biology texts or of school administrators removing the chapter from the science textbooks as reported by Wolowesky (1997) and Landa (1991); the latter, as we have seen, was recommended by Rabbi Feinstein (1982), one of the most important ultra-Orthodox rabbinic decisors of Jewish Law in the twentieth century.

Selya (2006) showed that ten of the schools surveyed taught evolution in the classroom and that eight of them suggested that this scientific theory was religiously compatible. Not surprisingly, schools that separated the sexes, a sign that a school is more religiously oriented, either did not teach evolutionary theory or criticized it as being incompatible with religion.

As part of this research, Selya (2006) also interviewed teachers and administrators at five of the schools, all of which were coeducational, with strong college preparatory programs, and which both teach evolution and stress its compatibility with religion. All of these schools share certain philosophical and/or historical roots, including a commitment to the Torah Umadda philosophy. Three of the schools were founded by prominent rabbinic figures, one of whom was Rabbi Joseph Soloveitchik who is considered to be the unofficial leader of modern Orthodoxy during much of the twentieth century.

In sum, Selya's (2006) survey seems to show that evolution is being taught in some form in the majority of modern-Orthodox day schools. However, caution should be applied to her small-scale survey, as in the United States (alone), there are 86 schools, accounting for more than 27,000 students, classified as being modern Orthodox (Schick 2009).

Although further studies, like Selya (2006), are needed, Schick's (2009) demographic studies of Jewish day schools in the United States indirectly may point to a trend of increased resistance to science subjects that are considered to be controversial, such as evolution, among Orthodox Jews. Although the numbers of students increased in modern-Orthodox schools from 1998 to 2009, the number of students that were learning in ultra-Orthodox schools increased at a much faster rate. This is due to the much higher birth rate of the ultra-Orthodox which is more than twice that of the modern Orthodox.[20] And if the school is based on an ultra-Orthodox philosophy, it is more than probable that evolution was not part of their science curriculum.

Moreover, among the modern Orthodox, there are factors that indicate some of its adherents are moving towards ultra-Orthodoxy, a process Waxman (1998) labeled "Haredization" (based on the Hebrew term for ultra-Orthodox). This phenomenon has been documented over a 20-year period by a collection of historians and social scientists.[21] A small (educational) indicator of this shift is the fact that *Torah Umesorah*, the National Society of Hebrew Day Schools, an umbrella organization that provides educational materials to Orthodox schools is increasingly distancing itself from coeducational institutions, which is one indication of increased religious practice.

There are many reasons for this shift, but the most important factor for science education is the increasing number of ultra-Orthodox Jewish teachers who are now teaching in modern-Orthodox schools (Heilman 2005; Helmreich and Shinnar 1998). As most in the modern-Orthodox world have avoided teaching, due to its lower remuneration and lack of prestige in comparison to many other professions, the modern-Orthodox school system has turned to ultra-Orthodox teachers (especially for its Jewish studies departments), which in turn affects the philosophy of the schools and their students (Heilman 2005; Helmreich and Shinnar 1998).[22]

Inside Israel, research has focused on teachers within the National Religious system, rather than the school as the unit of analysis. Such research has importance because teachers, like the schools they teach in, are one of the most critical factors influencing the balance between Judaism and science education. We say this because, as Rutledge and Mitchell (2002) have noted, teachers' attitudes and views about a subject directly influence their instructional decisions on how to teach a subject. Their research shows that teachers' background in the philosophy of science and knowledge of evolution influences their acceptance of and willingness to teach evolution. One would assume that a similar relationship exists for scientific subjects that are considered to be challenging to Judaism.

In a similar vein, Dodick et al. (2010) surveyed teachers in the National Religious school system to understand their philosophical approaches towards the interaction between Judaism and science. In total, 56 teachers were extensively surveyed using a Likert-type questionnaire developed for this research, which surveyed the

---

[20] As Schick (2009, p. 12) notes, "In the 1998 census, I reported that there were 3.26 children in the families of Modern Orthodox eighth graders as compared to 6.57 and 7.92 children respectively in yeshiva-world and Hassidic families."

[21] Friedman (1991), Heilman (2005), Helmreich and Shinnar (1988), Liebman (1988), Soloveitchik (1994), and Waxman (1998)

[22] Heilman (2005, p. 265), based on a personal communication with Schick, who has completed a series of demographic studies on Jewish day schools in the United States, claims that "nearly two-thirds of today's Judaica teachers in day schools come from the haredi [ultra-Orthodox] world."

teachers' approaches to the nature of science in general, geologic time, cosmology, and evolution. Eleven of the teachers were also randomly selected for interviews.

Additionally, 15 (Orthodox) scientists from the major branches of science were surveyed with the same instruments to both contrast their views with the teachers, as well as to better understand their coping strategies when confronted by scientific topics that challenge their beliefs. In the cases of both teachers and scientists, their philosophical approaches were classified according to Rosenberg's (1988) typology.

Results indicated that no single philosophical approach earned an overwhelming support from the teachers or scientists. Instead, the teachers and scientists related separately to each source of possible conflict, such as evolution, in accordance with the philosophical approach that appears to be the most fruitful for resolving a specific conflict.

The teachers did differ from the scientists in their stronger preference towards philosophical approaches which help them better integrate the domains of science and religion. Thus, the teachers favored the explanatory and complementary approaches, whereas the scientists most preferred the explanatory and parallel approaches. Possibly, the teachers favor an integrative approach because they prefer answers that avoid delivering an open, contradictory message to their students and through them to their parents and school administrations.

With regard to the scientists, tenured in academia as they are, they have the security to research issues that are both open and controversial. This also explains why some scientists adopted a conflict approach (their third most favored approach), as they acknowledge that some problems are open and (currently) unsolvable, while concurrently accepting the inherent contradictions in this situation. Unlike the teachers, however, none of the scientists adopted a limiting approach, as they saw no reason to constrain the science they practiced. This last result is important because it counters critiques (such as Nussbaum 2002) that highlight Orthodox Jewish scientists who are charged as being antiscience towards issues such as evolution. In other words, it supports the idea that there truly is a spectrum among scientists who are also Orthodox in practice.

On specific issues of conflict, geologic time was much less controversial for teachers than either cosmology or evolution. With this issue, the teachers referred directly to religious sources which implied that were either multiple creations of older worlds or that each day of creation was much longer than 24 h. The teachers' flexibility was based on the openness of classic Biblical commentators on this issue. Such commentators provide sanction for interpreting the Bible, but particularly with the age of the Earth, this sanction has greater impact because there is no direct reference within the Bible to the traditional Jewish calculation of the age of the Earth.[23]

---

[23] Some Jews believe that the Earth is currently 5,722 years in age (in 2012 CE). In fact, this figure, which has also influenced Christian fundamentalists' understanding of the Earth's chronology, has been calculated based on the interpolation of ages of Biblical personalities mentioned in Genesis starting from Adam's creation on the sixth day of creation (this calculation can be found in the book Seder Olam Rabbah, ascribed to the second century CE Rabbi Yossi ben Halafta). In turn, this calculation leaves the possibility of interpreting the first 6 days of creation before man's appearance as being much longer than six 24-h days (Dodick et al. 2010).

Thus, it becomes easier for teachers, who are familiar with such commentaries, to accept geologic time.

In contrast to the age of the Earth issue, approximately half of the teachers saw some conflict between the theory of evolution and Biblical creation because its random nature contradicts the belief in creation directed by the "hand of God"; moreover, some cited the fact that it also conflicted with their belief in man as the "crown of creation." It should be noted that some scientists also felt such conflicts but they were willing to live with them.

At the university level, inside Israel there is one comprehensive university that integrates "Jewish heritage" and secular studies – Bar Ilan. Its Faculty of Life Sciences provides courses in evolution, as well as integrates this subject within its various course offerings. In the United States there is a strong dichotomy between the approach of Yeshiva University, whose very motto incorporates Torah Umadda and other Orthodox institutions of higher learning. Indeed, university President Richard Joel (2003, p. 3) in *YU Review* claimed that a "moral underpinning" for science at his university was "to marry the wisdom of faith with the need to explore our universe's mysteries."

In the same issue of this magazine, biology Professor Carl Feit noted that he saw no contradiction between Judaism and biology while arguing that the evolutionary ideas could actually be used to serve to strengthen one's faith (Eisenberg 2003). In a conversation with Selya (2006), Feit notes that he includes evolution as part of his course syllabus while adding readings from the philosophy of science, philosophers, and Jewish Biblical commentaries.

In contrast, Touro College, which was founded in 1971 to "enrich the Jewish heritage" and serves a largely ultra-Orthodox student population, takes an unsympathetic view towards evolutionary biology. As a psychology instructor at Touro, Nussbaum (2002) elicited great opposition from his students for his support of teaching evolution. Moreover, the science professors at this institution routinely criticized evolution while teaching creationism.

Schools and teachers set the curricular standards which ultimately affect students; thus, to complete our understanding of the interaction of Judaism and science education, we will be looking at studies dealing with students. Of these studies, those concerned with k-12 students have emanated from Israel.

Ruach and colleagues (1996) performed a comparative survey study with 185 students evenly distributed among National Religious and secular state students in middle (grade 9) and high schools (grades 11 and 12). The middle grade high school cohort had not yet learned evolution in contrast with the high school cohort. After learning evolution the high school students from both school systems substantially increased their knowledge of evolution. However, their attitudes towards this subject were in opposition. The students of the National Religious stream increased their acceptance of creationism, whereas the Secular State students increased their acceptance of evolution.

More recently, Allouch (2010) also examined the attitudes of middle (grade 9) and high school (grade 10) students from the National Religious school system. This sample consisted of 369 students, 79 of them who were studying evolution.

The design of this study relied upon a Likert-type questionnaire (37 statements) that focused on evolution but also included a small number of statements dealing with the nature of science, cosmology, and geologic time.

Similar to the teachers sampled by Dodick et al. (2010), prior to studying the unit, the students were more accepting of a nonliteral reading of the Biblical creation time line, as well as the "Big-Bang" explanation of cosmology, than they were of evolution. Post-program, a similar result occurred. Positive attitudes connected to time and cosmology improved significantly (despite the fact that this was not the focus of their learning), whereas for the most part, their attitudes towards evolution remained at a no agreement level, even after learning the unit.

Again, similar to the teacher sample of Dodick et al. (2010), the students displayed a variety of philosophical approaches towards different issues, although based on Allouch's (2010) results, the students seem to be more conservative (religiously) in their attitudes towards these creation issues than their teachers. Nonetheless, like the student sample of Ruach and colleagues (1996), the students significantly improved their understanding of some of the issues connected to evolution (most notably Natural Selection). In sum, the results from both Ruach and colleagues (1996) and Allouch (2010) parallel the findings of Lawson and Worsnop (1992) with US students who found that a change in knowledge (about evolution) was not necessarily associated with a change in (religious) attitudes.

It must be remembered that in the case of the students in the religious stream they are exposed to far more religious learning than learning about evolution and this would likely affect their attitudes. In fact, Allouch's (2010) study showed that one of the external factors which influenced the students developing a greater acceptance of evolution was the number of curricular hours devoted to this subject. Moreover, for this group of students, part of their school success is measured by how they understand and apply their religious training; in their community, such application is seen as having great value.

It would be expected that difficulties with issues connected to evolution would also affect Orthodox students who attend university. This was addressed by Nussbaum's (2006) survey study among a sample of 176 Orthodox Jewish students at a single public college in New York City. This study provides for some rather disheartening conclusions about the state of science education among Orthodox Jews. The responses received to questionnaire probes dealing with evolution, such as "Evolution correctly explains the origin of life," and geologic time, such as "What is the age of the universe?" indicate that the subjects tended towards creationist or intelligent design perspectives. Moreover, Nussbaum's (2006) data also seems to show that the students that were science majors were even less accepting of mainstream science than those who were not science majors.

However, we should be careful in viewing this study as a summary of the attitudes of all Orthodox university students in the United States because of its methodological problems. The sample consisted of 176 subjects, surveyed at one university, with little demographic data collected concerning the subjects (such as school background). Moreover, the wording of some of the probes is to be questioned. For example, "Evolution correctly explains the origin of life" with a binary answer format would necessarily exclude theistic-evolutionist approaches.[24] Finally, interviews were not held with any of the subjects, which would have more deeply probed their philosophical approaches. Still, given the fact that Jewish Orthodox society is moving towards more ultra-Orthodox views, the results of this study do seem to reflect such societal change.

54.6 Conclusion

In looking at the relationship between Jews and science education in our modern world, we see mostly positive trends. This might be a surprising conclusion in light of what was written in the previous section; however, these trends are supported by historical, sociological, and demographic factors.

Those denominations in Judaism who have difficulties with science learning, most notably the ultra-Orthodox, and some of the modern Orthodox represent a demographic minority; in total, the Orthodox in the United States represent no more than 13 % of the Jewish population (Ament 2005).[25] Thus, over all, it is possible to say that among Jews connected to their Judaism, methods have developed, historically, in order to deal with the conflicts posed by modern science.

Indeed, it is possible to say that Reform and Conservative Jews have few or no problems with modern science education; this is why their role is downplayed in the previous section which discussed science education. There is simply no evidence that what is considered to be a challenge by some in the Orthodox world is considered to be the same in schools belonging to the Conservative and Reform movements. Thus, it would seem that science is taught in their day schools in the same ways as it is taught in the public school systems.

Moreover, it must be remembered that even among those Orthodox Jews that are challenged by scientific findings, it is *not all of science* that is considered to be a challenge, but specific sciences that touch upon issues of Biblical creation. This is the reason why our review of the science education research has not focused on science in general, but specific issues, such as evolution which are considered to be threatening to the religious sensibilities of its followers.[26] In fact, most modern-Orthodox day schools in the United States are known for the high quality of their secular studies including science education.

---

[24] Theistic evolution claims that God's method of creation was to design a universe in which various systems would naturally evolve.

[25] Among those of Jewish origin, who see their faith as an integral part of their lives, the Orthodox represent a higher percentage than stated; still the Orthodox do represent a minority when compared to the number of Jews belonging to movements such as the Conservative and Reform.

[26] Simply put, there are no science education studies that have examined Jewish attitudes/approaches towards science as a whole. All of the known studies focus on one or a few specific subjects such as geologic time, cosmology, and especially evolution, which (supposedly) are threats to the Jewish worldview.

It should also be remembered that although there is large demographic growth within the worldwide Orthodox sector and, especially among the ultra-Orthodox, their philosophical approach to challenging issues of science does not carry over to other school systems, largely because of their isolationist approach. Such physical and social isolation was historically adopted by the ultra-Orthodox to limit contact with and infiltration of foreign ideas (which included ideas promulgated by other Jewish denominations) that do not fit into their religious worldview (Liebman 1983; Heilman 2005). In terms of educational policy, this has meant that in Israel the ultra-Orthodox and their independent school system do not affect curricular policy within the Secular and National Religious school systems.

Outside of Israel, a similar isolationist approach has been adopted by both ultra-Orthodox and their school system towards other Jewish denominations. This is very different from the situation in the Christian world, most notably in the United States, where fundamentalists have sometimes successfully gained elected control of school boards leading to critiquing evolutionary theory (http://www.discovery.org/a/9851) and even removing the teaching of (macro)-evolution, as occurred in Kansas in 1999 (http://www.agiweb.org/gap/legis106/evolution.html). Nonetheless, it was noted previously that there is a more subtle influence from the "Haredization" of the modern-Orthodox education system due to the increased number of ultra-Orthodox religious teachers entering that system (Heilman 2005; Helmreich and Shinnar 1998). Such sociological factors could have a stronger influence than the actual content of the science education curriculum. However, there are no studies indicating how that is specifically affecting science education.

Thus, there are challenges to the science education enterprise in the Jewish world. Many Orthodox elements see the challenges posed by the secular philosophy of science as being more of an educational threat than science per se; however, the larger issue of how various groups see secular learning in general, especially secular higher learning, is an indication of how they see science as well.

Certainly Reform and Conservative Jews attend university with no limits to what they study. So too, the modern Orthodox also attend college, although as Soloveitchik already noted in 1994 (p. 64) with "somewhat less enthusiasm" than in previous years. The ultra-Orthodox, who are known historically for their opposition to higher education, are divided in their approaches (Soloveitchik 1994). In the United States, there is recognition of the (economic) utility or even necessity of a degree, and various arrangements have been made to enable ultra-Orthodox to receive such degrees, albeit with (societal) restrictions on what is studied. In Israel, the opposition to higher education is much stronger, although due to the very weak economic condition of most ultra-Orthodox, colleges specifically designated for training this populace have been rapidly developing (Lamm 2010).

Certainly, economic incentive is a path towards increased involvement in secular learning, in general and science, specifically. And in fact it may be the only path that the ultra-Orthodox will accept in the near future. But some in the modern-Orthodox world desire a synthesis represented by a Torah Umadda philosophy because they see the inherent value in secular knowledge and learning. How is this possible?

One possible synthesis is provided by Rabbi Norman Lamm (2010) who has articulated a series of models, based on the philosophies of important rabbinic thinkers of the past. Obviously, to understand and then adopt any of these models requires a deep investment in studying the religious sources and their philosophy, as well as science and its nature.

Indeed, such an investment in learning fits well with one of the recommendations made by the Orthodox scientists interviewed by Dodick et al. (2010) when they were asked how Orthodox Jewish teachers might cope with what they felt were controversial scientific topics, such as geologic time or evolution.

It must be remembered that the Orthodox (high school) science teachers in Israel are adequately educated in science, and many received training in a religious seminary. However, such education rarely deals, systematically, with the possible philosophical conflicts between science and religion. Therefore, the scientists argued that it was important to improve the teachers' understanding of both scientific and Jewish sources that will permit them to settle their internal conflict while providing them with the tools to teach such conflicting subjects with confidence.

Indeed, Lamm (2010) shows how both in the past and today confusion has been created by the lack of understanding about the Jewish philosophical approaches to all secular learning. Moreover, he even shows how traditions that normally would never be considered to be in a Torah Umadda world (specifically, his "Hassidic" model) can be designed to create a synthesis between Judaism and science.

Although knowledge is a primary tool, the Jewish education world is a hierarchical system, especially among the Orthodox, in which teachers must answer to a series of authorities including rabbis, administrators, and parents. Thus, teachers feel more comfortable if they have experts upon whom they can rely (scientists, rabbis, and texts) which allow them to teach scientific issues that are considered to be challenging. Unlike academic scientists, teachers have less freedom to express controversial notions in science or religion, nor are they as well trained in science. Thus, their desire to have a support network of rabbis and scientists who can deal with this conflict is understandable.

This approach also has support from a previous science education study in which Colburn and Henriques (2006) interviewed a group of eight Christian clergymen for whom evolution and religion were compatible and who also believed that Scripture was not meant to be understood, literally. Based on their findings, Colburn and Henriques (2006) suggested that the science education community might find in the educated clergy an articulate ally in helping citizens better understand contentious issues surrounding science and religion.

Because they are not constrained by authority, the scientists interviewed by Dodick et al. (2010, p. 1541) instead recommended that teachers focus on two interrelated issues connected to *application* and *education* to deal with possible conflicts. *Application* is connected to how scientists see religion and science possibly integrating; by *education*, the scientists were referring to how they would like to see the conflict being taught.

Concerning application, the scientists showed a divergence in their choice of philosophies, with the two dominant approaches being the parallel and explanatory approaches. These philosophical differences fit well with application in that some of the scientists favor an approach which emphasizes the points integrating science and religion (comparable to the explanatory approach); in contrast, some of the scientists would rather avoid using science in building religious understanding (comparable to the parallel approach), as the use of science in this way resonates with a fundamentalism with which they don't identify.

Regarding "education," some of the scientists which Dodick et al. (2010) surveyed emphasized critical understanding of learning materials dealing with this conflict. Moreover, some of the scientists desired to see issues of conflict being taught pluralistically by showing students the different philosophical approaches in science and religion that deal with this conflict. This suggestion connects nicely with scientists holding either an explanatory or complementary philosophy as they connect between the domains of science and religion. As these approaches are sympathetic to the preconceived desires of the teachers to also bridge the gap between science and religion, this pluralistic approach might be easier for teachers to implement.

Such integration also has support from the literature (Jackson et al. 1995; Shipman et al. 2002; Smith and Siegel 1993). For example, Jackson and colleagues (1995, p. 605) noted that the current treatment of controversial scientific topics in schools, such as the evolution of humans, is independent of any other way (including via religion) that a student or teacher might seek answers to such topics. They argue that "Scientists and science teachers cannot continue to see themselves as participating in an epic struggle to eradicate mystical superstition and hasten the irresistible ascendancy of materialistic naturalism."

What is missing from this discussion is empirical research. As was seen, much of the education research concerning Judaism and science have focused on the attitudes of students, teachers, and scientists, mostly within the Orthodox world, towards issues of controversy, such as evolution. Future work needs to be more expansive in widening its perspective to other denominations within Judaism[27] and other branches of the sciences. Moreover, for those issues that challenge religious sensitivities much more research must be invested in testing different models of instruction, based on the philosophical approaches that have developed in Judaism. Selya's (2006) work shows that in the modern-Orthodox world, schools have already adopted a number of instructional philosophies for dealing with such controversy; however, research has not yet been conducted to determine their effectiveness. If the goal of Jewish educators is to attain some sort of balance between the world of science and Judaism, then these next steps are crucial.

---

[27] We could reference only one paper concerning the interaction between science education and Judaism from a non-Orthodox perspective. Authored by Rabbi Laurie Green (2012), who comes from the Reform movement, this policy paper argued for greater integration (similar to the explanatory approach) between religion and science studies for students belonging to the Reform movement.

Jeff Dodick is lecturer in the Department of Science Teaching at the Hebrew University of Jerusalem. His training is in biology and earth science (B.Sc., the University of Toronto), with specializations in paleontology and evolutionary biology (M.Sc., University of Toronto). His doctorate is in Science Education from the Weizmann Institute of Science in Rehovot, Israel. He did postdoctorate research at McGill University in Montreal, QC, Canada, and also served as a research assistant professor in the Faculty of Education and Social Policy at Northwestern University, in Evanston Illinois, United States. Broadly stated, his research interests focus on the reasoning processes that are used in sciences which investigate phenomena constrained by long spans of time, such as evolutionary biology and geology; such scientific disciplines fall under the general rubric of "historical-based sciences." In the past he has published research papers dealing with how students of different ages understand geologic time; this research interest has also extended towards testing how visitors to the Grand Canyon understand a new geoscience exhibit that explains "deep time." More recently, he has been comparing how scientists, graduate students, and high school students understand the epistemologically derived differences between experimental- and historical-based sciences.

Raphael B. Shuchat is lecturer in the Center for Basic Jewish Studies at Bar-Ilan University in Ramat Gan, Israel. His undergraduate degree in Psychology is from Empire State, SUNY Saratoga Springs, New York. He received an MA in Jewish Philosophy from the Hebrew University in Jerusalem, Israel, and a Ph.D. in Jewish Philosophy from Bar-Ilan University. He has written three books and over 30 articles. His latest book *Jewish Faith in a Changing World – A Modern Approach to Classical Jewish Philosophy* is an attempt to bring the issues of Jewish philosophy to the modern reader. His articles on the issue of science and Judaism include "Rabbinic attitudes to Scientific Cosmogony and Evolution in the nineteenth and twentieth century," "R. Isaac Halevi Herzog's Attitude to Scientific Evolution and His Dialogue with Velikovsky," "Did the Medieval Kabbalists Believe that the World was created in 6 Days?," and "From Monologue to Dialogue: Between Jewish Thought and World Culture."

Chapter 55

Challenges of Multiculturalism in Science Education: Indigenisation, Internationalisation, and *Transkulturalität*

Kai Horsthemke and Larry D. Yore

55.1 Introduction: Philosophy, Transfer, and Transformation in Education

The central purpose of this chapter is to position the indigenous–Western knowledge debate within the context of contemporary philosophical views of science and pedagogical insights into science learning and teaching. This will be done by providing a respectful, honest, and straightforward commentary on the strengths and weaknesses of including indigenous knowledge and wisdom (IKW) about nature and naturally occurring events in school science programs. The prior debates between traditionalists, modernists, and postmodernists about the issue have been unproductive. The conflict resolutions that were seeking binary judgements of *good* or *bad* and *science* or *pseudoscience* have not fully reflected the realities of world and science classrooms. These debates have neither considered the sociopolitical and social justice influences nor provided learners with opportunities to engage science without being misinformed about what they were learning—let alone its ontological assumptions and epistemological beliefs. IKW about nature and naturally occurring events is different from Western modern science (WMS), but each has personal value within the parallel worlds of interpersonal-/place-based and public/generalised knowledge systems.

Philosophy might be claimed, cautiously, to be one of the deliberative and critical resources that ought to be brought to bear on questions of accessibility and relevance and on the transfer and transformation of educational systems, knowledge, concepts, and practices—if such processes are to be justifiable, consistent, and effective.

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_55,

'Cautiously', because the contribution that philosophy can offer is likely to be modest—for at least two reasons. First, philosophy is only one of the deliberative and critical resources relevant to educational transfer and transformation. Second, deliberation and criticism may be necessary but are not sufficient for the justifiability, consistency, and effectiveness of the processes in question; there are vast and significant contingencies in context and practice that are likely to remain decisive (McLaughlin 2000; Schily 2009).

Over the last 50 years, pedagogical insights into this debate about science education, teaching, and learning have been based on a changing array of learning theories—behaviourism, cognitive development, cognitive psychology, and learning sciences. Based on an integration of cognitive psychology, linguistics, philosophy, and pedagogy, the most recent dominant stance has promoted a learner-activated and learner-controlled meaning-making process that combines prior knowledge, sensory input, interpersonal interactions within a sociocultural context, and intrapersonal reflections within *self*. However, this interpretation of learning might conflict with some philosophers' view of the nature of science.

A promising approach to establishing the appropriate contribution of philosophy to science education in this regard is arguably to focus on the embeddedness of philosophical considerations in many concerns and processes driving transfer and transformation (McLaughlin 2000). Many of these contain, to a greater or lesser extent, concepts, beliefs, values, assumptions, and commitments that—although they themselves may not be of a directly philosophical kind—can be subjected to philosophical scrutiny and analysis. In considering the issue in this chapter, a philosophical distinction might be drawn between worldview and critical activity. Unless seriously mentally impaired, everyone has a worldview (e.g. thoughts or ideas, views or opinions about one's own life and one's place in nature, natural events, and about the world, life, and nature in general); consequently, there exists a multitude of frequently competing and conflicting worldviews. When applied to knowledge about nature and naturally occurring events, people's views range from folklore, religious, indigenous, to scientific. Each can be personally useful, but they should not be confused, confounded, or equated (National Research Council [NRC] 1996).

However, is WMS merely one such worldview among several (Aikenhead 1996; Fakudze and Rollnick 2008)? Alternatively, does it also involve a special type of activity, a process of critical interrogation in which we are concerned with examining and evaluating the ways in which our views, opinions, thoughts, or ideas about the world, life, and nature in general are or have developed (epistemology) and are explained (ontology)? In other words, this involves critical reflection on our ontological and epistemic assumptions, the implications of our views, and the problems that have to be considered in order to reach these conclusions. Even if worldviews 'are culturally validated presuppositions about the natural world' (Aikenhead 1996, p. 4), this does not necessarily mean that that they are equally valid and congruent in terms of epistemology and ontology (Yore 2008), which does not discount their practical and personal value.

A further contribution that philosophy can make concerns the analysis of knowledge and the grounds for knowledge claims, in science education as elsewhere. The debate is between those who treat science and scientific knowledge as a 'cultural enterprise' and those who attest to the 'universality of science' (Stanley and Brickhouse 1994, p. 9). Many people would agree that some folklore about agriculture, meteorology, and navigation is laypeople's well-based expressions of fact, while other folklore in these areas is deemed myth or fancy. Religious-oriented statements about nature and naturally occurring events based on only faith may be of great personal value, but they generally lack the ontological features and epistemic means to be tested and validated using empirical evidence, standardised means, and accepted processes set by scientific communities. There is debate about whether science should be used to test one's religious beliefs, with some maintaining that religious claims about the natural world and its processes (evolution, faith healing, etc.) should be amenable to normal scientific appraisal. The more difficult issue is the consideration of IKW about nature and naturally occurring events, where claims were place based and developed over time using reasonably rigorous epistemologies and oral traditions, but the ontology allows a hybrid explanation of spiritualism and physical causality (Snively and Williams 2008).

55.2 Indigenisation and Internationalisation

The IKW–WMS deliberations need to be placed within the context of worldwide sociopolitical, economic, and social justice influences and efforts. With rapid changes in recent decades of scientific and technological advances, transnational mobility, communication and travel, economic connectivity and dependencies, and—even more recently—increasing democratisation of societies, it comes as no surprise that corresponding changes have occurred and continue to occur in education. These changes concern not only how education, its nature, and its aims are or will be conceptualised but also the very transfer and transformation of educational systems, knowledge, concepts, and practices.

The biggest challenges facing science education have arguably been accessibility and relevance to mainstream boys and girls; these challenges have become more pronounced with the increasingly multicultural nature of teaching and learning environments. How does one render accessible a discipline that has often been viewed as unnatural, difficult, and the intellectual playground of a select, gifted few? How does one instil in students a sense of relevance of science to their lives and experiences, especially if teaching and learning take place in a language and cultural context other than their home language and culture? Many people can remember the shock of entering primary school after years of the free, informal, and unstructured experiences of early childhood to the middle-classed, formal, and structured classroom. Your non-standard forms of the dominant language were not allowed; *stuff*, *ain't*, other colloquialisms, or localisms were deemed inappropriate language. *The gods bowling* as an explanation for thunder was replaced with an abstract idea about a sonic boom caused by rapid thermo-expansion of the atmosphere associated with a static electrical discharge—lightening. This culture shock would be magnified by powers of ten for nondominant language speakers and underserved or underrepresented students who entered the new culture and language environs.

There have been a variety of responses to the transformational implications of globalisation for education and, in particular, for higher education. Chief among these are the drives toward indigenisation, on the one hand, and toward internationalisation, on the other. The radical, extreme versions of these approaches reject any claim to validity or legitimacy by the rival approach. Thus, radical indigenisation involves a back-to-the-roots traditionalism and nationalism that more often than not are inspired by negative effects of the colonial experience and the need for political consolidation or cultural restoration. Globalisation is nothing new; its roots are in the historical explorations and immigrations of the fifteenth and sixteenth centuries when adventurers or refugees picked up their place-based cultures, languages, knowledge claims, and technologies and moved to a new place. It has continued at a more rapid pace today with mobility of populations leading to many free-choice immigrants—such as the two authors of this chapter. Traditionalism and nationalism are forms of sociopolitical priorities designed to conserve or restore cultural identity or forge a national identity.

The Māori Nation's successful efforts to establish the Putaiao curriculum in Aotearoa New Zealand to address colonialism (McKinley and Keegan 2008) and the First Nations' continuing efforts at linguistic and cultural restoration/conservation in Canada to address the social justice ills of residential schools (Snively and Williams 2008) are readily documented examples. Like most political and democratic endeavours based on majorities, not all people involved agree with the fundamental premises. Webb (in press) found that many parents did not want their traditional language and IKW to be the medium and focus of science instruction in South African schools; instead, they supported the English language and WMS curricular mandates with some consideration of IKW. None of the transfer and transformation issues and solutions to this point has considered how people learn—other than that the target learning content needs to be relevant to the target learners. Clearly, many people involved in this debate still adhere to the passive transmission model (i.e. knowledge is passed from teacher to learner, 'teacher directed') rather than the more contemporary interactive-constructive interpretations (i.e. shared student-teacher directed) that involve accessing, engaging, and challenging prior knowledge and supporting learners as they make meaning, store these new ideas in existing knowledge structures, or reorganize knowledge structures to accommodate discrepant ideas (Henriques 1997; NRC 2000, 2007).

Indigenisation involves what Wolfgang Welsch, a cultural theorist, has referred to as the 'return of tribes' (Welsch 2000, p. 349) and may be interpreted as a reaction against globalisation and colonisation. Given the historical, political, and socioeconomic background of exploitation and oppression that motivates and explains indigenisation, the eagerness of people to return to what they perceive to be the sources of their cultural identity—their roots—is perfectly understandable. While this desire to return and to reembrace local values and indigenous traditions is not implausible, the move toward indigenisation has produced some collateral damage. Compounded by problems emanating from unhelpful immigration legislation and bouts of xenophobia (violent actions against foreigners), there has been no transfer, exchange, or mobility on the African continent comparable to that within, or produced by, European Union (EU) member states' secondary and higher education. Instead, the net result has been a marginalisation of Africa, not only of the continent as a whole but also within Africa in terms of increasing isolation of sub-Saharan African countries from each other. Indeed, these policies of 'indigenisation may exacerbate existing societal divisions and lead to new forms of intolerance and discrimination' (Andreasson 2010, p. 427). The reverse racist rhetoric and growing Zulu nationalism as an example of internal dislocation has been highlighted by Chetty (2010). Furthermore, there is the real danger that indigenisation in science education may mislead students and ill prepare them for future higher studies and careers in science, technology, and engineering.

By contrast, radical internationalisation envisages the spread of a universal, more or less monolithic, educational, and socioeconomic culture and tends to ride roughshod over local indigenous histories, values, beliefs, and cultural ways of knowing and explanatory traditions about IKW (Auf der Heyde 2005). Furthermore, such approaches may not engage students' actual prior knowledge, beliefs, and values about science and technology—thereby disenchanting more indigenous and culturally diverse students from actually learning about nature and naturally occurring events from a scientific perspective.

It is evident that neither position holds much promise for science and science teaching and learning. While the former errs in favour of increasing insularity and self-marginalisation, the latter errs in favour of dogmatic homogenisation and lack of regard for difference and diversity. More seriously still, apart from manifesting an essentialist conception of culture and identity, both perpetuate a cycle of disregard, disrespect, and intolerance, with ever-increasing ossification of the opposing fronts and polarisation.

Depending on one's sympathies, it is easy to eulogise one's preferred orientation by pitting it against a straw person that is swiftly and summarily dismissed. Consider, for example, Aikenhead's characterisation of First Nations knowledge of nature as contrasted with Western scientific knowledge:

> Aboriginal knowledge about the natural world contrasts with Western scientific knowledge in a number of ways. Aboriginal and scientific knowledge differ in their social goals: survival of a people versus the luxury of gaining knowledge for the sake of knowledge and for power over nature and other people. They differ in intellectual goals: to co-exist with mystery in nature by celebrating mystery versus to eradicate mystery by explaining it away. They differ in their association with human action: intimately and subjectively interrelated versus formally and objectively decontextualised. They differ in other ways as well: holistic First Nations perspectives with their gentle, accommodating, intuitive, and spiritual wisdom versus reductionist Western science with its aggressive, manipulative, mechanistic, and analytical explanations (Aikenhead 1997, pp. 5–6).

Elsewhere, Aikenhead listed the following attributes characterising the 'subculture of science': 'mechanistic, materialistic, reductionistic, empirical, rational, decontextualised, mathematically idealised, communal, ideological, masculine, elitist, competitive, exploitive, and violent'.[1]

---

[1] See Aikenhead (1996, pp. 9 & 10, 1997, pp. 2 & 5, 2001, pp. 11 & 12). Similar attributes of science were purported by Bishop (1998, pp. 200, 201, 210) and Witt (2007, p. 227).

It is not difficult to sympathise with the concerns that underlie advocacy of IKW projects, but it must be ensured that any contrasts of WMS and IKW about nature and naturally occurring events are based on accurate, informed views about the ontological and epistemic aspects of both knowledge systems. Loving (2002) mapped views of science on an ontological–epistemic plane, which led Yore et al. (2004) to identify three general clusters of views (traditional absolutist–realist, modern evaluativist–naïve realist, and postmodern multiplist–idealist) as anchor points for interviews with scientists that delved into their beliefs about their research enterprise. They found that although some scientists use the metalanguage of and identify with the traditional view, most scientists agree with the description of the modern view; a few scientists, mainly from the newer hybrid biosciences, lean toward the postmodern view. However, at the practical and historical perspective, people must be aware that Western knowledge, science, technology, and rationality have led to, or have had as a significant goal, the subjugation of nature; thus far, it has been devastatingly efficient.

The pursuit of nuclear energy (Fig 2005), wholesale deforestation, and the destruction of flora and fauna are arguably deplorable and irrational or, at least in hindsight, questionable applications at times and in certain places. Similarly, apart from being ethically suspect, factory farming of nonhuman animals for human consumption and, especially, vivisection are also examples of bad science (Horsthemke 2010). However, many of these examples used in defining *whose* science and knowledge systems in the modern–postmodern debates about the North–South divide may be more technological rather than strictly scientific (Good 1996; Harding 1991, 2011). Clearly, the definitions of technology as design or as applied science change these debates and claims. Wolpert stated, ‘Much of modern technology is based on science, but this recent association obscures crucial differences and the failure to distinguish between science and technology has played a major role in obscuring the nature of science’(1993, p. 25). The ‘central distinguishing characteristic between science and technology is a difference in goal: The goal of science is to understand the natural world and the goal of technology is to make modifications in the world to meet human needs’ (NRC 1996, p. 24). However, the disparagement and belittling of indigenous peoples’ practices, skills, and insights has, to a large extent, been arrogant and of questionable rationality. If honest engagement is desired in education and public awareness activities, it will require recognising cultural values, lived experiences, and prior knowledge and beliefs of those being engaged. Finally, current attempts by industrial, first-world nations to colonise or appropriate for commercial gain indigenous people’s knowledge, practices, skills, and insights in the name of globalisation and worldwide development are exploitive and contemptible.

People hold many misconceptions and myths about the nature of science regarding the singularity of the scientific method, hypotheses as educated guesses, evolution of hypotheses and theories growing into laws, absolute truths based on accumulated evidence, procedural nature of inquiry, scientific enterprise can address all questions, scientists as supernatural people, all science is experiment-based, and all science claims are peer-reviewed to ensure honesty (McComas 1996). Therefore, a pro-Western/Eurocentric perspective might mislead one to characterise the differences as follows: the celebration of knowledge as intrinsically valuable versus the view of knowledge having no value in itself; reliance on a critical, rational scientific method versus superstition, magic, witchcraft beliefs, ancestor worship, and unquestioning obedience toward traditional authority; commitment to universal applications and solutions versus ethnocentrism and thoroughgoing cultural and epistemological relativism; and the value of scientific evidence versus faith and reliance on revelation. These binary positions have led to polarised controversy and winner-takes-all solution strategies, whereas in the pragmatic worlds of science education and science teaching, the greater good might lie or involve moving between these poles—two-way border crossing with mutual honour and respect (Chinn et al. 2008).

55.2.1 Knowledge Claims and Justification

If anything qualifies as science, there are certain criteria that must hold. It needs, at minimum, to involve reference to regularity, observation, description, explanation, prediction, and testable hypothesis. If it does not meet these criteria, it is not ‘science’, as commonly understood to be people’s endeavour to search out, describe, and explain patterns of events in nature and naturally occurring phenomena where the claims are based on evidence and are generalisable and the explanations involve physical causality (Good et al. 1999). When only the epistemic beliefs and practices are considered, there is little difference between traditional IKW and WMS; but when the ontological requirements are considered, the two knowledge systems demonstrate critical differences (Yore 2008). Both indigenous and scientific epistemologies have well-established, rigorous systems and routines of observations, interpretative frameworks, and feedback loops to make, update, and revise descriptions of patterns and knowledge claims (Snively and Williams 2008). However, on the ontological dimension, indigenous explanations involve a mixture of spiritual and physical cause–effect mechanisms, while scientific explanations are limited to physical causality devoid of mysticism, magic, and spiritual causes.

With regard to scientific knowledge, one generally distinguishes between two kinds: practical knowledge and theoretical knowledge. The former denotes craft knowledge, skill, ability, practice, or custom taught or passed down from one generation to another without evidence, justification, or explanation. Some historical technologies and practices within skilled trades demonstrate such characteristics. Apart from necessarily incorporating belief, theoretical knowledge involves commitment to truth and justification (i.e. scientific evidence; Haack 2003). In other words, a person knows that something is the case if she believes that it is so and she has adequate evidence for believing that it is. Science, as well as being about inquiry, is about evidence-based empirical argumentation. Toulmin’s (1958) pattern and elements (data, backings, warrants, evidence, claim, counterclaim, and rebuttal) were used frequently to describe and evaluate the quality of an argument. Adequacy, however, cannot be determined by a checklist of elements; it must be determined by the kind, degree, and context of evidence (Gott and Duggan 2003; Tytler et al. 2001; Walton 2005; Walton et al. 2008).

Different kinds of evidence pertain to the different sciences, natural as well as social. They include observation, sensory experience, oral and written testimony, and deductive and nondeductive (inductive, abductive, and analogical) reasoning. As far as the requisite degree is concerned, minimal evidence is clearly not enough, while conclusive evidence is usually not available. Normally, other than in mathematics and deductive logic, we accept evidence that is less than conclusive, that is, reasons that are nonetheless compelling within an evaluative context (argument–critique–analysis). These science and engineering practices were recently included as a central part of the new framework for science education regarding scientific inquiry and technological design, which will influence the next generation of science education standards in the United States of America (NRC 2012).

Yet, what makes evidential reasons compelling has partly, and importantly, to do with context—not only the particular scientific context but also, for example, the problem space, the environment, the cultural and social biography, and the reasoning level of the person making the knowledge claim (Aikenhead 2005). Considerations of context determine leniency or stringency, and ascription of scientific knowledge reflects the social component of knowledge, which reveals that attributions of knowledge are context sensitive (Cohen 1986). Scheffler argued that the idea of *suitability* is:

> [A] matter of appraisal, involving standards of judgment that may differ from age to age, from culture to culture, and even from person to person. The variability of such standards does not, however, imply that assessments of knowledge are arbitrary or that the would-be assessor is somehow paralyzed. He needs to assess in accord with his own best standards at the time, but he may hold his assessment subject to change, should he later have cause to revise these standards (Scheffler 1965, p. 57).

He pointed out that these standards might be applied more strictly in some cases, more approximately in others, 'thus giving rise to multiple interpretations of *knowing*' (p. 58). Therefore, the justification component permits some leeway toward a multiplist view of science where multiple interpretations of datasets are expected as the interpreters apply their lived experiences and individual interpretative frames, but the alternatives will be evaluated in the public arena of the involved science community. What counts as suitable justification in the case of a young child or person from a remote rural area—with limited opportunities, resources, or access to information—differs from that required of an older, more mature person from an industrialised, technologically advanced, privileged, and urban background. Scheffler noted the implications for education when he stated, 'As the child grows and as his prior learning takes hold, his capacity increases, allowing us to tighten the application of our standards in gauging his current performance' (p. 57). Thus, with this growth in the child's cognitive capacity, 'the same subject may thus come to be known under ever more stringent interpretations of *known*' (p. 57).

Yet, in all the various cases, the justified belief must be true and present. In the absence of truth, one cannot meaningfully speak of, or ascribe, knowledge. Scheffler suggested a subtle shift from examining beliefs to examining the *contexts* in which beliefs were advanced as knowledge-claims when he distinguished the question concerning justification of a belief from the 'question of *appraisal of the believer* …. To speak of the right to be sure is, in the present context, to appraise the *credentials* of belief from the vantage point of our own standards; it is to spell out the attitude of these standards toward specific *credentials* offered for a belief' (p. 64).

Like Scheffler, Cohen (1986) argued that the suitability of justification, or having good reasons, depends on the relevant epistemic community. He advanced his argument through an analysis of what it means to have good reasons for believing something. The concept of *defeasibility* is crucial. One's reasons for believing something are *defeasible* if there is something else that could count against them, that is, something that could defeat them or undermine their feasibility. According to Cohen, we can say that someone (e.g. a 6-year-old) has good reasons if, given her reasoning ability, it is epistemologically permissible for her to believe that something is the case. Scheffler would be inclined to apply the standards of justification more leniently in the case of the 6-year-old and more strictly in the case of the 16-year-old. Both the 6-year-old and the 16-year-old may form a justified true belief that the table they see in a darkened room is red. However, when they are informed about the presence of a red light bulb in the room (hidden from their view), the younger child will hardly be able to appreciate the significance of the presence of this *defeater*. Therefore, if she continues to cling to her belief that the table is red, we would normally credit her with sufficient justification for her knowledge claim. On the other hand, if the older child fails to see anything wrong with clinging to her belief, we would normally be more reluctant to credit her with knowledge that the table is red. What passes for sufficient or adequate justification, then, will differ, and a progression of plausible reasoning would be established.

The important point for science teachers is that what counts as a good reason depends on who is giving the reason and in what context. One of the responsibilities of a science teacher is to assess learners' knowledge *of*, *for*, and *as* learning in ways that are sensitive both to their level of understanding and to the context of assessment—accountability (of), empower learning and inform teaching (for), and stimulate learning (as). Another related responsibility is to develop the learners' grasp of the intersubjective standards of different learning areas, such as common core learning outcomes in English, social studies, science, and technical subjects (National Governors Association Center for Best Practices and Council of Chief State School Officers 2010) and cross-cutting concepts with science and engineering domains (NRC 2012). In Cohen's terms, to help learners move from a level of reasoning that provides *subjectively evident* grounds for believing something to a level that provides *intersubjectively evident* grounds for beliefs about conceptual systems and socioscientific issues.

The concept of having good reasons is not without ambiguity. A person can have subjectively good reasons (i.e. reasons that are clear and convincing to her, given her level of understanding) or intersubjectively good reasons (i.e. reasons that are clear to her and that comply with the standards of reasoning of the social group to which she belongs). How are these different applications of justification relevant to the concept of knowledge? When is an educator entitled to say that a learner knows something in the sense of knowing that in a deep way? To put the question more formally: Under what conditions may a teacher attribute knowledge to a learner?

Scheffler urged that someone possesses suitable justification when that person possesses reasons for the quality of understanding: 'In saying he knows, we are not merely ascribing true belief but asserting that he has proper credentials for such belief, the force of which he himself appreciates' (1965, p. 74). Scheffler's and Cohen's arguments imply that even if a learner has subjectively good reasons for believing something to be true, she does not have knowledge unless she also has intersubjectively good reasons for a true belief or knowledge claim. One of the tasks of effective science teaching is to assist learners to acquire the relevant concepts and intersubjective standards of justification for evidence-based empirical arguments. Here, one's sense experiences must be reliably connected with the world, one's sense organs must be intact, and one's reasoning must be correct. An analysis of good reasons indicates why reference to them is context sensitive and why neither reasoning nor our sensory experiences are infallible. Nonetheless, if they are generally reliable sources of justification, the reasons they produce might be called *intersubjectively certain*. Cohen stated, 'Reasons can be permissible grounds for belief, relative to that standard, even though they are not ideally correct'(1986, p. 575). Essentially, both the beliefs and the justifications (reasons) given for them, but not their truth, may depend on particular social and cultural contexts or circumstances. Therefore, people can acknowledge differences in cognitive resources, skills, and opportunities without thereby having to commit to epistemic relativism.

In Plato's cave parable, whatever the enlightened person knows about reality stands in stark contrast to the (majority) view that the prisoners in the cave claim to know is reality. The cave parable indicated that knowledge is ambiguous between various concepts, when each is based on a different standard. Is knowledge context dependent? Scheffler's and Cohen's arguments suggest that it may be better to say that attributions of knowledge are context sensitive. The term *context sensitive* does not offer an open invitation to or endorsement of epistemological relativism. It is important to note that, in terms of the present definition, while belief and what counts as evidence may vary from individual to individual, society to society, and culture to culture, truth does not.

The present account acknowledges that people do not have the same cognitive resources, skills, and opportunities. They do not all act or operate in the absence of constraints. Their situations are characterised by different levels of expertise, by different opportunities to access and gather information, by different levels of cognitive maturity and training, and by considerable differences in available time and deadlines. Goldman cautioned that a 'social epistemology for the real world needs to take these constraints into account' (1991, p. 233). So, when Aikenhead argues that 'the knowledge, skills, and values found in the typical secondary science curriculum have been widely criticised throughout the world for being isolated and irrelevant to everyday events that affect economic development, environmental responsibility, and cultural survival' (1997, p. 7), one might respond by acknowledging the need for science education and education in general to be anchoring in and connected to the real world and to each other.

55.2.2 Politics and the Knowledge Enterprise

A central theme of this chapter has been a social justice motive within a rigorous epistemological and ontological stance applied to IKW, WMS, science education, and science teaching. Occasionally these motives can run opposed to one another, but they need not. Worldwide there have been efforts to rationalise educational and economical energies and programs across diverse cultural and ethnic communities. In June 1999, the EU ministers of education stated in the Bologna Declaration:

> *A Europe of Knowledge* [emphasis added] is now widely recognised as an irreplaceable factor for social and human growth and as an indispensable component to consolidate and enrich the European citizenship, capable of giving its citizens the necessary competencies to face the challenges of the new millennium, together with an awareness of shared values and belonging to a common social and cultural space (European Commission 1999, p. 1).

Among the central concerns of the Bologna Declaration were the transformation of educational systems and the transfer of educational experiences and knowledge, as well as the possibility of active and meaningful engagement across historical, social, cultural, and linguistic borders. The Bologna Declaration was a pledge by each of the 29 signatory countries. In the explanation prepared by European university administrators, the following points were listed:

- [A] commitment freely taken … to reform its *own* higher education system or systems in order to create overall convergence at European level. …
- The Bologna process … is not a path toward the "standardisation" or "uniformisation" of European higher education. The fundamental principles of autonomy and diversity are respected.
- The Declaration reflects a *search for a common European answer to common European problems*. The process originates from the recognition that in spite of their valuable differences, European higher education systems are facing common internal and external challenges related to the growth and diversification of higher education, the employability of graduates, the shortage of skills in key areas, the expansion of private and transnational education, etc. (Confederation of EU Rectors' Conferences and Association of European Universities 2000, p. 3).

In addition,

The Declaration specifically recognises the fundamental values and the diversity of European higher education:

- It clearly acknowledges the necessary *independence and autonomy of universities*; …
- It stresses the need to achieve a common space for higher education within the framework of the *diversity of cultures, languages and educational systems* (p. 6).

This agreement attempted to make the transfer of university experiences, course work, and certifications possible and to expedite the movement of students and professionals among the various jurisdictions of the EU member states. These efforts within the founding EU member states have gone reasonably well, but there have been some concerns with the blending of different university systems, traditions, and conventions. The long, historical, collaborative efforts in science, technology, and mathematics in the academies and research institutions have helped the rationalisation efforts of the Bologna Declaration. The real test will be the integration of new members of the EU without long records of collaboration and similar traditions. Will this effort in Europe influence similar reform efforts in other regions of the world where knowledge systems, epistemologies, and ontologies might differ drastically, like Africa?

55.3 Transformation in Africa

Finger (2009) suggested that people should disregard the new system for the inherent value of knowledge (as contrasted with its purely instrumental value) and this would provide a similar motive and advocacy of *Africa of knowledge* as that which drives toward a *Europe of knowledge*. This pertains not only to political leaders opening tertiary institutions in recently liberated African countries in the 1950s and 1960s and potential changes to established knowledge-building institutions resulting from the Arab Spring but also and especially of contemporary theorists and academics emphasising the need for secondary and higher education to develop an African identity. Makgoba stated:

> The issue of pursuit of knowledge for its own sake and the so-called standards have … become contentious factors around the African university. … The pursuit of knowledge for its own sake has been one of the cornerstones of university education; but is there such a thing as knowledge for its own sake today? Knowledge is a human construction that by definition has a human purpose. Knowledge cannot be sterile or neutral in its conception, formulation and development. Humans are not generally renowned for their neutrality or sterility. The generation and development of knowledge is thus contextual in nature (Makgoba 1997, p. 177).

Does this mean that funding and support for curiosity-driven inquiries (science) will be threatened and replaced by this call for mission-driven inquiries (technology/engineering)?

That knowledge ascription and justification have a crucial contextual component is surely not in doubt (Horsthemke 2004), but this does not mean that the pursuit of knowledge must be described and explained in consequentialist or constructivist terms. It might be the *object* of knowledge that is and continues to be the legitimate cornerstone of secondary and higher education. 'The global competition, the involvement of industry in universities, and the social, economic and political pressures of modern society have made the [pursuit of knowledge for its own sake—curiosity-driven pursuits] obsolete. … The pursuit of knowledge and the truth with a purpose and social responsibility [mission-driven pursuits] is what universities are about' (Makgoba 1997, pp. 181–182). Surely, setting up a commission like the Truth and Reconciliation Commission also involved a noninstrumental understanding of knowledge and truth (Horsthemke 2004). If they had an exclusively instrumental function, then substituting them would be entirely permissible—say, with an amnesia drug—as long as the desired end effect or outcome was the same. With regard to the traditional roles that universities throughout the world have in society, Makgoba considered the social responsibility of knowledge systems when he stated:

> [The] preservation, the imparting and the generation of knowledge. … It is important to recognise … that the imparting of inappropriate or irrelevant education, even of the highest calibre, would … lead to a poor and ineffective product. Thus, university education has to be relevant not only to the people, but also to the culture and environment in which it is being imparted (Makgoba 1997, p. 179).

Without doubt. The trick, of course, is to avoid an education system that is impoverished as a result of excessive concerns with people's culture and user-friendliness. Makgoba's comments are equally applicable to elementary and secondary education and especially to science education and science teaching.

However, the resolution of this pedagogical issue in learning and teaching science can place politicians, philosophers, and educators at odds. Some politicians have stressed that the social justice issue overrides any considerations of the nature of science and how people learn science. Some philosophers have questioned the validity of constructivism applied to the scientific enterprise (Matthews 2000; Nola 1997; Suchting 1992), while science educators advocate an interpretation of how people learn that has a constructivist flavour (NRC 2000, 2007). Henriques (1997) investigated the conceptual mix of science and pedagogy (behaviourism, cognitive development, and learning sciences) within the sociocultural contexts of schools and found that inquiry teaching within the constructivist learning perspectives ranged from information processing, interactive constructivist, social constructivist, or radical constructivist. She considered the underlying factors (i.e. nature of science, ontological, epistemological, cognitive, pedagogical, discourse/language influences, and realities of classrooms) in these interpretations and found little support for the strong sociocultural and radical constructivist approaches, some lingering uses of behavioural-based information processing, and sizeable support for the centralist approaches and modified learning cycle (engage, explore, consolidate, assess).

55.3.1 Africanisation and Afrocentrism

Nowhere have indigenisation and internationalisation efforts been more apparent than in Africa—a continent of diversity. Africanisation (continent-wide/global perspective) and Afrocentrism (cultural/ethnic perspective) have included radical endorsements, which tend to reject any outside (e.g. colonial, Western, Northern, European, Eurocentric, etc.) influence and also segregationist forms of nationalism (such as some trends manifested in the former Soviet Union, Yugoslavia, etc.). What they arguably share, apart from an intense belief about internal homogeneity and an equally strong rejection of heterogeneity is an instrumental usage of the concept of indigeneity. Indigenisation was not only seen as an effective instrument for political persuasion, mobilisation, and justification but also as a tool in transformation, educational, socioeconomic, and cultural aspects of the larger issue and national goals. As such, it becomes symbolic and may actually produce a virulent form of the 'ethnicisation' of education, politics, and the economy (Andreasson 2008, p. 7).[2] A characteristic of this approach, one of its 'normative entanglements', is the rejection of Eurocentrism, which is linked to an express sympathy with the ethnocentrism of non-European cultures (Cesana 2000, p. 452). Yet, to respond to Eurocentrism by embracing Afrocentrism is relevantly like responding to school-ground bullying with corporal punishment or to murder with capital punishment. Motivational reasons do not amount to justification of the prescribed solution in any of these cases (Horsthemke 2006).

So much for the caricatures. There are obviously more nuanced versions that deserve correspondingly serious consideration. Thus, in the instance of indigenisation, there is an emphasis on the local that nonetheless acknowledges the significance, if not the inescapability, of the global. 'We [Africans] have to construct our own epistemological framework from which we can explore ideas and build our own knowledge. … Africans must create our own paradigm from which we can also dialogue meaningfully with Europeans' (Masehela 2004, p. 11). A vice chancellor of the University of KwaZulu-Natal in South Africa maintains:

> It is the duty of academics and scholars to internationalise, articulate, shape, develop and project the image, the values, the culture, the history and vision of the African people and their innovations through the eyes of Africans: African people should develop, write, communicate and interpret their theories, philosophies, in their own ways rather [than allow these to be] construed from foreign culture and visions (Makgoba 1997, p. 205).

Moreover, he stated, 'global economic competition is high and unless we develop a competitive high technology economy we face economic ruin, stagnation and under-development, with dire consequences for the impoverished rural and urban communities' (p. 179). While the latter insight is surely correct, Makgoba does not elaborate on the assumption that Africanisation is compatible with internationalisation or with developing a competitive high-technology economy. Furthermore, he appears to use technology and science interchangeably and does not differentiate the ontological and epistemic characteristics of science, technology, engineering, and traditional knowledge systems. Fuller deliberations are needed to establish how an Afrocentric orientation is supposed to cater for the demand, 'as we enter the era of globalisation, … to rethink ourselves anew, and bring in new ideas if we are to be a significant part of the information age and an era of knowledge industries' (Ntuli 2002, p. 66) and with the 'need to develop people and prepare young South Africans for the future and the tough world of global competition' (Makgoba 2003, p. 2). Conversely, in the instance of internationalisation, the emphasis on the global is seen as compatible with or perhaps even requiring an acknowledgement of diversity, difference, and locality/indigenousness. This sociopolitical, socioeconomic, and techno-science problem space requires fulsome and rigorous considerations

---

[2] For a thinly veiled endorsement of this kind of reverse racist, indeed ethnocentric orientation, also see Makgoba and Mubangizi (2010), especially the chapter on Leadership Challenges.

and deliberations regarding those involved, ensuring fair distribution of risks and benefits are appropriately distributed across the participants.

There are further, remarkable parallels between the Bologna Declaration and the call for the Africanisation of education: emphasis on the Africanisation of knowledge, teaching and learning, and finding *African answers to African problems*, the endeavour to make the African university internationally attractive and competitive, to establish international respect for Africa's rich and extraordinary cultural and scientific traditions. The major difference is that Africanisation and Afrocentrism emanate less from the political/economic precedent of the African Union and the common objectives of convergence and transnational mobility than from a shared rejection of the European education system and Eurocentrism. While the Bologna Declaration may be interpreted as a call to unity by harnessing Europe's many strengths, the emphasis in Africanisation and Afrocentrism is more on unity as a means of resisting the external economic, cultural, and political influences.

Africanisation is closely associated with educational and institutional transformation and embodies traits of both internationalisation and indigenisation in which the former link may be more controversial. Africanisation of education has a clearly *international* element (i.e. between African nations/nation states), just like Europeanisation of education has been between EU member states. Moreover, the idea of Africanisation of knowledge bears more than a fleeting resemblance to the Bologna Declaration's internationalist reference to a Europe of knowledge. Africanisation binds together a plethora of Saharan and sub-Saharan nations and states. The late Libyan head of state Muammar Gaddafi's vision of a United States of Africa, with himself as Emperor of Africa, may have been a delusional, autocratic fantasy—but at least the first part of it is shared by many people in Africa. This desire for pan-African unity is captured in the frequent appeal to communalism as a typically African value and reference to the essence, identity, and culture of Africa (note the singular).

On the other hand, there is a strong emphasis in Africanisation and Afrocentrism on indigenous, local—as contrasted with, say, global, international, European/Eurocentric—educational knowledge, practices and values. For example, there is a frequent endorsement of African mathematics as ethnomathematics, traditional knowledge about nature and naturally occurring events as ethnoscience, and African knowledge systems as indigenous knowledge systems as opposed to academic or mainstream mathematics and science and world knowledge, respectively. The African *is* the indigene: colonised, exploited, marginalised, and historically excluded from the international mainstream.

A South African report on transformation, social cohesion, and the elimination of discrimination in public higher education institutions stated that 'at the centre of epistemological transformation is curriculum reform—a reorientation away from the apartheid knowledge system, in which curriculum was used as a tool of exclusion, to a democratic curriculum that is inclusive of all human thought' (South Africa Department of Education 2008, p. 89)—later referred to as 'the Africanisation of the curriculum' (p. 91). The report contends that 'resistance to Africanisation is often advanced under the guise of a spurious argument suggesting that the debate is not about privileging Western scholarship, but rather emphasizing the universality of knowledge' (p. 91). It is 'the local context [that] must become the point of departure for knowledge-building in universities [across Africa and, indeed,] the world' (p. 92). However, not all stakeholders and scholars fully endorse an Africanised curriculum and knowledge (Horsthemke 2004; Webb in press).

55.3.2 Cosmic Africa

Efforts to identify and document an African perspective on knowledge about nature and naturally occurring events have taken many forms. The film *Cosmic Africa* (Rogers et al. 2003) documents the journey of South African astrophysicist Thebe Medupe in his mission to connect occidental science and astronomy to the cosmological models of some of the oldest civilisations on earth. Astronomy survives in these ancient societies despite the eroding effects of colonialism and its modern heir, globalisation. Medupe emphasises that astronomy has never just been a science in these cultures, where it is an 'intimate tapestry merging into their prayers, their lives, their dreams and their deaths'.[3] Occidental culture, on the other hand, has separated astronomy from daily experience and turned it into pure science from astrology. Medupe's mission was stated at the very beginning of the film: 'I need to discover whether my science has a place in Africa, and whether Africa has a place in my science.' His journey leads him to the Ju/'hoansi in northeastern Namibia, the Dogon in Mali, and finally to Nabta Playa in the southern Egyptian Sahara, to what is conceivably the site of the first solar observatory (see also Rogers 2007, p. 19).

During his visit to Namibia, Medupe learns not only of Ju/'hoansi reliance on the stars as to when to plant and to harvest as an astro-calendar but many of the stories connected to the sun, moon, and stars:

> One memorable night, Kxau Tami and /Kunta Boo, two elderly shamans, demonstrated how they would throw burning sticks in the direction of a very bright meteor—as they threw the sticks into the air, they uttered swear and curse words which they said would help to divert the meteor's path and thereby prevent its dangerous potential. They believe that bright shooting stars with fiery tails are invested with very powerful !nom (extreme potency) and that they have the potential to cause sickness (Rogers 2007, p. 21).

Medupe's visit to the Ju/'hoansi coincided with a total solar eclipse. He worried about whether he should tell the people about what is going to happen but decided not to; they would want to know how he knows. Instead, he sets up his equipment. When the eclipse happens, people talk about the return of winter and blame the intruder and his equipment: 'The telescope is eating up the sun.' After the eclipse and subsequent reconciliation, Medupe says, 'For the first time, I see how the stars interact with long-held beliefs to affect the way people live. My science and my Africa are beginning to come together.'

---

[3] Note that quotations attributed to Medupe in this and following paragraphs are taken from the film's dialogue; hence, no page or paragraph numbers are provided.

This impression was deepened with the visit to the Dogon, whose knowledge of the stars is legendary. Their daily and seasonal activities, routines, and customs are guided, for example, by the appearance of Venus (for which the 'Dogon have a number of different names …, depending on its station in the sky'; Rogers 2007, p. 21), 'Toro Jugo—the Pleiades' (Rogers 2007, p. 20), etc. One of the elders, spiritual leader Annayé Doumbo, claimed, 'In our Dogon way, the man who makes technology is the sorcerer of the sun'. Given the harsh conditions under which they live, to the Dogon, knowing the stars can mean the difference between life and death. Does the elder know that human beings have walked on the moon? 'There is no gate to the moon', is the reply, 'it is not possible for anyone to go there, unless they are the little brother of God'.

The last leg of Medupe's journey was presented as the origin of astronomy, Egypt. However, there was no mention of the innovations and discoveries of the Maya and Aztecs, which can be taken as evidence of the lack of knowledge transmission between continents in the southern hemisphere. In the southern Egyptian desert, near the border of Sudan, he discovered what is conceivably the oldest observatory conceived and constructed by the Nabtans, nomadic pastoralists, now long dead. Predating Stonehenge in England by almost 1,000 years, it consists of stones emanating from a centre, in order to trace the rising and setting of the sun during the year, as well as the passage of the moon and stars. Medupe stated, 'The origin of astronomy, its measuring and predicting is in Africa … Stones took the place that my computer takes now.'

It was Medupe's prime intention to create an African star chart; unfortunately, he and the research team never explored any of the tensions between IKW and WMS worldviews, knowledge claims, and explanations. They seem satisfied with just noting the different perceptions and appear to assume that there is no problem of reconciliation of myth or legend with scientific claims and explanations. At the end of the film, Medupe stated that he has come 'full circle', that his journey has served to (re)unite 'his [postmodern] science' and 'his Africa', without any attempt to account for the contradictions encountered between spirituality and astronomy.

55.4 Reflecting on Attempts to Indigenisation/Africanisation and Internationalisation

Attempts to promote specific geographic, cultural, or ethnic interpretations of knowledge and knowledge construction have encountered problems in the search for truth and wisdom within a global society. Continental landmass or geopolitical boundaries and ethnocultural groupings cannot confine knowledge, especially knowledge about nature and naturally occurring events. Efforts to indigenise or Africanise and internationalise have received philosophical, pedagogical, and practical critiques.

55.4.1 Problems with Indigenisation

Medupe's long-term goal was to develop a database and to set up a formal ethnoastronomy research group. The pertinent questions, for present purposes, were: Does the idea of ethnoastronomy make sense? What, if anything, distinguishes ethnoscience from mainstream, academic science? Is it a spiritual, contextual, or cultural element? The differences between WMS and IKW about nature and naturally occurring events may vary across science domains and between science and technology.

Jegede (1999) emphasised that the local and contextual character of his interpretation of scientific knowledge and truth, in terms of learning and teaching where a 'strong relationship that exists between the prior knowledge and sociocultural environment [of the student. It is] deemed primitive, inferior and unscientific' (p. 120) by/in the 'Western view, especially with regard to science teaching and learning' (p. 123). No wonder, the cynic might question his four fundamental features of the African belief and thought system—belief in a creator/god, belief in life after death/reincarnation, anthropocentrism or the idea that human beings constitute the centre of the universe, and the theory of causality, which 'is the sociocultural cloak the African child takes to the science classrooms' (p. 125)—and their application to knowledge, cognition, or science. Good (2005) expressed sincere concern about mixing scientific and religious habits of mind and related ontological requirements for explanation of nature and naturally occurring events.

Aikenhead and Jegede stated:

> In the culture of Western science, students learn that the refraction of light rays by droplets of water causes rainbows; in some African cultures, a rainbow signifies a python crossing a river or the death of an important [traditional] chief. Thus, for African students, learning about rainbows in science means constructing a potentially conflicting schema in their long-term memory. Not only are the concepts different (refraction of light versus pythons fies") (Aikenhead and Jegede 1999, p. 276).

Aikenhead and Jegede appear to have confounded the ways of knowing as a learning process with the established procedures for doing and knowing science. They were actually, at best, using the contrast to differentiate epistemologies since they have provided little insights into the differences in metaphysics and underlying ontological requirements for scientific explanations. This raises the question: Which of these accounts constitutes science? Traditional African education appears to discourage critical interrogation of received knowledge, wisdom, and practice. In terms of validity and usefulness (explanation limited to physical causality void of magic, mysticism, and spiritualism; prediction and predictive power; etc.), there is no equivalence here—WMS and traditional African IKW are different! However, if Jegede's account was meant to exemplify an initial engagement strategy and 'collateral learning' (which is principally about students holding a multitude of worldviews at the same time), it might be argued that 'traditional thought' or 'explanation' (1999, p. 131) might access and engage students with traditional prior knowledge and experiences; frequently, however, it fails to involve acquisition of facts or truth and, therefore, does not constitute knowledge. For this reason, one might even consider the reference to different epistemologies/ontologies incomplete, inappropriate, or misleading.

In a related vein, le Grange mentioned the *localness* of all knowledge systems: All knowledge is local, 'located/situated and motley (messy situatedness)'. While it makes some sense to say that 'all knowledge systems have localness in common', they also share objectivity and *trans*localness (Le Grange 2004, p. 87). Le Grange would probably concur with Visvanathan's statement that 'Morality, like science, has to be invented individually' (Visvanathan 2002, p. 51). However, this view indicates a basic misconception since neither science nor morality is an individual invention. There is also a disconcerting relativism manifest in views like these. WMS attempts to make evidence-based claims, generalised explanations involving physical causality, and public evaluation where Nature is the final arbiter (Ford 2008). However, some science events and several technologies are place based, which make them suitable engagements for students in these locations.

When Māori scholar Russell Bishop refers to *Kaupapa Māori*, 'the philosophy and practice of being and acting Māori', as an 'orientation in which Māori language, culture, knowledge and values are accepted in their own right' (Bishop 1998, p. 201), this points to a fairly thoroughgoing relativism. He adds a disclaimer: 'It is also important not to ignore the impact of European colonialism by claiming that Māori culture has all the answers. Nor is this to say that *all* knowledge is *completely* [emphasis added] relative' (p. 210). The postmodernist relativist phrase 'all knowledge is completely relative' is troublesome for many philosophers of science, nature of science in education researchers, and curriculum developers as it implies that all claims are equally valid and should not be evaluated for fear of disempowering the people making the claims. Such a position might represent the slippery slope in educational thinking for WMS, public evaluation of science claims, nature as final arbiter, rigorous epistemologies, and restricted ontological assumptions. Application of these relativistic ideas will not allow biologists to differentiate among divine creation, intelligent design, and evolution explanations of changes in living organisms (including humans), which has been the focus of much legal deliberation and scholarly debate.

Relativism as a social justice stance, in particular, is problematic in that one would not be able to compare and evaluate competing knowledge claims. However, many postmodern curriculum theorists welcome this implication as a solution to the disciplinary power structure that disempowered minority scholars and silenced underrepresented voices. Onwu and Mosimege were worried about the gatekeeping mechanisms set up by WMS to determine 'what is to be included or excluded as science' (2004, p. 4). If relativism were true, for the sake of the present argument (i.e. assuming that its truth could be established nonrelatively and that this would not constitute a vicious logical inconsistency), then there would be no epistemic or veritistic grounds for choosing between the claim that rain is the result of a chain of physical cause–effect relationships involving condensing moisture that occurred as a result of evaporation driven by solar radiation and the belief that 'rain can arise at will as a result of human action' and 'the rain by-passes the farm/field of the person who stands while drinking during the ploughing season' (Onwu and Mosimege 2004, p. 7). Most disturbingly, this kind of approach would thwart all scientific inquiry into, or curiosity about, phenomena for which there already exists a traditional, folkloric account or explanation. This barrier to continuous disbelief and inquiry is similarly deterred by an absolutist–realist view of science for established ideas.

55.4.2 Problems with Internationalisation

The critique of internationalisation as a viable, defensible approach to transformation of science education—and the teaching and learning of scientific knowledge, concepts, and practices in non-Western or indigenous societies—was diverse in both articulation and geographical orientation. Bishop has argued that

> [a]ttempts to locate Kaupapa Māori research within the broad framework of international perspectives on *participatory research*, [emphasis added] indeed even to search for a methodology of participation, may defeat the very purpose of Kaupapa Māori research, which is to reduce researcher imposition in order that research meets and works within and for the interests and concerns of the research participants within their own definitions of self-determination (Bishop 1998, p. 210).

Participatory research has a distinct political action function that sets it apart from most educational research approaches. Embracing a First Nations–Aboriginal perspective and referring to transmission and transformation of science education in particular, Aikenhead stated that the 'nature of the transformation [requires] science to articulate with practice' (Aikenhead 1996, p. 29). Elsewhere, he added:

> Science education's goal of transmission runs into ethical problems in a non-Western culture where Western thought (science) is forced upon students who do not share its system of meaning and symbols … the result is not enculturation, but assimilation or "cultural imperialism"—forcing people to abandon their traditional ways of knowing and reconstruct in its place a new (scientific) way of knowing … (Aikenhead 1997, p. 11).

Similarly,

> if … science is generally at odds with a student's everyday world, … then science instruction can disrupt the student's view of the world by forcing the student to abandon or marginalise his/her indigenous way of knowing and reconstruct in its place a new (scientific) way of knowing. The result is assimilation … [which] has caused oppression throughout the world and has disempowered whole groups of people (Aikenhead 1997, p. 4).

Abrams et al. (in press) discussed 'pedagogy of hope' regarding culturally relevant science teaching involving traditional knowledge systems, mathematics, and science. They identified contemporary research findings that outline the successes and failures involved in engaging indigenous students with traditional indigenous knowledge, which have been promoted by the Alaska Native Knowledge Network (http://www.ankn.uaf.edu/) and the Indigenous Science Network Bulletin (http://members.ozemail.com.au/~mmichie/network.html).

Education can inculturate or assimilate students into a specific culture, forcing them to leave behind their home culture, or it can acculturate students into living in two cultures with free movement between these cultures. Many practicing scientists report having both religious and scientific beliefs representing their professional and personal cultures where they strategically move between these cultures as needed. Several science educators have endorsed a two-way bridge or border-crossing analogy for working with indigenous and nonindigenous students in IKW and WMS.

The notion of internationalisation, then, involves the assumption that the worldwide trend of cultures and societies is toward increasing synchronisation of local environments—presumably following the Western model. This is clearly not a wholly accurate assumption, as evidenced by the complementary development or resurgence of indigenisation and particular phenomena like Africanisation, which is about cultural identity and language restoration as the face of culture conservation. Despite its lip service to diversity, differentiation, and particularities and however benevolent its motivation and intentions, internationalisation is by its very nature ultimately unable to accommodate these differences and countercurrents, especially if and where these are at odds with its central tenets (e.g. where they are manifestations of religious fundamentalism, involve nondemocratic practices). A less favourable view considers this rival trend to be a bothersome, regressive phenomenon that is facing imminent extinction.

With regard to science education, the major challenges facing internationalisation are those of accessibility and relevance. Unfortunately, Aikenhead stated that 'the "taught" science curriculum, more often than not, provides students with a stereotype image of science: socially sterile, authoritarian, non-humanistic, positivistic, and absolute truth' (Aikenhead 1996, p. 10). The traditional absolute realist view of science found in many textbooks represents a 'real science' that is outdated with few scientists endorsing it and may have never existed (Yore et al. 2004; Ziman 2000). Aikenhead characterised:

> [school] science [as] conveying an ideology that exalted Western science over all other ways of knowing… [an] ideology [that] assumed that science was purely objective, solely empirical, immaculately rational, and thus singularly truth confirming. … Scientism is scientific fundamentalism (science is the only valid way of knowing). …[Science teachers, he continued] tend to harbour a strong allegiance to values associated with scientism, for instance, science is: non-humanistic, objective, purely rational and empirical, universal, impersonal, socially sterile, and unencumbered by the vulgarity of human bias, dogma, judgments, or cultural values. … For the vast majority of students, however, enculturation into Western science is experienced as an attempt at assimilation into a foreign culture. Because students generally reject assimilation into the culture of Western science …, they tend to become alienated from Western science in spite of it being a major global influence on our lives (Aikenhead 2001, p. 2).

Haack (2003) provided a readable and understandable defence of WMS, scientism, and cynicism within reason and common sense that questions and clarifies some of these assertions. However, based on his understanding of *culture* as 'the norms, values, beliefs, expectations and conventional actions of a group' (Aikenhead 1996, p. 7) and of science as a *subculture*, Aikenhead outlined a cultural perspective on science education and culturally responsive pedagogy founded on several tenets:

1. WMS is a cultural enterprise itself, one of many subcultures of Euro-American society,
2. People live and coexist within many subcultures identified by, for example, language, ethnicity, gender, social class, occupation, religion and geographic location,

3. People move from one subculture to another, a process called "cultural border crossing";
4. People's core cultural identities may be at odds with the culture of WMS to varying degrees,
5. Science classrooms are subcultures of the school culture,
6. Most students experience a change in culture when moving from their life-worlds into the world of school science,
7. Learning science is a cross-cultural event for these students,
8. Students are more successful if they receive help negotiating their cultural border crossings, and
9. This help can come from a teacher (culture broker) who identifies the borders to be crossed, who guides students back and forth across those borders, who gets students to make sense out of cultural conflicts that might arise, and who motivates students by drawing upon the impact WMS and technology have on the students' life-worlds. (Aikenhead 2001, p. 4)

Aikenhead's context-sensitive argument, although initially attractive, rests on some rather problematic assumptions. Thus, the claim that science, science education, teaching, resources, and learning were cultural entities remains open to counter-argument. The claim that WMS is no more than one worldview among several equally valid worldviews about nature and naturally occurring events, too, remains unsupported (Yore 2008). Each of these worldviews has personal value, but they are not based on the same ontological assumptions and epistemological beliefs (NRC 1996). Surely, science is not just 'another cultural point of view' (Aikenhead 2001, p. 6); it has been a very successful human endeavour leading to positive and negative outcomes and implications. However, most people do not want their scientific beliefs to be tested by hermeneutics of religious scriptures. Nor do they want their religious beliefs to be tested by established scientific procedures. Evolution is a theory in the scientific sense—an umbrella idea that integrates other ideas and has predictive and explanatory powers; it is not merely a theory in the common lay sense—a *crazy ass* guess or a speculation among several competing, equally valid ideas (e.g. divine creation, intelligent design).

The assertion that people's core cultural identities may be at odds with the culture of WMS to varying degrees is perhaps true—in the sense that creationists' core cultural/religious identities may be at odds with science. However, many scientists and science educators report holding religious ideas and attend houses of worship, which would indicate that they maintain parallel worlds, each with specific purposes. An example might be a religious scientist standing atop a tall building and considering suicide takes time to pray, which is not for the grand architect of the universe (his god) to discontinue gravity for a few seconds after he jumps but is most likely for the grand architect to console his family and forgive his bad deeds.

Aikenhead's understanding of the aims or purposes of science education raises serious questions, when he stated that 'if the subculture of science generally *harmonises* [emphasis added] with the student's life-world culture, science instruction will tend to support the student's view of the world' (Aikenhead 1996, p. 4).

Harmonisation is the critical point here. Does this mean sensitive and respectful engagement of prior knowledge, beliefs, and experiences—a basic axiom of contemporary learning theory—or does it mean uncritical acceptance of all opinions as equally valid? '[Teachers] should teach science embedded in a social and technological milieu that has scope and force for students' worlds, worldviews, or practical experiences (respectively); and [they] need to dismantle barriers between students and science' (1996, p. 18). He later stated:

> Most students have a chance to master and *critique aspects of Western science* [emphasis added] without losing something valuable from their own cultural way of knowing. By achieving smoother border crossings between those two cultures, students are expected to become better citizens in a society enriched by cultural differences. This is an essence of cross-cultural teaching (Aikenhead 2001, p. 16).

This invites the question whether critique of Aboriginal ways of knowing, perhaps by way of critical self-reflection, is equally encouraged. If not, then how could one speak of *successful* cross-cultural teaching and learning? How does one draw a distinction between what is scientific and what is unscientific? Moreover, how does one get students to grasp the difference—if there is one? Why, according to Aikenhead, should students learn and appropriate the content of Western science at all? These are just a few questions that would need to be addressed by a compelling critique of internationalisation and its idea of the universality of science and applicability of their knowledge about nature and naturally occurring events outside of the classroom, in future studies, and for career preparation.

There is also the issue of language. In a study that builds in part on Aikenhead's ideas of cross-cultural science education and border crossing, Fakudze and Rollnick pointed out that

> African students enter the classroom with a rich heritage of traditional beliefs that, if handled sensitively and with understanding, can play an important role in enabling learning of science. Recent developments in the understanding of how students acquire this knowledge may assist in promoting this process (Fakudze and Rollnick 2008, p. 69).

They stated that

> Most learners in Southern Africa speak one language at home and are expected to study in a different language at school. The extent of separation of these two contexts is determined by whether the school is urban or rural. … [The] learning of science is further distanced from the home culture by its expression in either a second or foreign language, creating further logistical borders to be crossed (Fakudze and Rollnick 2008, p. 73).

Yore and Treagust (2006) pointed out that all learners of science face the 3-language problem (i.e. home, school, and science language), but nonspeakers of the language of instruction face much more distinct barriers and difficult transitions between these languages. Fakudze and Rollnick explored two significant possibilities: (a) using a discourse-based model to demonstrate 'how accessing either spoken or written mixed discourse may facilitate learners' comprehension of scientific discourse and allow a teacher to assist in its production' (Fakudze and Rollnick 2008, p. 76) and (b) how code switching is a useful strategy to 'facilitate the establishment of meaning by providing a linguistic and cultural bridge to understanding' (p. 78), that is, to assist border crossing in the science classroom. In so doing, they seek to augment Aikenhead's 'Cultural Border Crossing Hypothesis', which 'has not considered the issue of language' (p. 81):

> The use of language is an important aspect of border crossing and its management. … Where the two sides of the border are reinforced by a difference of language and the need for code switching, the gap can appear wider and more difficult to cross (p. 91).

Given that 'the issue of language … plays a very important role in the acquisition of science concepts' (p. 81), any account of internationalisation (or indigenisation, for that matter) that ignores this is likely to remain somewhat impoverished.

Guo (2008) examined traditional Chinese and indigenous cultural and language practices in Taiwanese science classrooms and found that the habits of mind of traditional Chinese philosophers tend to be intuitive, metaphorical, descriptive, and holistic in contrast to the rational, causal, analytical, and reductive ways of thinking that are emphasised in WMS. He also suggested that distinctive features of Chinese words and cultural beliefs might influence students' learning of science. Any teacher who believes in and uses an interactive–constructivist teaching approach (conceptual change, guided inquiry, etc.) needs to realise that nondominant language speakers will have much of their meaningful prior knowledge, experiences, and linguistic resources stored in their home language, which cannot be accessed, engaged, challenged, and applied in the dominant language of instruction. Furthermore, many of their knowledge-building language resources will be in their home language; therefore, these students need time in science classroom to share, negotiate, construct, argue, explain, and apply the prior knowledge and cognitive resources in peer groups using the same home language before whole-class deliberation in the languages of instruction and science (Yore 2012).

An additional problem with *both* internationalisation *and* indigenisation is that these approaches commit what might be called the fallacy of the collective singular. This is an essentialist fallacy that pervades reference to, say, German culture, European identity, Asian humility, the African university, the essence of Africa, and the like. The Bologna Declaration also seems to contain what Welsch has defined as 'the traditional concept of culture', where cultures are seen as separate and distinct 'islands' or closed 'spheres' (Welsch 2000, p. 330):

> The vitality and efficiency of any civilisation can be measured by the appeal that *its culture*[emphasis added] has for other countries. We need to ensure that the European higher education system acquires a world-wide degree of attraction equal to our extraordinary cultural and scientific traditions (European Commission 1999, pp. 2–3).

Botha (2010) provided a similar critique applied to Africa. In fact, neither internationalisation nor indigenisation appears to be able to do justice to the ways in which scientific content, principles, and practices—let alone culture and identity—are learned, developed, and transformed. It also remains unclear how these approaches could satisfactorily account for the worldwide attractiveness of 'the European' or 'the African' secondary and higher education system, respectively.

55.5 Multiculturality and Interculturality

Welsch's (2000) analysis of the traditional notion of culture was characterised by three pillars: social homogenisation, an ethnic foundation, and cultural delimitation. The problem, concisely, was that the depiction of cultures as separate, distinct islands or self-contained spheres was both unrealistic and normatively dangerous. It was unrealistic because it is descriptively and empirically weak, if not altogether mistaken. Throughout human history, there have been extensive transmission and dissemination (transsemination) among cultures and civilisations. Even during the eighteenth century for German philosopher Johann Gottfried Herder (to whom Welsch attributes this notion), there would have been few, if any, cultures completely untouched, uninfluenced, or not otherwise inspired by coexisting cultures. The idea of single cultures is also normatively dangerous because of its proximity to what might be called *culturism* (cultural racism, elitism, or exclusivism).

Given recognition of the significance of these problems, both empirical and normative, there have been two trends (not least in educational theory) in the latter half of the twentieth century to account for the ever-increasing transsemination and, importantly, to promote recognition, tolerance, and respect among human beings. Both multiculturality and interculturality seek to transcend the narrow confines of the traditional concept and to foster mutual understanding among cultures. Does either of these ideas provide a resolution to the impasse in the internationalisation–indigenisation debate?

Welsch (2000) argued that both concepts are problematic in that their very structure (one might say, more accurately, their grammar) still presupposes the very notion of the single cultures they purportedly repudiate. The idea of multiculturality emphasises the coexistence of different cultures within one and the same society. While this constitutes an improvement on the demand for social homogenisation, multiculturality is unable to address the resultant problems of this cultural plurality. It is not able to do so because of its conception of this multitude of cultures as individually homogenous. In fact, all it implies is the mere fact of coexistence—it says, or can say, very little about transsemination, whether descriptively or prescriptively. Welsch suggested it comes as no surprise that circumstances in the United States should have entailed some kind of justification of and increasing appeals to intercultural delimitation by theorists of multiculturality.[4]

The idea of interculturality does not appear to fare much better, for very similar reasons. It does go beyond emphasising mere coexistence of different cultures, by concerning itself with the issue of difficulty in cooperation and collaboration[5]—but it, too, conceptually presupposes the traditional conception of single, distinct cultures. Therefore, the problems it hopes to address must remain elusive since they arise because of the very presupposition that cultures are separate islands or self-contained spheres. The diagnosis of intercultural conflict is followed by

---

[4] Welsch cites Amy Gutmann and Will Kymlicka, among others.

[5] See Council of the European Union (2010, p. 2).

advocacy of intercultural dialogue.[6] Yet, the basic problem remains, encapsulated in the thesis of essential separateness or distinctness of the conflicting and dialoguing cultures.[7] Thus, any of the envisaged changes would ultimately be little more than cosmetic. Nevertheless, is this thesis, which constitutes not only the traditional conception of culture but also underlies the ideas of multiculturality and interculturality, *correct*? If it were, then the problems of the coexistence and cooperation/collaboration of different cultures would remain with us—and would arguably remain unsolvable.

55.6 Transkulturalität

The central goal of this chapter—to position the IKW–WMS debate within the context of contemporary philosophical views of science and pedagogical insights into science learning and teaching—remains unsatisfied since multiculturalism and interculturalism appear to be a weak solution; one last position would be transculturalism. In Africa, *Transkulturalität*, or transculturality, presents itself as a possible response to the impasse. The central thesis is that the conception espoused in the traditional view of culture, and more or less unintentionally adopted or presupposed by the views that have succeeded it, is simply false. In other words, the depiction of cultures as islands or spheres is factually incorrect and normatively deceptive. Our cultures, Welsch (2000) suggested, no longer have the purported form of homogeneity and separateness but are, instead, characterised by mixtures and permeations. Welsch described this new structure of cultures as '*trans*cultural'—insofar as the determinants of culture now *traverse* (i.e. go *through*) cultures and *cross* their traditional boundaries and insofar as the new form *transcends* (i.e. goes *beyond*) the traditional conception (Welsch 2000, p. 335).

The understanding of transculturality so explained applies both on a macro-level, pertaining to the changed and changing configuration of present-day cultures, and on a micro-level, referring to the cultural make-up and shape of individuals. The mixtures and permeations that characterise our cultures are the result of technological advances, communication and travel, economic connectivity and dependencies, and—even more recently and importantly—of the increasing democratisation of societies. Examples of these permeations include moral and social issues and states of awareness that characterise many, if not all, allegedly different cultures: the debates about human and nonhuman rights, feminist thinking, same-sex relationships, and ecological consciousness, to mention only a few. Examples from commercial interaction (*trans*actions), sport and popular culture abound—rugby has invaded Asia, Eastern Europe, and North and South America; smart phones, hand-held technologies, and electronic gaming are ubiquitous, while hip-hop can be found in

---

[6] See Aikenhead (2001, p. 4), described earlier, Problems with Internationalisation.

[7] See Welsch (2000, pp. 334–335).

Africa, Asia, Australia, and Europe. Welsch suggested that contemporary cultures are generally marked by 'hybridisation' (Welsch 2000, p. 337). Nonetheless, some critics would disagree with him when he claimed that the grounds for selectivity between one's own culture and foreign (or other) culture have all but disappeared and that

> there is little, if anything, that is strictly 'foreign' or 'other'; everything is within reach. By the same token, there is little, if anything, that can be called 'own': Authenticity has become folklore. It is ownness simulated for others, to whom the indigene himself has long come to belong (Welsch 2000, p. 337).

The transcultural (transmission between cultures) can be seen in the uptake of procedures and products among cultures and nation states. The Truth and Reconciliation process, underpinned as it was by a commitment to restorative justice, was historically and recognisably South African—even though it has been successfully applied and has transformed judicial thinking and practice, globally. Similarly, knowledge of the thirst- and appetite-suppressing qualities of the *!khoba* cactus (or *Hoodia gordonii*) originated with the San community, although the product has since been commercialised and is now available at pharmacies all over the world. Transculturality also operates on a micro-level (i.e. individual) where the vast majority of human beings are constituted in their cultural formations by a multitude of cultural origins, affiliations, and connections. 'We are cultural hybrids' (Welsch 2000, p. 339) or 'individuals in any cultural context are multiply situated/positioned' (López 1998, p. 227). We may have a particular national identity, but we may also have a multitude of cultural identities.

So, does transculturality yield a pertinent philosophical perspective on transmission of knowledge and practices, on the transformation of educational systems, or on the IKW–WMS issue? It *may*, but this verdict may require some additional conceptual clarification as well as more empirical substantiation. Welsch asserted that transculturality is itself a temporary diagnosis, which refers to a transition or, rather, a phase within a transition. It takes as its starting point the traditional idea of single cultures and maintains that this idea—whatever the appeal it may still hold for many—no longer applies, at least not to the vast majority of contemporary cultures. The concept of transculturality seeks to capture an understanding of a contemporary and future constitution of cultures that is no longer monocultural but transcultural. This does not mean that the concept of culture has become empty; according to Welsch, it makes good sense to speak of a coexistence of reference cultures and of new, transcultural nets or webs that emanate from these anchor points.

An objection that might be raised at this point may take the form of the *argument from entropy*—that the ever-increasing transsemination will itself logically lead to a kind of homogenisation, that the erstwhile individual (trans)cultural systems will become indistinguishable from one another, and that transculturality will level out in a kind of bland pan-cultural sameness, a global closed system. The argument is that not only that the idea of cultures will have been rendered redundant but the very notion of transculturality will also have ceased to apply. It would appear that Welsch himself has brought on this objection, by claiming that transculturality is itself a *temporary* diagnosis. However, further elucidation shows that the new reference cultures will themselves have transcultural configurations that are the reference point for the weaving of new transcultural webs. In addition, the different individual, social, geographical–environmental, and historical–political contexts will more than ensure that an entropic end state is highly unlikely to be bought about.

How does transculturality help address the central issue of IKW and WMS in teaching indigenous and nonindigenous students ideas about nature and naturally occurring events? Yore and Guo (2008) suggested that transcultural science instruction in Taiwan might be less conflicting (philosophy pedagogy) if indigenous technologies (e.g. animal traps, food preservation, fabrics, games, house construction, household tools, jewellery) were used to engage students and build social capital and trust before considering WMS ideas. Modern information communication technologies (smart phones, hand-held devices, etc.) and young people's ubiquitous engagement in electronic games and gaming might provide a common platform for exploring technological design and technologies. Thereby, historical technologies would serve as bridge into modern technology as design and engineering/technology practices (NRC 2012).

A prototypical example of transcultural science instruction in Taiwan illustrated the underlying principles and procedures for development of responsive and respectful approach to IKW and WMS (Lee et al. 2011). They reported on a case study of collaborative curriculum planning and teaching of a Grade 4 unit about the conception and measurement of time in an Amis (indigenous peoples of southeastern Taiwan) community school, which enrolled both indigenous and nonindigenous students. The planning involved Amis elders (knowledge keepers), the classroom teacher, and science educators identifying IKW about time events and devices and resource people that could be embedded into the prescribed unit of study and textbook coverage. Ideas about ritual celebrations, appearance of plants and animals, lunar phases, tides, and other cyclic events were embedded into the normal study of the Earth–moon–sun system; definitions of days, months, and years; and measures of minutes and hours. A reflective–responsive mechanism was used to monitor and adjust the teaching sequence and contents. Qualitative information indicated that the indigenous and nonindigenous students were engaged in the lessons and the teacher believed that the achievement of all students was much better than normal based on previous classes of students. Lee et al. stated:

> Although the current decline of Amis culture is difficult to halt, the "Measuring Time" module at least promotes student interest in learning and helps restore their cultural identity and pride. Although a cultural gap will continue to exist, we believe that students individually will adjust their innermost thoughts in ways that make sense to each student' (Lee et al. 2011, p. TBD).

Furthermore, indigenous and nonindigenous students will have a better appreciation of each other's cultures.

55.7 Conclusion: Philosophy of Education and the Role of the University

French philosophers Gilles Deleuze and Félix Guattari claimed, ‘La philosophie … est la discipline qui consiste à créer des concepts’ [Philosophy … is the discipline of creating concepts] (Deleuze and Guattari 1991, p. 10). Far more, one might argue, apart from its task being the creation of concepts (*if* it is that!), philosophy—including philosophy of education—addresses conceptual clarification and helps in determining the appropriateness or applicability of concepts, their interconnectedness, role in argumentation, etc. One of the most important functions of philosophy is arguably that of tireless critical interrogation—not only of concepts but also of premises, beliefs, values, assumptions, and commitments—and, by inquiring into their meaning and justification, not to mention their truth, to attempt to resolve some of the most fundamental ontological, epistemological, ethical, and educational questions.[8]

As Thomas Auf der Heyde (former dean of research, University of Johannesburg; 2005) has pointed out, universities clearly stand to benefit from globalisation—so, from an economic point of view, the question whether they are justified in embracing globalisation (e.g. of the knowledge economy) receives a quick and simple answer. The more interesting and difficult question is in what way, if any, their role as social observer and commentator, and their responsibility to critically reflect on the phenomenon of globalisation (Auf der Heyde 2005), can be made to complement the interest of the state, the universities’ key stakeholders, etc. If Auf der Heyde is correct in saying that ‘universities … should also be critically appraising the issues raised by [globalisation]’ (p. 41), then this is where philosophy of education arguably has its natural home. The role of philosophy consists in part in counteracting the hegemony and despotism of both homogenising (colonising) and traditional (indigenising) authority.

Acknowledgements The authors accept responsibility for the message in this chapter but would like to recognise the collective contributions that included insightful comments provided by reviewers, Cathleen Loving (Texas A&M University, USA), Christine McCarthy (University of Iowa, USA), Dawn Sutherland (University of Winnipeg, Canada), and Don Metz (University of Winnipeg, Canada), and the insights and help provided by Michael Matthews (University New South Wales, Australia) and Ron Good (Emeritus, Louisiana State University, USA). We wish to express special thanks to Sharyl Yore for the technical editing and blending two dispersant voices and languages into a reasonably understandable text. Thank you all!

Kai Horsthemke is an associate professor and current head of the Division of Studies in Education at Witwatersrand University. He was educated both in Germany and in South Africa and was awarded his Ph.D. in Applied Ethics in the Department of Philosophy, University of the Witwatersrand. A professional musician for several decades, he has been involved in stage, studio, television, and cruise ship work (in South Africa, Namibia, Mozambique, Germany, Luxembourg, England, Indian Ocean islands, Japan, Hawaii, and Colombia). He teaches philosophy of education—ethics, social and political philosophy, epistemology, philosophy of science, and logic and critical thinking, all with a strongly educational focus. He has published extensively since 2004, including a book entitled *The Moral Status and Rights of Animals* (Porcupine Press 2010). Apart from animal rights, his research interests include African philosophy (of education), indigenous knowledge (indigenous science, ethnomathematics, ethnomusicology), as well as humane and environmental education. He is currently working on a book with the provisional title *The myth of 'indigenous knowledge'*.

Larry D. Yore is a University of Victoria distinguished professor emeritus, retiring in June 2011 after 41 years. He was educated at the University of Minnesota (B.S., 1964; M.A., 1968; Ph.D., 1973). In over four decades of postsecondary teaching and research, Larry has been engaged in developing provincial science curricula, national science frameworks, national K-12 assessment projects in North America, and he has published widely in major science education journals and anthologies. He has served on or is currently a member of the editorial boards or review panels of the *Journal of Research in Science Teaching*, *School Science and Mathematics, Science Education*, *Journal of Science Teacher Education*, *Journal of Elementary Science Education, International Journal of Science Education*, *L1—Educational Studies in Language and Literacy, Science and Technology Education*, and *International Journal of Science and Mathematics Education*. Larry currently serves as associate editor and founding member (2001) of *International Journal of Science and Mathematics Education*, a SSCI listed journal. He received the 2005 Association for Science Teachers Education's Science Teacher Educator of the Year Award and 2012 National Association for Research in Science Teaching's Distinguished Contributions through Research Award. His 2012 publications include chapters entitled 'Science Literacy For All—More than a slogan, logo, or rally flag!' In K. C. D. Tan, M. Kim, and S. Hwang (Eds.), *Issues and challenges in science education research: Moving forward* (pp. 5–23) and with Carole L. Yore 'Toward convergence of metacognition, reflection, and critical thinking: Illustrations from natural and social sciences teacher education and classroom practice' In A. Zohar and J. Dori (Eds.), *Metacognition in science education: Trends in current research* (pp. 251–271); both books were published by Springer.

Chapter 56
Science, Religion, and Naturalism: Metaphysical and Methodological Incompatibilities

Martin Mahner

56.1 Introduction

In many countries, children receive both science education and religious education.[1] "Religious education" is here understood as an education under denominational auspices, however liberal. That is, students are not taught some unbiased comparative, historical, cultural, and social aspects of religion, but are expected to accept and internalize the doctrines of a particular religious belief system, usually the one their parents are affiliated to.[2] From a nonreligious perspective, this situation is unfortunate as it appears that an education emphasizing the need for empirical tests and evidence is incompatible with an education that allows for, or even encourages, the acceptance of factual beliefs without or even contrary to evidence. In other words, learning to accept statements only if there is sufficient evidence for them and learning to accept claims on sheer faith appear to be antagonistic educational goals (Mahner and Bunge 1996a; Martin 1997).

Evidently, this concern rests on the assumption that science and religion are mutually incompatible, whereby "incompatible" means that one cannot rationally accept both a scientific and a religious world view. Though common among (consistent) naturalists and secular humanists,[3] this view is of course contested by many

---

[1] This contribution uses material published earlier in the journal *Science & Education*, namely, from Mahner and Bunge (1996a, b) and Mahner (2012).

[2] Of course, there are approaches to teach religion in a very general sense of "spirituality," whatever that exactly means (see, e.g., Stolberg and Teece 2011). Even so the presupposition is that this spirituality comprises more than what can be obtained in a comprehensive scientific worldview.

[3] See, e.g., Clements (1990), Dawkins (2006), Dennett (2007), Edis (2007, 2008, 2009), Kanitscheider (1996), Kitcher (2004), Kurtz (2003), Mahner and Bunge (1996a, b), Martin (1997), Provine (2008), Rachels (1991), Smart (1967), Stenger (2007, 2011), and Suchting (1994).

religionists and even some naturalistically inclined scientists and philosophers.[4] Therefore, it will be necessary to defend it. If we succeed in showing that science and religion are incompatible, it is a mere corollary that science and religious education are also incompatible.

Any argument for either the compatibility or incompatibility of science should work with a reasonably clear definition of both *science* and *religion*. However, the very existence of such definitions has been contested for a long time (see, e.g., Glennan 2009). There have been arguments to the effect that there is no reasonable demarcation between science and nonscience, in particular pseudoscience (Laudan 1983), and that, similarly, religion is so diversified that any attempt to formulate a definition that covers all religions is futile (Platvoet and Molendijk 1999). As this is not the place to review these arguments,[5] it will be helpful to narrow down what we take science and religion to be, so that we can focus on those aspects that may or may not be compatible. Before we get to this point, however, it will suffice to work with the undefined everyday usages of "science" and "religion." So we start with the question of how to avoid conflict between religion and science.

56.2 How to Avoid Conflict Between Religion and Science

Claims, theories, or world views may be in mutual conflict only if there is an at least partial overlap in their subject matter. Indeed, traditionally religions have offered general cosmologies (or metaphysics) helping to explain the major features of the world, in particular the place of humans and their relationship to the various supernatural entities allegedly populating the world alongside humans. After all, "[a]ll religions do share a feature: ostensible communication with humanlike, yet nonhuman, beings through some form of symbolic action" (Guthrie 1995, p. 197) – and this requires some factual background assumptions. While science has emerged from such a religious cosmology, it has now superseded the latter, it has significantly changed its metaphysical framework, and it has taken over the explanatory function of the old cosmologies. It appears therefore that, concerning matters of fact, religion has ceded this explanatory role to science, focusing now on other tasks. And it appears as if this concession has removed any former conflicts. While we shall see later on that this appearance is deceptive, let us first take a look at the attempts at reconceptualizing either religion or science to prevent them from being in conflict.

---

[4] See, e.g., Alston (2004), Barbour (2000), Clayton and Simpson (2008), Drees (1996), Gould (1999), Harrison (2010), Haught (1995), Peacocke (1993), Polkinghorne (1987), Rolston (1987), Ruse (2001a, 2011), Stenmark (2010), and Wentzel van Huyssteen (1998).

[5] For critiques of Laudan's view, see Mahner (2013) and Pigliucci (2013). For a comparison of concepts of religion, see Guthrie (1995). As for the demarcation of science in general, see Mahner (2007) and Thagard (2011).

56.2.1 Science and Religion Deal with Different Aspects of the World or Even with Different Realities

There are several ways to render science and religion independent so that they cannot be in conflict. One way is ontological. It splits the world into two radically different parts: a material world (nature) and a transcendent world (supernature). Whereas nature is studied by science, supernature is studied by religion.[6] A historically important example of this approach is deism, which allowed scientists to study the natural world without resorting to supernatural interventions (apart from the initial act of divine creation). However, conflict with science can only be avoided if these two worlds are causally independent: if there are causal interactions, we sooner or later face conflicting explanations. Yet if such a supernature is causally independent of the natural world, there can be no evidence for its existence so that it remains merely a conceptual possibility, moreover, one without any explanatory function as its existence or nonexistence would make no difference to our world. Such a radical split then is not very attractive to most religious believers, who usually long for a connection between themselves and the divine.

A second ontological possibility is to assume that supernatural agents are not agents in the familiar sense, but only "underlying" causes. While natural causes are (merely) "secondary causes" studied by science, God works as the "primary cause" behind the scenes. Indeed, according to some authors, God has been rather busy pulling the strings behind quantum physics and evolution, for example (Freddoso 1991; Barbour 2000; Plantinga 2011). The concepts of agency and cause involved here are best understood from the viewpoint of Scholastic metaphysics, which, though long superseded in science, is still going strong in Catholic philosophy. From a naturalist perspective, the involvement of supernatural agents "behind" natural causes is an unparsimonious and hence superfluous add-on to natural causes.[7] Assuming sustaining supernatural causes behind the web of natural causes does avoid conflict at the superficial level of the daily business of science and religion, but it does not avoid conflict at the deeper metaphysical level.

A third way of keeping science and religion separate is methodological and referential. Science and religion have different tasks, and they study different objects, or different properties or aspects of the world. For example, Rolston (1987) claims that religion is concerned with morality and meaning (not in the semantic sense of course, but in the sense of "purpose"), not material facts.[8] Following this

---

[6] It may be argued that attempts to split the world into two or more "worlds" are incoherent because, by definition, the world is everything that exists (Worrall 2004). However, if our metaphysics requires that not any old collection of causally unconnected things is itself a material thing and hence a real entity, worlds are real things (or, more precisely, systems) only inasmuch as their parts are causally connected, however weakly. Two causally unconnected universes would then be two different things, and there would be no supersystem of which they would be physical parts.

[7] For the metaphysical and epistemological problems of the idea of divine intervention, see Fales (2010).

[8] For an analysis of the various meanings of "meaning" in this context, see Martin (2002). For a critique of related noncognitive concepts of religion, see Philipse (2012).

idea, the evolutionary biologist Stephen J. Gould devoted an entire book to the "nonoverlapping magisteria" (NOMA) of science and religion (Gould 1999). Of course, if two areas have different referents, goals, and methods, they can hardly be in conflict. Dancing tango and doing science are not in conflict because they are quite different pursuits. Moreover, the NOMA approach allows for the claim that science and religion are not just compatible, but even complementary: morality and the search for purpose belong to human life just as the factual study of the world.[9]

The average religious believer, however, has to pay a high price for NOMA, because the concept of religion has to be redefined in a major way; so much so that no ordinary believer may recognize it afterwards.[10] For example, Gould considers as religious "all moral discourse on principles that might activate the ideal of universal fellowship among people" (Gould 1999, p. 62). This definition is so wide that it even applies to secular ethical discourse. So if an atheist engages in such discourse, he would be religious. While being too wide on the one hand, this definition is too narrow on the other, because it presupposes that religion has no factual content. For example, whatever people have said about the soul and the afterlife, or about the existence and properties of gods or cosmic forces, is illegitimate because it involves factual, not ethical, discourse. As a consequence, most traditional religious "truths" are excluded from the legitimate business of religion. Worse, without some factual assumptions about gods (for instance, god's will) or the order of creation (natural law doctrine) or the karma, moral values and norms cannot even be justified in a religious world view (Nowell-Smith 1967). As McCauley states:

> Religions certainly do try to make sense of our lives and of the world in which we find ourselves. The problem, though, is that that process of making sense of things inevitably involves appeals to explanations about the origins, the makeup, and the behavior of things generally and about our origins, makeup, and behavior in particular. (McCauley 2011, p. 229)

Last but not least, it can be argued that ethics cannot even be based on religion (see, e.g., Rachels 1995; Martin 2002). Thus, the identification of religion with ethics fails and hence also the "different domains" approach.

56.2.2 Religion Is Not Necessarily Bound to Supernaturalism

If science is tied to naturalism, whereas religion is based on supernaturalism, as is widely held, there is ample room for conflict at both the metaphysical level and the level of scientific explanation. But is religion really tied to a supernaturalist metaphysics? According to quite a number of scientists and philosophers, it is not. Indeed, Auguste Comte, John Dewey, Henry Wieman, Julian Huxley, Charles

---

[9] In science education, Sinatra and Nadelson (2011) follow this approach by postulating different epistemologies for science and religion, that is, "epistemologies that have different roles and explain different aspects of the human condition" (p. 175). Obviously, and sadly, this is an instance of epistemological relativism.

[10] See McCauley (2011), Orr (1999), and Worrall (2004).

Hardwick, and others have argued for religious naturalism.[11] Thus, "God" is redefined as the unity of our ideals, or as a cosmic process unfolding for the benefit of humans, or as the creative exchange among humans, etc. Often feelings of awe towards nature or the universe are regarded as religious feelings or as a feeling of the "sacred." For example, Einstein (1999) believed that the scientist's religiosity lies in "the amazement at the harmony of natural law."

Whether pantheism is a form of religious naturalism remains unclear. In an everyday understanding according to which the world is God, pantheism does appear to be a naturalist conception. In this sense, however, Schopenhauer's criticism applies: "to call the world 'God' is not to explain it; it is only to enrich our language with a superfluous synonym for the word 'world'" (Schopenhauer 1951, p. 40).[12] Levine (2011) rejects Schopenhauer's criticism for resting on a misunderstanding of what the pantheistic "divine unity" of the world means. However, Levine's own characterization of "unity" is fuzzy to the point of being incomprehensible, and he regards "divine" simply as experiential: whatever someone experiences as numinous is divine. Thus, the divine is turned into a subjective category.[13]

With the exception of traditional pantheism, it appears that the common motif of such non-supernaturalist approaches is to redefine "religion" in terms of either feelings or experiences, leaving no room for any factual content of religion. As Barbour (2000, p. 159) rightly remarks, religious naturalism thus simply conflicts with "most of the heritage of religious traditions."

56.2.3 Defining Religion in a Merely Functional Way

Psychologists and sociologists usually refrain from defining "religion" in a substantive way, that is, with regard to its content. Instead, they define it in terms of the functions religious beliefs, practices, and institutions have in human life and society

---

[11] See, e.g., Alston (1967), Drees (1996, 2008), and Hardwick (2003).

[12] To the consistent naturalist, the attempt to naturalize religion reduces to a game of words:

> The bogus procedure is this: When there is something that clearly does not exist, but one wishes that it did exist and wants to be able to say that it does exist, then choose something real that is similar in some respects and give it the name of the nonexistent entity. Voilà! You have now proved the existence of something that doesn't exist. Suppose one wants to prove that God exists. Find something awe-inspiring, or powerful, or infinite, or fundamental …. and call it "God". Now God exists, and the various practices with respect to that God are "religious". Unfortunately, in reality, all you've done is play with words and, thereby, pull off a shabby, unconvincing trick. (Pasquarello 2002, p. 51)

This applies not only to religious naturalism but also to the various hermeneutic approaches in modern theology, such as Paul Tillich's definition of God as "ultimate concern" (for a criticism of hermeneutic theology, see Chap. 5 in Albert 1985).

[13] Peacocke's (1993) panentheism does not seem to be a consistent naturalism, as it makes God only partly natural, so I shall not discuss his view here.

(see, e.g., Yinger 1970). That religious beliefs and practices have evolved along with humankind and that they have various functions for individuals and groups is of course nothing but a scientific description and explanation of religion.[14] It is exactly these functions that remain once the cognitive content of religion is removed for being illusory. Obviously, a naturalist, scientific view of religion cannot be in conflict with science. Yet again, the problem remains that such characterizations do not match the self-conceptions of most religions.[15]

56.2.4 The Argument from Religious Scientists

Another psychological and sociological argument to consider is the claim that science and religion cannot be in conflict because there have been many religious scientists. Indeed, quite naturally there is no shortage of historical examples, which are often used to reject the historical conflict view (see, e.g., Russell 2002). And even today the number of religious scientists is high.[16] Interestingly, average scientists tend to be more religious than elite scientists (Gross and Simmons 2009). According to the latest study of Ecklund (2010), about 64 % of elite US scientists are atheists or agnostics.

The argument from religious scientists, however, is a weak one at best. At worst, it is an *argumentum ad populum*. It would come as no surprise that a large number of people can be mistaken about something. And as we know from psychology, many people hold inconsistent beliefs. This applies also to scientists. For example, it is quite telling that most religious scientists have not used religious concepts in their scientific work (Mahner and Bunge 1996b). There are no variables referring to supernatural entities or processes in scientific theories. If someone believes in the reality of the supernatural, it is inconsistent to not make use of religious entities and methods in science. Rather, we should expect religious scientists to defend a theistic science, as Ratzsch (1996) and Plantinga (2001) consistently (though of course unsuccessfully) do. But this is rarely the case. Therefore, pace Ratzsch (2004) and others, it is not implausible to suspect the world views of religious scientists to be inconsistent.

So the problem of whether science and religion are compatible or not is not a matter of psychology and sociology but of philosophy, more precisely, of metaphysics, epistemology, and methodology. If there is no conflict at this level, then the world view of religious scientists may be consistent; otherwise, it is not.

---

[14] See Boyer (2001), Dennett (2007), and Guthrie (1995).

[15] Further criticism of religious functionalism in Guthrie (1995).

[16] See, e.g., Ecklund (2010), Gross and Simmons (2009), Larson and Witham (1998), and Margenau and Varghese (1992).

56.2.5 Religious Discourse Is Nonsense

According to neopositivism, metaphysical sentences including religious ones are semantically nonsensical because they are not verifiable (Ayer 1990). If religious discourse is nonsense, it can be neither compatible nor incompatible with scientific discourse. So there is no conflict with science. As a consequence, however, atheist discourse is nonsensic too: if "God exists" is nonsense, its negation "God does not exist" is also nonsense.

It is rather obvious that the neopositivist answer is not a good option for religious believers. After all, they believe that they make meaningful statements about nature or supernature or both. Indeed, the neopositivist meaning criterion of verifiability has long been abandoned: in order to verify or falsify a statement, it must be semantically meaningful in the first place, not the other way round. So we cannot keep religion away by declaring it nonsense *tout court*. However, in particular academic theology does have meaning problems, as it often resorts to an irrationalist, fuzzy discourse that helps to immunize theology from factual criticism (Albert 1985; Bartley 1984). And as we shall see later, it is not at all clear what the very term "God" exactly means.

56.2.6 Distorting Science

Removing the cognitive content of religion is not the only way to avoid conflict between science and religion. There are also attempts to remove all truth claims from science by adopting antirealist views of science, such as instrumentalism or relativism. If scientific theories are not attempts at approximating truth by stating something about how the world really is, but only more or less useful tools for systematizing or predicting empirical statements, or if scientific theories are nothing but yet another way at looking at the world, on the same par as any other, even mythical way, then science may of course peacefully coexist with religion (Byl 1985; Stenmark 2010). A less radical view is constructive empiricism, which replaces truth by empirical adequacy, but it too is a view that castrates science. Given the fact that both instrumentalism and constructive empiricism are still popular in the philosophy of science, at least much more so than relativism, it may appear bold to charge them with distorting science, but this is not the place to defend this view.[17]

56.2.7 Conclusion

As we have seen, there are many ways to construe "religion." Some of them would indeed be compatible with science. But as we have also seen, the believer has to pay a high price if he accepts them. Religious entities are either rendered causally

---

[17] More on this in Vollmer (1990), Psillos (1999, 2003), Worrall (2004), and Ladyman (2012).

inefficacious and hence irrelevant, or religion is emptied of any factual content so that it can no longer make any (objective) truth claims. Notwithstanding the attempts of modern theology at immunizing religion from criticism by obfuscating and subjectifying its concepts (Albert 1985), the vast majority of believers of all ages has believed that their religion does make some true factual statements about the world, in particular about humans and their relation to the divine or at least to certain spiritual entities (McCauley 2011). That is, real life religions have always included a cosmology.[18] The following characterization reflects this situation. Accordingly, religion can be seen as

> …the belief in numinous personal or impersonal entities - gods, spirits, demons, angels, or divine powers - which have certain causal powers, and which therefore are relevant to human fate and salvation, as well as […] an associated practice of the believers, which is adequate to make allowance for the powers of these entities and to influence them for the benefit of the believers' salvation, that is, a cult characterized by a salvation technology. (Albert 2000, p. 142, my free translation)

Both religion and science thus have an overlap in that they are epistemic enterprises. Both search for truth, partly in the same, partly in different domains. We can therefore construe both as epistemic fields.

56.3 Science and Religion as Epistemic Fields

In the following, science and religion are compared by means of a list of criteria that helps to define epistemic fields.[19] By "science" I mean factual science as opposed to formal science like logics and mathematics. Now, factual science is often called "empirical science." However, "empirical" refers to the methods of science, not to the concrete facts it studies. Science studies concrete facts (material things having certain properties and the processes they undergo) by both theoretical and empirical means. So by "fact," I do not mean *statements* about concrete facts but the referents of such factual statements. I shall ignore the question of whether there are formal or abstract facts as these do not exist in the same way as concrete facts. The following questions yield some of the criteria that help to define an epistemic field:

---

[18] This is echoed by Plantinga who has the gall to call naturalism a quasi-religion because it fulfills this world view aspect: "It offers a way of interpreting ourselves to ourselves, a way of understanding our origin and significance at the deep level of religion. It tells us where we come from, what our prospects are, what our place in the universe is, whether there is life after death, and the like. We could therefore say that it is a 'quasi-religion'" (Dennett and Plantinga 2011, p. 16f., see also Plantinga 2011). Needless to say, it is disingenuous to call a world view that has overcome religion a quasi-religion. A similar theological ploy is to compare the philosophical underpinnings of science to religious faith.

[19] Modifiyng earlier analyses by Bunge (1983), Bunge and Mahner (2004), Mahner (2007), and Mahner and Bunge (1996a).

1. Which objects does it refer to? What is the domain of facts it is concerned with?
2. What is its fund of knowledge?
3. Which background knowledge does it use in the study of its domain?
4. What are the aims of the given field?
5. Which methods does it work with?
6. Which are the philosophical background assumptions presupposed in its work? That is, what are its metaphysical, methodological, axiological, and moral foundations? Finally, which general attitude or mind-set is considered to be exemplary for those who work in the given field?

56.3.1 Science

1. The domain of factual science comprises everything existent, i.e., the whole world. Although there are certainly things that are de facto beyond scientific investigation for lack of information, there is nothing natural that could not be de jure studied scientifically. As a matter of principle, the domain of science also includes, for instance, the how and why of subjective feelings and emotions in general, as well as the origins and functions of morality and religion – fields of inquiry that are sometimes believed to be beyond scientific understanding.
2. The fund of scientific knowledge is a body of factual knowledge, in particular law statements, which grows along with research. (More on laws in Sect. 56.4.1.)
3. The background of a specific scientific field is the collection of up-to-date well-confirmed knowledge (data, hypotheses, theories) borrowed from neighboring fields. Each scientific discipline connects thus to other scientific fields. Science consists of a network of subfields or disciplines, aiming at a consilient description of the world.
4. The aims of a basic science are purely cognitive. They include, for example, the discovery of the laws of its referents, the explanation of the facts it studies, the systematization of its knowledge base (e.g., by constructing general theories), and the refinement of its methods. By contrast, the aims of technology are practical: it is concerned with design and application.
5. The *methodics* of a scientific field is the collection of its specific and general methods, where specific methods are often called "techniques." (The term "methodology" is reserved here for normative epistemology.) For example, scanning electron microscopy is a specific method, whereas the scientific method is the most general method of the sciences. Specific methods must be scrutable and objective, and we must be able to explain, at least roughly, how they work. The scientific method in general may be conceived of as consisting of the following ordered sequence of cognitive operations: Identify a problem–search for information, methods, instruments–try to solve the problem with the help of those means; if necessary, invent new means, produce new data, or design new experiments–derive the consequences of your solution (e.g., predictions)–check

the solution (e.g., try to replicate your findings by alternative means)–correct the solution if necessary in repeating the cycle–examine the impact of the solution upon the body of background knowledge and state some of the new problems it gives rise to. The structure of any scientific paper roughly reflects these steps and is thus an instance of the scientific method. Of course, there is no single specific method that could be applied to each particular case of research.

6. The philosophical background assumptions of science comprise a naturalist ontology (or metaphysics), a realist epistemology, and a system of values that is particularly characterized by the ethos of the free search for truth.[20] The value system of science includes such logical values as exactness, systemicity, and logical consistency; semantical values such as meaning definiteness (hence clarity) and maximal truth (or adequacy of ideas to facts); methodological values such as testability and the possibility of scrutinizing and justifying the very methods employed to put ideas to the test; and, finally, attitudinal and moral values such as critical thinking, open-mindedness (but not blank-mindedness), veracity, giving credit where credit is due, and more.

These philosophical assumptions are by no means generally accepted in the philosophy of science, so each of them would need further justification. Since there is no room to justify all of them here, the focus will be on the two most important aspects: the metaphysics and methodologies of science and religion. But let us take a closer look at religion first.

56.3.2 Religion

1. In addition to all religiously relevant parts of nature and society, the domain of religion comprises also supernature. Of particular interest are of course the relations of natural things (especially humans) to supernatural entities, and vice versa.
2. The fund of knowledge is a fixed or at most slowly changing collection of (mostly untestable) doctrines and beliefs, whether conveyed by means of an oral tradition or through sacred scriptures. Whatever change in religious beliefs may appear to take place is not due to research and hence newly discovered facts but is almost entirely a result of either (a) a change in the exegesis and interpretation of traditional doctrines, which, if taken literally, often are unpalatable to modern people, or (b) squabbles or even wars between rival factions in the same religious community. Hence, any substantial changes in the belief system are due to authority or external influence, not research. If genuine research takes place, such as historical investigation, this research is not accomplished by religious but scientific means even if undertaken by theologians. Accordingly, it has to be regarded as an external influence.

---

[20] "Ontology" is used synonymously with "metaphysics" in this paper.

3. The factual background of religion contains at best ordinary knowledge, not scientific knowledge. This is just because most religions are older than science. Some scientific knowledge may be compatible with religious doctrines up to a certain point, and some theologians may make use of scientific knowledge in certain arguments, but in the end this should not be necessary for the (alleged) truth of any religious doctrine.
4. The aims of religion are foremost practical. Moreover, they are ultimately, though mostly tacitly, a matter of self-interest in that they consist in attaining personal advantage such as salvation or eternal life (individual or cosmic). Religions are salvation technologies after all. To obey and worship the divine, or to live a virtuous life, though the explicit goal of the religious person, is, in the end, only a means to attain the blessings expected from the supernatural. All religion is ultimately anthropocentric.
5. The methodics of religion is a collection of practices, such as prayer, incantation, fasting, meditation, and other rituals that are supposed to connect human beings to the supernatural. As far as a cognitive aim is pursued, the religious person may make use of intuition, contemplation, meditation, or revelation. There is neither use for the scientific method in general nor use for specific scientific techniques.
6. The philosophical background assumptions of religion consist of a supernaturalist metaphysics, which is a collection of doctrines about the supernatural and our relations to it. Supernatural entities may be impersonal forces such as karma or more or less anthropomorphic "persons" such as gods. The epistemology of religion is usually a realist one, though religion may be consistent with any epistemology. The value system of religion seems to have only one item in common with science: the quest for truth. However, whereas the truth looked for by religionists is absolute or ultimate, scientific truth is partial or approximate. Neither exactness nor logical consistency and neither clarity nor testability are strong in religion. Moreover, it can be argued that many religious beliefs can only be upheld by disregarding such values. Otherwise, it would not be possible to cherish the mysterious or to confess *credo quia absurdum*. A religious value that is alien to science is (blind) faith, which allows the religionist to always retreat to commitment or fideism if pressed by rational analysis (Bartley 1984). Finally, religion contains an ethos of acceptance and defense of unquestionable doctrines, i.e., dogmas. As for the latter, witness Augustine's dictum, "Greater is the authority of Scripture than all the powers of the human mind," or Paul's injunction "Beware lest anyone cheat you through philosophy and empty deceit, according to the tradition of men, according to the basic principles of the world, and not according to Christ" (Col. 2: 8).

56.3.3 Conclusion

The above listed several commonalities and differences between science and religion, among them some obvious incompatibilities. Both science and religion aim at gaining knowledge about the world. Both operate from a realist perspective, and both are truth seekers. While, today, most of the world is left to science to study and explain, there is an area of overlap the closer we get to the description and explanation of the place of humans in the world. The differences concern the nonnaturalist metaphysics of religion as well as, among others, the methodological status of evidence versus faith and the role of authority versus the free search for truth. And these differences will turn out to be the major incompatibilities.

56.4 The Metaphysics of Science and Religion

Modern science emerged from a mixture of prescience, philosophy, and religion. These areas were strongly intertwined during Scholasticism, but developed apart from the early sixteenth century on (Schrader 2000; Matthews 2009). The emancipation of science from theology is thus one of the characteristic features of its development. Mainstream philosophy also emancipated itself from theology, although even today philosophy in general is still so diverse that it ranges from materialism to quasi-religious thinking and even obscurantism. Even authors who come to a rather conciliatory conclusion concerning the historical relationship between science and religion admit that the main area of conflict concerns metaphysics: "The famous episodes of conflict between science and religion are not strictly conflicts between science and religion. Rather, they are instances of a more general conflict that arises within the process of changing metaphysical frameworks" (Schrader 2000, p. 400). For example, science superseded Scholastic metaphysics, in particular the teleology inherent in its Aristotelian foundation. It also abandoned the intentional teleology of the long-respectable argument to design. Indeed, the result is that, today, the metaphysics of science is consistently naturalist, which is incompatible with any supernaturalist metaphysics, however minimally furnished it may be.

This raises the question of whether the naturalism of science is just the result of a contingent historical development or whether this historical development has just brought forward what had applied all along: naturalism as a metaphysical condition of science. This latter thesis will be defended here.

Now, metaphysical conditions or presuppositions are not exactly popular in contemporary analytic philosophy because they smack of Kantianism. Kantian apriorism is the very antithesis of the aposteriorist approach of epistemological and methodological naturalism, which is widespread in contemporary analytic philosophy. However, metaphysical presuppositions need not be apriorist in the Kantian sense. But what is meant then by "condition" or "presupposition"?

A presupposition is often understood in the sense of a statement that is entailed by a set of premises or in the sense of a necessary condition implied by some antecedent statement. Is metaphysical naturalism entailed by science in one of these senses? From a formal point of view, it is not. It is not part of a deductive argument in the sense that if we collected all the statements or theories of science and used them as premises, then metaphysical naturalism would logically follow. After all, scientific theories do not explicitly talk about anything metaphysical such as the presence or absence of supernatural entities: they simply refer to natural entities and processes only. Therefore, naturalism rather is a tacit metaphysical *supposition* of science, an ontological *postulate*. It is part of a metascientific framework or, if preferred, of the metaparadigm of science that guides the construction and evaluation of theories and that helps to explain why science works and succeeds in studying and explaining the world. As such, it is the best framework available yet, justified by its very success and its unifying and heuristic power.

56.4.1 The Metaphysical Presuppositions of Scientific Research

> …what Kant and Hume show, I think, is that limiting oneself to seeking natural causes for natural effects is not […] a metaphysical principle with no inherent grounding in science but rather a disciplinary condition of doing science, the only way to get the particular kinds of answers that science seeks within the terms of the evidentiary warrants it demands. (Loesberg 2007, p. 96f.)

A popular view among scientists maintains that science need not bother with philosophy, let alone metaphysics, at all; scientists should just apply and follow the scientific method or, if preferred, the collection of scientific methods. Somewhat more sophisticatedly, if science is ultimately about finding the truth, all that counts is evidence. Whether it confirms the natural or points to the supernatural, we should follow the evidence wherever it leads (Fishman 2009; Monton 2009). This antimetaphysical stance is importantly wrong because it rests on the assumption that both scientific methods and the evidence they produce are free of metaphysical presuppositions.

To show that there is quite a number of metaphysical postulates of science (Bunge 1983), we take a look at the three (overlapping) general empirical methods in science by means of which we gain data, which, in turn, may function as evidence: observation, measurement, and experiment. The question is whether these methods can work in a metaphysical vacuum, or whether their successful application rests upon certain metaphysical assumptions. In other words, could these methods work successfully in just any world, or can they work only in a world with a particular nature? A simple experiment chosen from a high school biology textbook will function as an example (Fig. 56.1, following Mahner 2007).

Let us focus here on the question of how much metaphysics is hidden in this simple experiment, addressing possible objections mostly in footnotes so as not to interrupt the exposition.

First, we assume that this experiment involves real entities in a real world, not just objects existing in our mind. That is, we work on the basis of ontological realism, which helps to explain not only the success but in particular the failure of scientific theories.[21]

---

[21] A very general ontological realism is probably the least controversial metaphysical presupposition of science (Bunge 1983, 2006; Alters 1997; Gauch 2009; Ladyman 2012), although there is an ongoing realism/antirealism debate in philosophy. However, this debate concerns mostly epistemological

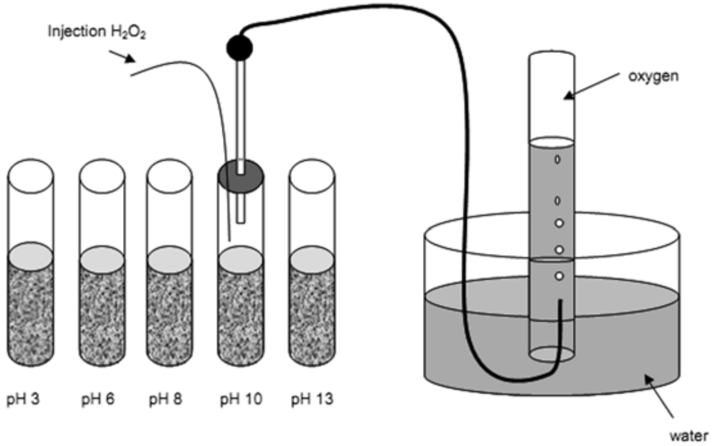

Fig. 56.1 By determining the pH optimum of the enzyme catalase, this experiment is used to demonstrate that the functioning of enzymes is pH dependent. The experimental setup is as follows. Five test tubes are halfway filled with water. We add a piece of yeast to each of them. By adding different amounts of hydrochloric acid (HCl) or caustic soda (NaOH), we arrange for a different acidity or alkalinity, respectively, in each tube, say, pH 3, pH 6, pH 8, pH 10, and pH 13. The yeast cells contain the enzyme catalase, which enables them to break down hydrogen peroxide into water and oxygen (i.e., $2\ H_2O_2 \rightarrow 2\ H_2O + O_2$). We inject a certain amount of hydrogen peroxide solution into the test tubes (e.g., by means of a syringe). Each time, we close the tube and measure the amount of gas produced after 2 min by collecting it in a measuring tube, which is connected to the given test tube by a thin rubber hose. We do not need to specify the precise amounts and conditions here, because the basic setup of this experiment will be clear anyway (from Mahner 2007; redrawn and modified from Knodel 1985, p. 39). The result of this experiment: the oxygen production is highest at pH 8 (in fact, at pH 8.5, which can only be discerned by refining the experiment)

Now that we are talking real test tubes with real yeast and real chemicals, we may ask why an experiment like this is found in a textbook. Obviously, we assume that we can repeat this experiment as many times as we see fit, and that we will obtain (roughly) the same results, provided we do not make any mistakes. The gas produced is always oxygen, neither nitrogen nor carbon dioxide. The test tubes remain test tubes, and do not spontaneously transform into chewing gum or thin air. It appears then that things and their properties remain the same under the same conditions. Certain properties of things seem to be constantly connected, so that they change together: they are covariant. In other words, certain properties of things are lawfully related.

Of course, ordinary experience already indicates that the world is lawful, but the thesis of a lawful world is not a piece of empirical knowledge: it is a necessary condition of cognition. Without things behaving regularly due to their lawful properties, no organism would be able to learn much about the world. Note that

---

problems regarding the justification of more detailed realistic claims such as the status of unobservable entities and the truth of scientific theories. Thus, someone who rejects more specific forms of realism, such as scientific realism, usually is still an ontological realist. I shall not defend ontological realism in more detail here (for such a defense, see, e.g., Vollmer 1990), because both ontological naturalists and supernaturalists share a basic realist outlook anyway.

what I am referring to here are laws in an ontological sense of lawfully related properties, not general law statements as conceptual representations of such ontic laws (Bunge 1983, 2006; Ellis 2002). This must be emphasized because the view that laws of nature are nothing but universal statements is still popular.[22]

Imagine next that we fail to obtain oxygen in our measuring tube. In this case we would look for mistakes in the setup, like a leakage in the rubber tube. We would check whether the yeast is still alive, whether we have correctly set the pH value of the water, or whether the substance we add is really a hydrogen peroxide solution. No scientist would seriously entertain the idea that somewhere in the experimental setup the gas has literally dissolved into nothing. Conversely, no scientist would assume that we can produce gas out of nothing. There is simply no point in doing experiments and "wiggling parameters" if things simply could pop out of or into nothing. Let's call this the ex-nihilo-nihil-fit principle.[23]

What initiates the production of oxygen? Oxygen does not originate spontaneously: it starts to emerge only after we add some hydrogen peroxide solution. Thus, by meddling with certain parts of the setup, we can produce a certain effect: we can

---

[22] I submit that the mainstream view of laws in the philosophy of science is inadequate. Science calls for a (neo-)essentialist view of laws, according to which "the laws of nature are immanent in the things that exist in nature, rather than imposed on them from without. Thus, [. . .] things behave as they do, not because they are forced or constrained by God, or even by the laws of nature, but, rather, because of the intrinsic causal powers, capacities and propensities of their basic constituents and how they are arranged" (Ellis 2002, p. 1). Thus

> not even an omnipotent God could change the laws of nature without changing the things on which they are supposed to act. Therefore, the idea that the laws of physics are contingent, and superimposed on intrinsically passive things that have identities that are independent of the laws of their behavior, is one that lies very uneasily with modern science. (Ellis 2002, p. 5)

The lawful behavior of things neither entails that we can always represent them as law statements nor that every scientific explanation is a subsumption under some law. For example, due to the enormous variation of organisms, many biologists believe that there are no laws (= law statements) in biology. But this does not entail that organisms do not behave lawfully: it is just that it often makes not much sense to try to find general, let alone universal, law statements because their reference class is rather small, holding only for some subspecies, variety, or even smaller units, for example, that is, only for those organisms sharing the same lawful properties (more on laws in biology in Mahner & Bunge 1997, Ellis 2002). Finally, even some cases of randomness are lawful because they are based on stochastic propensities such as in quantum physics. That is, there are probabilistic laws. For the neo-essentialist approach to laws adopted here, see Bunge (1977), Mahner and Bunge (1997), Bunge and Mahner (2004), and Ellis (2002).

[23] Note that "nothing" really means "nothing," not some form of radiation or some other massless form of matter. For example, what is called particle annihilation is just a transformation of a particle with mass into one or more massless particles, that is, into some form of radiation. However, it seems that the ex-nihilo-nihil-fit principle is being challenged by cosmologists, who keep entertaining the idea that the universe originated from nothing (see, e.g., Stenger 2011). In particular, according to multiverse cosmology, some primordial "nothing" keeps randomly popping out universes. But since this "nothing" has at least one property, namely, the propensity to pop out universes, it doesn't seem to be a genuine nothing which should have no properties at all and hence be unable to change.

(causally) interact with the setup. Moreover, the steps in this chain of events are ordered: their sequence is not arbitrary. That is, we must assume that causation is for real and hence an ontological category, as well as that there is a principle of antecedence: causes precede their effects in time, so that the present is determined causally or stochastically by the past, but not conversely. In other words, we need to assume not only that the experimental setup (or the world in general) is real but also that we can interact with it and that our actions can trigger orderly chains of events. Otherwise, no deliberate effect could be produced, variables could not be controlled for, etc.

If the results of our empirical methods are expected to be the results of real processes in a real world, we must rule out the possibility that the experimental setup can be causally influenced in a *direct* way solely by our thoughts or wishes (or more precisely our thinking and wishing), that is, without the interposition of motoric actions by our bodies (Broad 1949). Indeed, if the world were permeated by causally efficacious mental forces, we would have no reason to trust the reading of any measuring instrument or the results of any experiment. In other words, the data obtained through observation, measurement, or experiment could not function as evidence if they were literally the telepathic or psychokinetic product of wishful thinking. Worse, we could not even trust our own perceptions and conceptions, as they could be the result of telepathic manipulation. We may call the assumption that no such mental forces exist the "no-psi principle" (Bunge 1983, p. 106).[24] This principle must hold not only for humans but for any organism anywhere that is able to think. Neither humans nor little green aliens from another galaxy must be able to meddle, just by thinking alone, with empirical methods or our perceptional and conceptual processing of their results.

What holds for natural entities applies a fortiori to supernatural entities. We must stipulate, then, that no supernatural entity manipulates either the experimental setup or our mental (neuronal) processes or both.[25] We can even make the case that this holds not only for science but for perception and cognition in general. Indeed, this "no-supernature principle" as we may call it is also needed to avoid Cartesian skepticism. In his *Meditationes*, Descartes (1641) wrote:

> I will suppose, then, not that Deity, who is sovereignly good and the fountain of truth, but that some malignant demon, who is at once exceedingly potent and deceitful, has employed all his artifice to deceive me; I will suppose that the sky, the air, the earth, colors, figures, sounds, and all external things, are nothing better than the illusions of dreams, by means of which this being has laid snares for my credulity.... (*Meditation* 1, §12)

---

[24] The no-psi principle was one of Broad's (1949) so-called basic limiting principles of science. Being a strong believer in the paranormal, Broad maintained that this basic limiting principle had been refuted by parapsychology. However, Broad was fooled by the sloppy and partly even fraudulent parapsychological research of his time.

[25] This was already acknowledged by J. S. B. Haldane (1934), who stated that his "practice as a scientist is atheistic," that is, when he sets up an experiment, he assumes "that no god, angel, or devil is going to interfere with its course" (p. vi).

Unlike Descartes, we no longer have reason to believe that the supernatural is dominated by an all-good God, who, by his very nature, not only refrains from malicious manipulation but even functions as the guarantor of the truth of our cognition and thus our knowledge.[26] Even in traditional Christianity, there are many other supernatural entities than God, like devils, demons, and angels. Now add the many supernatural entities of other religions and finally everything we can imagine. As the fantasy and horror movie genre shows, the possible inhabitants of supernature are only limited by our imagination. If we admit the supernatural, there is no reason to rule out a priori the existence of a malicious entity that could meddle with the world including our cognitive processes. So we need to start with the postulate that no such entities exist.

Let us summarize then the metaphysical suppositions of the general empirical methods of science:

(a) Ontological realism
(b) The (ontological) lawfulness principle
(c) The ex-nihilo-nihil-fit principle
(d) The antecedence principle and an ontological conception of causation
(e) The no-psi principle
(f) The no-supernature principle

Whoever subscribes to empirical scientific methods and their function to generate evidence must also subscribe to these metaphysical principles: without them, what we are doing would not be scientific measurements or experiments but rather meaningless games. Thus, these principles are part of the ontology behind science's methodology. In a world that has these properties, science is possible.

It may be seen as problematic that the principles (c), (e), and (f) are formulated negatively. It would not be a problem, though, to reformulate the above in positive terms, for example, by offering a full-fledged metaphysical theory, elucidating the notions of property, thing, event, process, lawfulness, etc. (see Bunge 1977; Bunge and Mahner 2004; Mahner 2012). In the sense of an axiomatic definition, we could then claim that everything which works that way is natural, and that the only real existents are such natural things and events. The above negative principles, then, would simply be corollaries of such a metaphysics formulated in positive terms. However, for the sake of simplicity and convenience, I shall stick to the negative formulations.

Now, are these principles also necessary conditions, perhaps even a priori conditions? Or could the scope of at least some of these principles be somewhat restricted while science could still work successfully? In other words, are they just default principles? For example, the traditional metaphysical principle of strict causality (every event has a cause) has been shown by quantum physics to be false, because some events such as radioactive decay are spontaneous (uncaused). This is why a

---

[26] As Fales (2010) argues, even God may not know whether his thinking is manipulated by some evil demon. Does this require a second-order God of higher power who guarantees the truth of God's knowledge? If so, we would end up with an infinite regress of truth guarantors.

principle of strict causality is not part of the above list. And if the universe had popped out of nothing (however magical this would be), principle (c) would still hold within the universe. This suggests the possibility that some metaphysical principles could be revised. Similarly, it may be argued that even if the universe were initially created by a supernatural being, science would still be possible if there had been no further interventions since or if the number of interventions were very small. As our focus here is on metaphysical naturalism, the principles (a)–(e) will not be further addressed, so that we turn right to this possible objection to the no-supernature principle.

56.4.2 Naturalism or Noninterventionism?

We have just seen that observation, measurement, and experiment must not be subject to supernatural manipulation because they would then lose their status as empirical methods for the generation of evidence. Does this really warrant a no-supernature principle? Prima facie, it does not, at least not without further ado: it seems to warrant at most a principle of nonintervention with respect to scientific research and cognitive processes. How, then, can we justify a no-supernature principle?

To see how, it will be helpful to take a closer look at the definition of noninterventionism. It may be tempting to analyze it as a conditional statement such as "If supernatural entities exist, they do not intervene in the course of the natural world." However, this would turn nonintervention into a necessary condition for the existence of the supernatural. Indeed, by contraposition, we would obtain the absurd statement, "If supernatural entities intervene in the course of the world, they do not exist." Therefore, we better analyze "noninterventionism" as the conjunction of two statements, namely, "Supernatural entities exist really & Supernatural entities do not intervene in the course of the natural world."

This analysis shows that while at first sight noninterventionism appears to be a reasonable minimal supposition, it is in fact not, because it presupposes the existence of supernatural entities. The first statement of the above conjunction, "Supernatural entities exist," cannot be a metaphysical supposition of science because there is no reason why science should postulate the existence of something that, by not intervening in the course of the natural world, plays no part in any scientific explanation of the world.

Indeed, it is common practice in science to adopt the null hypothesis until there is evidence for an alternative substantive hypothesis. The null hypothesis usually negates that something is the case, such as that something exists or that two variables are related. Examples are the following: "Junk food is not the cause of obesity," "Men and women do not perform differently in mathematical tests," or "The Loch Ness monster does not exist." In order to prove some substantive hypothesis, its corresponding null hypothesis must be refuted empirically. The null hypothesis approach is not restricted to science: it is also adopted in modern law where a defendant is presumed innocent until proven guilty. Mutatis mutandis, the null hypothesis principle may – nay, should – be applied also in metaphysics, in particular when it comes to existential claims. For example, in the philosophy of religion, Antony Flew (1972) was the first to suggest defining "atheism" in this sense, although he did not use the scientific term "null hypothesis." An atheist, then, is not someone who positively and dogmatically denies the existence of gods, but someone who just adopts the "presumption of nonexistence" as a court of law adopts the presumption of innocence. Correspondingly, one way to conceive of metaphysical naturalism is as a metaphysical null hypothesis, stating that a supernature does not exist.[27]

Of course, there is an important difference between scientific and metaphysical null hypotheses; the latter are usually regarded as unfalsifiable by direct empirical evidence. This distinction at least was the upshot of both the neopositivists' and Popper's demarcation efforts. If we disregard the neopositivist view that metaphysics is untestable because it is nonsense, and thus accept Popper's distinction for the time being, we can say that at least some metaphysical hypotheses can be refuted (or, more cautiously, disconfirmed) *indirectly*, for example, by turning out to be incompatible with scientific practice or in being unable to explain it. For example, science could fail as a cognitive enterprise, either in its entirety or in some particular area, so that we would have to reconsider metaphysical naturalism.

In any case, the notion of a metaphysical null hypothesis implies that even metaphysical assumptions remain fallible in principle. At the same time it allows us to consider metaphysical naturalism as a necessary condition of science: if metaphysical naturalism fails, science fails too.

56.4.3 The Metaphysics of Supernaturalism

It appears that the supernatural can be characterized by simply negating most of the metaphysical principles listed in Sect. 56.4.1. Thus, a supernatural entity would be one that:

- May be able to create things out of nothing or annihilate them
- May not be subject to the antecedence principle in that it could make past events undone or change the natural sequence of events
- May not be subject to the lawfulness principle because it may be able to change the lawful properties of (natural) things or the lawful course of (natural) events
- May be able to influence (or to manipulate, if not fully control) natural things, including thinking entities and their perceptions and conceptions

---

[27] In his debate with Plantinga, Dennett has recently called naturalism a null hypothesis (Dennett and Plantinga 2011, p. 49). Plantinga had argued that science is compatible with theism, because science doesn't explicitly state that there is no God. This shows that Plantinga is not familiar with the concept of a null hypothesis. The same seems to apply to Flanagan (2008, p. 437), who argues against "imperialist naturalism" that we would simply not know everything that there is or is not. Yet this is exactly the reason why we have to start with naturalism as a metaphysical null hypothesis.

This is essentially what is behind the common characterization of a supernatural entity as one that has magical abilities and can thus perform miracles. Whether or not supernatural entities are subject to any supernatural laws (whatever these may be) is irrelevant here. All that matters is that, in principle, they could be able to interfere with the lawful course of natural events, hence also with our brain functions. This is why a supernaturalist ontology invites (and maybe even entails) a nonnaturalist epistemology and methodology in which special forms of cognition, such as revelation, religious experience, a *sensus divinitatis*, or whatever nonnatural ways of communication with the supernatural may obtain, are accepted as legitimate sources of knowledge and means of justification. For example, Ratzsch (1996) and Plantinga (2001) defend the idea of a "uniquely Christian science" or a "theistic science," respectively, so that there is no reason why a Christian should not make use of particular religious "methods" in science. These examples illustrate that methodology is not free of metaphysics. It comes as no surprise therefore that accommodationist scientists and philosophers, who reject metaphysical naturalism to make room for religion yet at the same time want to keep supernaturalism out of science, struggle hard to make a consistent case (see Sect. 56.5.3).

That the supernatural is characterized mostly, if not exclusively, in negative terms has been shown in more detail by Spiegelberg (1951). Even prima facie positive attributes of the supernatural turn out to be negative ones in that they are just denials of known natural characteristics. For example, "transcendence" is the negation of "immanence," that is, *not* being "located" within the confines of our spatiotemporal world. Or being a first cause is nothing but being an *uncaused* cause. And the few positive attributes such as omnipotence or omniscience are actually natural properties raised to an absolute degree. In this regard they are not fully supernatural – a statement that may require some elaboration.

Spiegelberg distinguishes two conceptions of the supernatural, quantitative and qualitative. In the former case supernatural entities are ascribed properties that differ from the natural only in degree, though often to an absolute degree. For example, a supernatural entity is more powerful than a natural entity, perhaps even all-powerful, or more knowledgeable, perhaps even omniscient.[28] The attributes of supernatural entities are then still conceived of on the basis of familiar natural properties. Thus, such conceptions are more or less anthropomorphic, which suggests that the quantitatively supernatural, if any, would still have to be spatiotemporal. By contrast, according to qualitative supernaturalism, supernatural entities are *categorically* different from natural ones, so much so that their properties are essentially mysterious, ineffable, and incomprehensible. God, then, is the *Wholly Other*, not someone or something to be understood even by the faintest analogy with anything known natural. Spiegelberg called these two types of the supernatural *overnatural* and *transnatural,* respectively (1951, p. 343). Whereas the overnatural seems to be somewhat intelligible by analogy with known natural properties, the transnatural is incomprehensible. To obtain or retain a modicum of intelligibility, conceptions of the supernatural usually combine overnatural and transnatural

---

[28] Despite many theological defenses, the notions of omnipotence and omniscience are incoherent (Martin 1990), so that we have reason to reject characterizations of the supernatural that employ them.

features. This allows the believer to oscillate between these two conceptions, depending on his argumentative needs. Modern theology tends to reject a merely overnatural conception of the supernatural as being too anthropomorphic and seems to prefer a more "sophisticated" conception of the supernatural in terms of the transnatural. Yet the transnatural is defined but negatively.

Spiegelberg's philosophical analysis is backed by cognitive psychology, which has shown that there is a rift between theological conceptions of religious entities and everyday religion. The latter is inevitably anthropomorphic but needs the counterintuitive features of the theological conceptions as an attention-grabbing potential.[29] It has been shown experimentally, for example, that although everyday believers know the theologically correct properties of God, they do conceive him in anthropomorphic terms when it comes to working with the concept of God in an everyday context (Barrett and Keil 1996). Whatever theology does to transnaturalize religious entities, believers will inevitably revert to overnatural concepts that better match their natural intuitive thinking. If religion is anthropomorphism, as Guthrie (1995) argues, this comes as no surprise.

Now, it may be argued that science faces a similar problem. Scientific concepts are often counterintuitive too, so ordinary people tend to stick to their more intuitive common sense understanding of the world. As McCauley (2011) shows, in this sense there is a divide between reflective attempts at cognition (science and theology) and non-reflective, popular – or as he calls them – "maturationally natural" attempts (commonsense cognition and popular religion). At the same time, however, both theology and popular religion are characterized by an unrestricted use of concepts of (intentional) agency or causality, whereas both science and commonsense cognition make a rather restricted explanatory use of intentional agents, that is, restricting it to the behavior of higher animals including humans. McCauley reminds us to not just compare science and religion simpliciter but in the correct respects. What is relevant here, then, is the metaphysical divide between science and commonsense cognition on the one hand and theology and popular religion on the other – which is the divide between naturalism and supernaturalism. Whereas the metaphysical divide, if any, between science and commonsense cognition is small, it is wider between theology and popular religion – which is the divide between the overnatural and the transnatural. In any case, both the overnatural and the transnatural are incompatible with the metaphysical naturalism of science.

56.5 Metaphysics and Methodology

56.5.1 Evidence Is No Metaphysics-Free Lunch

If metaphysical naturalism is a metaphysical presupposition of science, science should be unable to deal with anything supernatural. By contrast, if one believes that science is free of metaphysical presuppositions, the answer to the question of

---

[29] See Boyer and Walker (2000), Boyer (2001), and McCauley (2011).

whether the supernatural is testable is quite simply affirmative. For example, if angels descended from the sky and raised the dead or if studies on the effects of intercessory prayer yielded significant positive results, we would have empirical evidence for the supernatural and hence a valid test. (In the first case, we would have *direct* evidence, in the second case *indirect* evidence.) While many authors agree with this view,[30] others maintain that the supernatural is untestable as a matter of principle.[31] This disagreement can be explained by the distinction between the overnatural and the transnatural.

Those who maintain that the supernatural is testable seem to conceive of the supernatural as merely overnatural. That is, the supernatural is intelligible to a certain degree because its properties are not actually categorically different from natural properties: overnatural entities are more or less superpowered entities with quasi-natural properties. By contrast, those who believe that the supernatural is untestable seem to regard the supernatural as transnatural and hence as categorically different from anything known natural – which makes it both inaccessible and unintelligible and thus untestable.

But let us first take a look at the two central concepts of this debate, testability and evidence. In the broad sense, a statement, a hypothesis, a model, or a theory is empirically testable if there is empirical evidence for or against it (Bunge 1983), whereby the evidence e is another statement – a datum – that is relevant to the hypothesis h (or model or theory) in that e either confirms or disconfirms h. Now both e and h must be semantically meaningful (nonsense is untestable), and they must not be logical truths or falsities. For some evidential statement e to be relevant to some hypothesis h, e and h must share at least one referent or, if preferred, one predicate. For example, data about the crime rate in Australia in 2011 are irrelevant to quantum theory, because the data and the theory are not (partially) co-referential. Last but not least, we must demand that e has been acquired with the help of empirical operations that are accessible to public scrutiny, and – here enters metaphysics – both the empirical operations and our cognitive processes involved in the perception and processing (interpretation and evaluation) of the data gained by these operations must involve only lawful natural processes – that is, they must not be the result of supernatural manipulation.

So for there to be some evidence e about the supernatural, e would have to share at least one predicate with the respective hypothesis h referring to some supernatural entity. This, in turn, would require that the supernatural referred to in h possesses at least one property that can be represented by a meaningful (positive) predicate – which could only be a natural or quasi-natural property. But this is possible only if the supernatural is conceived of as *not* qualitatively or categorically different from the natural. For example, if we found reproducible significant positive effects of intercessory prayer and if these empirical data were supposed to function as evidence for a hypothesis involving a supernatural being as the cause of this effect, the

---

[30] See, e.g., Augustine (2001), Boudry et al. (2010, 2012), Fales (2010), Fishman (2009), Monton (2009), Stenger (2007), and Tooley (2011).

[31] See, e.g., Forrest (2000), Pennock (2000, 2001), and Spiegelberg (1951).

supernatural entity referred to would have to be able to "listen" to prayers, if only telepathically (however this would work), and understand and consider them in a way that is analogous to a human person listening to the requests of others and considering them on the basis of his or her background knowledge including a code of ethics. It is not intelligible how some solely negatively characterized transnatural entity should be able to do any of that; worse, we would not even know or understand what it means that any such entity *does* anything. For this reason, there could be evidence at most for the more or less anthropomorphically defined overnatural, so that only the overnatural may be testable in the broad sense.

Therefore, Pennock (2000, 2009) is right when he says that for the supernatural to be testable, it would have to be understood in a naturalized way, and the supernatural would have to be able to partly naturalize itself (or simply be natural to begin with) so as to interact with the natural world. If some process were actually transnatural, we could not observe it, however indirectly. Think of transubstantiation. Or think of the theological concept of continuous creation, according to which everything is constantly recreated ex nihilo by God, from moment to moment, and thus sustained in its existence. Continuity of existence is therefore just an appearance, whereas the reality behind it is a continuous transnatural intervention.

However, we still have to consider the last condition of evidence mentioned above, namely, the one that prohibits supernatural manipulation. Even if some empirical data fulfilled the formal conditions of evidence – provided the supernatural is construed as overnatural – we are still faced with the paradoxical situation that the empirical operations employed to produce such evidence presuppose the nonexistence of the very entities whose existence is supposed to be confirmed by this evidence. It may be tempting then to retreat to a principle of nonintervention with regard to our cognitive processes. But on what grounds could we defend noninterventionism? Of course, we could come up with various ad hoc assumptions. For example, the powers of the supernatural entities involved could somehow be limited, God could guarantee local noninterventionism with regard to our cognition, or God could even be the ultimate cause of our cognition and thus guarantee its correct functioning. But would it be epistemically warranted to accept any of these ad hoc contrivances, unless they are independently testable, that is, unless they are more than just logical possibilities? I don't think so. For this reason, naturalism remains the metaphysical default position of science, so that we have good reason to reject prima facie evidence for the overnatural as long as not all alternative natural explanations are exhausted.

56.5.2 Scientific Explanations Must Be Naturalist Explanations

Scientific theories are assessed (among others) with respect to their explanatory power. A scientific theory is expected to explain a certain fact or domain of facts. That is, it is supposed to tell us how something came about or how something works. In so doing, it employs law statements or reference to mechanisms (Bunge 1983;

Mahner and Bunge 1997). For example, a theory of photosynthesis informs us about the physiological processes (mechanisms) by means of which plants use light to transform carbon dioxide and water into carbohydrates and oxygen. These mechanisms are specific enough to explain what they are supposed to explain. Thus, they cannot be used to explain, for example, how birds fly or how earthquakes occur, because the respective laws and mechanisms are quite different. Do theories referring to supernatural causes or entities comply with this requirement?

They do not – even if we focus on the supernatural in the sense of the overnatural because transnatural entities devoid of positive properties are incomprehensible and hence nonexplanatory anyway. At first sight, invoking an overnatural cause to account for some fact does seem to have explanatory power. For example, intelligent design creationists claim that the theory of evolution cannot explain how certain complex organs have originated. So they invoke a supernatural entity, an intelligent designer (who allegedly need not be but is in fact considered to be God himself) who either created the organ or at least helped to accrue the given complexity. This answer appears to have explanatory power because, by analogy with human handicraft, we all understand what creating or developing artifacts is about. Yet in fact, it explains nothing because it explains too much. The problem is that an answer like "God made it the way it is" can be applied to all facts.[32] Whatever exists and whatever happens can be explained thus by reference to the will and actions of some supernatural entity. But an explanation that explains everything explains nothing.[33] Thus, supernatural explanations explain nothing because they are omni-explanatory.

The all-purpose God-did-it explanation is not something naturalists have come up with to ridicule supernaturalism. As a matter of fact, the philosophical doctrine of *occasionalism* seriously held that God is the cause of each and every event because matter is passive and cannot change or bring about anything on its own. If occasionalism, assuming 100 % supernatural causation, were true, there would be no need for natural explanations at all: a single supernatural cause would explain everything. So why do supernaturalists not adopt occasionalism? Why is science allowed to come up with natural explanations in some cases, but not in others? It seems that since the naturalist approach of science has been so successful, many supernaturalists have conceded its explanatory power and retreated to a god-of-the-gaps approach.[34]

Even some philosophers defend this view (e.g., Monton 2009), claiming that it is legitimate *in some cases* to fill an explanatory gap with a supernatural explainer, and that this would refute the charge that supernaturalist explanations are

---

[32] More on the problems of supernaturalist explanations in Pennock (2000), who also explores the consequences of supernaturalism for the legal system, which would have to reconsider the-devil-made-me-do-it arguments including historically superseded forms of evidence based on "higher insights" and revelations.

[33] Note that the famous "theory of everything" in theoretical physics is a misnomer, because it would not explain everything. It would just offer a unified theory of the fundamental forces of physics. But this would not even begin to explain all the emergent properties of higher-level systems.

[34] Those supernaturalists who dislike the god-of-the-gaps approach for theological reasons have retreated to a transnatural conception of the supernatural, which is immune to any empirical refutation.

omni- explanatory. However, it is doubtful that this rejoinder works. After all, supernaturalist explanations come with two proliferation problems. First, if we admit one supernatural entity into the explanatory realm of science, we are on a slippery slope to admitting as many as we fancy (Kanitscheider 1996). Christian creationists, for example, will of course tell us that the number of supernatural entities is limited by scripture. But if science admits entities from the biblical cosmos, nothing prevents it from admitting entities from other religions as well. There is no a priori reason why a Christian supernatural entity is a better explainer than a Hindu one, for example. The more supernatural explainers we get, however, the closer we get to omni-explanation again. Second, even if science were able to incorporate the overnatural into its explanations, how do we know that reference to such entities provides ultimate explanations? If science could study the overnatural, what would happen if we encountered explanatory gaps in the overnatural world too? The analogous procedure would be to resort to super-supernatural entities to fill these gaps in the first-order supernatural world, and so on, possibly ad infinitum. Just think of the famous question, “Who created the creator?”.

In any case, there is another and perhaps better reason for rejecting supernatural explanantia than their omni-explanatory power. As we know nothing about the laws and mechanisms, if any, of the supernatural, we better argue that supernatural explanations explain nothing, not because they are omni-explanatory but because they are pseudo-explanatory. Indeed, to explain the unknown by means of something even more unknown and, worse, something magic and occult is an argumentative flaw known as *ignotum per ignotius* or *obscurum per obscurius*. Of course, believers in the supernatural may object that they do know something about the supernatural, for example, by reading sacred texts, by revelation, by some special form of experience, or by simply having some special insight or epistemic faculty such as a *sensus divinitatis*, as claimed, for instance, by Plantinga (2011). However, all these “methods” are no longer acceptable because they are arbitrary: just any claim could be justified by them, and they are not intersubjective.[35] For this reason, appealing to the supernatural for explanatory purposes is tantamount to saying that we do not know how a certain fact works or has come about. Supernatural explanations are therefore *argumenta ad ignorantiam*: appeals to ignorance (see also Smith 2001). Thus, they cannot, as Clarke (2009) claims, function as inferences to the best explanation: proposing a pseudo-explanation is an inference to the worst explanation.

For those who believe that filling explanatory gaps with supernatural entities is a legitimate instance of an inference to the best explanation, hypothesizing supernatural entities is analogous to postulating unobservable (or theoretical) entities in science. However, this idea faces several semantic, methodological, and ontological problems.[36]

---

[35] See, e.g., Mackie (1982), Martin (1990), Forrest (2000), Fales (2010), and Philipse (2012).

[36] Philipse(2012) has recently shown that the inference-to-the-best-explanation approach of natural theology faces insurmountable problems, including the failure of Bayesianism, which is also championed by radical empiricists (e.g., Fishman 2009), who believe that scientific methodology has no metaphysical presuppositions.

In science, we must be willing to endow theoretical entities with a definitive set of properties. We cannot infer a best-explaining entity whose properties may vary arbitrarily (Kanitscheider 1996). Yet this is exactly the case with concepts of supernatural entities, in particular the concept of God, which is of course the most employed concept in supernaturalist explanations. Indeed, the properties of "God" vary from theologian to theologian, from tradition to tradition, even from believer to believer, so much so that "God" in theology *A* may have properties contradictory to the ones of "God" in theology *B*. A historical example is the God of Leibniz and Newton (Kanitscheider l.c.). Whereas Leibniz's God has set up the laws of nature at the beginning so that the world has been functioning without intervention ever since, Newton's God had to intervene more or less often in the natural world in order to adjust some imperfections. Thus, both a perfectly lawful and an imperfectly lawful world can be explained by reference to God. Whatever the factual evidence, then, some concept of God can always be applied.[37]

This is not to say that "God" is meaningless in the ordinary language of a certain group, because everyone has a rough idea of what "God" means in his or her religious tradition, in particular since these traditions employ rather anthropomorphic and thus overnatural conceptions of God. But this meaning is very restricted, as it is well known that religious sects have fought each other to death over the proper meaning of "God." However, being possibly meaningful locally and in ordinary language is not enough to qualify as a legitimate scientific concept and not even as a philosophical one. As Flew (1972) put it,

> Where the question of existence concerns, for instance, a Loch Ness Monster or an Abominable Snowman, [the introduction and defense of the proposed concept] may perhaps reasonably be deemed to be more or less complete before the argument begins. But in the controversy about the existence of God this is certainly not so: not only for the quite familiar reason that the word 'God' is used – or misused – in many different ways, but also […] because it cannot be taken for granted that even the would-be mainstream theist is operating with a legitimate concept which theoretically could have an application to an actual being.

This is important to remember because some scientists and oddly enough even some philosophers (like Monton 2009) seem to be so naive to think that the very use of the word "God" already amounts to postulating a legitimate theoretical entity with explanatory power. But it must first be ascertained that a sentence like "God caused some *x*" is more informative than "Tok caused some *x*" (Nielsen 1985).

---

[37] It may be argued that the variation in the meaning of "God" is not problematic, because scientific concepts often start out with fuzzy and variable meanings too. Think of terms like "gene" or "atom." However, the variations in the precise meanings of these concepts are adjustments guided by empirical research and theory development. These concepts could be made precise enough to even get hold of their referents: today, genes can be sequenced, and atoms can be photographed. The various concepts of God, by contrast, are not constricted and guided by empirical research, so there is no improvement in the sense of an approximation to reality. The conceptual "development" in theology is purely apologetic in that the traditional overnatural concepts of God have been transformed into transnatural ones, so that they can no longer conflict with science, or anything factual for that matter.

Assuming for the sake of the argument that it is possible to make "God" more informative than "Tok" and thus turn it into a meaningful theoretical concept and also into one whose meaning does not vary arbitrarily, an explanation referring to this God would still be arbitrary. For example, the origin of a complex organ such as the vertebrate eye may be explained by reference to some creative intervention by God. But in fact reference to any other supernatural entity would do the same explanatory work, be it a devil, an angel, a demon, or whatever. After all, we know nothing about the possible powers and intentions of such entities. So we have no empirical means for deciding among competing supernaturalist explanations (Augustine 2001). The only commonality supernatural explanantia for some fact *x* seem to share is this: some supernatural entity chose to do *x* for unknown reasons. This is hardly superior to "we do not know what caused *x*."

For all these reasons, postulating supernatural entities is *not* analogous to postulating theoretical entities in science. The semantic fuzziness, if not arbitrariness, of supernaturalist terms makes them useless as scientific concepts.

In sum, the semantic and ontological problems of supernatural concepts and statements affect both the concepts of evidence and explanation. Even if there were highly anomalous data, they would not constitute evidence for the supernatural unless there were scientifically meaningful statements about the supernatural in the first place. Until then, all we could state perhaps is that something spooky is going on, but such anomalous data could not be explained as the results of some supernatural intervention. This holds a fortiori when we are not even faced with anomalies. For example, a sentence such as "Due to its complexity, the human eye was intelligently designed by a supernatural creator" is at first sight meaningful by analogy to human design and creation. But even when applied to the merely overnatural, it is no longer clear what "intelligence," "design," and "creation" actually mean. Indeed, as Sarkar (2011) has shown, intelligent design "theorists" are unable to offer coherent and positive specifications of these concepts. This does not preclude that some overnatural concepts could be made more precise, but it shows that the road to evidence for the supernatural and the supposed benefits of its explanatory power are much rockier than the accommodationists believe.

56.5.3 Metaphysical Versus Methodological Naturalism

While it has become common knowledge that science goes together with naturalism, it is by no means commonly agreed upon what the exact nature of this relationship is. Compatibilist authors, for example, claim that science's naturalism is only a methodological naturalism, not a metaphysical one. Particularly in the philosophical context of the evolutionism/creationism controversy as well as in science education, which is concerned with *nature of science* issues, it has become common practice to distinguish methodological naturalism from metaphysical (or ontological or philosophical) naturalism and to claim that the former, not the latter, is the correct philosophical assumption of science. For the sake of convenience, let's abbreviate methodological naturalism by MN and metaphysical or ontological naturalism by ON.

Despite the popularity of MN, the characterizations of MN that we encounter in this debate are less than clear, so much so that we must guess what exactly MN is and how it differs from ON. Before substantiating this charge by taking a look at some of the most common definitions, it is important to point out first that, in this context, "MN" is used in a nonstandard way.

In philosophy, the standard meaning of "MN" is that philosophy ought to embrace the results of science and use some of its methods (weak MN) or that there is no unique philosophical method at all because only the methods of the natural sciences produce genuine knowledge (strong MN or strong scientism). In other words, weak MN states that science and philosophy are essentially continuous in that they pursue similar tasks with similar means, whereas strong MN leaves not much to do for philosophy.[38] By contrast,

> [i]n some philosophy of religion circles, 'methodological naturalism' is understood differently, as a thesis about natural scientific method itself, not about philosophical method. In this sense, 'methodological naturalism' asserts that religious commitments have no relevance within science: natural science itself requires no specific attitude to religion, and can be practised just as well by adherents of religious faiths as by atheists or agnostics. (Papineau 2007)

It is only this second meaning of "MN" that is relevant here, and it is this conception that in my view is ill-understood. The main problem is that it is unclear whether this MN actually is about scientific method rather than the metaphysics of science, in other words, whether it is a methodological (and hence an epistemological) view proper or whether it is just a covert metaphysical position, that is, a disguised form of ON. To illustrate this problem, let us take a look at some common definitions.

Pennock (2001) characterizes ON thus: "The Ontological Naturalist makes a commitment to substantive claims about what exists in nature, and then adds a closure clause stating 'and that is all there is'" (p. 84). By contrast

> [t]he Methodological Naturalist does not make a commitment directly to a picture of what exists in the world, but rather to a set of methods as a reliable way to find out about the world – typically the methods of the natural sciences, and perhaps extensions that are continuous with them – and indirectly to what these methods discover. (Pennock 2001, p. 84)

A commitment to method indicates that MN is epistemological. This is seconded by Forrest (2000), who tells us that MN is "an epistemology as well as a procedural protocol." Michael Ruse, by contrast, includes also ontological assumptions (lawfulness):

> On the one hand, one has what one might call 'metaphysical naturalism': this indeed is a materialistic, atheistic view, for it argues that the world is as we see it and that there is nothing more. On the other hand, one has a notion or a practice that can properly be called 'methodological naturalism': although this is the working philosophy of the scientist, it is in no way atheistic as such. The methodological naturalist is the person who assumes that the world runs according to unbroken law; that humans can understand the world in terms of this law; and that science involves just such understanding without any reference to extra or supernatural forces like God. Whether there are such forces or beings is another matter entirely and simply not addressed by methodological naturalism. Hence … in no sense is

---

[38] For further varieties of naturalism, see, e.g., De Caro and Macarthur (2008) and McMullin (2011).

> the methodological naturalist … committed to the denial of God's existence. It is simply that the methodological naturalist insists that, inasmuch as one is doing science, one avoid all theological or other religious references. (Ruse 2001b, p. 365)

Ruse's characterization reveals the main motivation behind MN: to assure the religious believer that science and religion are compatible.[39] Thus, the nonexistence of the supernatural (or rather its positive complement, ON) is not among the metaphysical presuppositions of science; it is just prohibited to refer to it. MN, then, boils down to the methodological rule, "Do not refer to anything supernatural!". The assumption of lawfulness, by contrast, is an ontological postulate. So Ruse's MN combines ontological and methodological aspects.

Even more ontological is another characterization of MN by Pennock:

> MN holds that as a principle of research we should regard the universe as a structured place that is ordered by uniform natural processes, and that scientists may not appeal to miracles or other supernatural interventions that break this presumed order. Science does not hold to MN dogmatically, but because of reasons having to do with the nature of empirical evidence. (Pennock 2009, p. 8)

Now, assumptions about the nature, structure, and workings of the world are metaphysical, not epistemological, even if most of the reasons for them are based on methodology. Moreover, Pennock's emphasis on MN as being nondogmatic indicates that in "MN" the adjective "methodological" could have a different meaning than the standard one, which is in the sense of methodology as normative epistemology, that is, the branch of epistemology concerned with the justification of beliefs and knowledge and the evaluation of methods. The standard adjective "methodological," then, classifies a position as epistemological – in contradistinction to adjectives describing some other philosophical category, such as a logical, semantical, ontological, or ethical. Another usage of "methodological," however, is in the sense of "provisional," "tentative," or "hypothetical." In this sense, "methodological" (sometimes also just "methodical") indicates either that the position in question is not regarded as an a priori truth or that it is not held dogmatically.

Consequently, there are at least two interpretations of MN:

1. MN is a genuine methodological/epistemological view, not an ontological one.
2. MN is an ontological position, namely, ON, but it is held provisionally rather than dogmatically.[40]

In the light of what was said about ON in this paper, only the second interpretation of MN is acceptable, although it would turn the name "MN" into a misnomer. The preference of "MN" over "provisional ON" could be due to the prejudice that

---

[39] That this is one of the main reasons behind MN has also been shown by Boudry et al. (2012).

[40] MN in the first sense can be held either dogmatically or provisionally. In the latter case, we may provocatively propose the name "methodological methodological naturalism," so as to point out the double meaning of "methodological." Note also that Boudry et al. (2010, 2012) distinguish intrinsic MN (in the sense of a defining feature of science) from provisional MN. The latter would be what I have just called methodological MN. Here I defend provisional ON as an intrinsic feature of science.

everything metaphysical is dogmatic. While traditional, and in particular religious, metaphysics often was dogmatic indeed, this is no longer true of a modern science-oriented metaphysics, which is fallible (Bunge 1977; Ladyman 2012). And even if modern metaphysics still were an a priori discipline, as some authors maintain (e.g., Lowe 2011), its rationalist claims would not be dogmas. For example, nobody would consider the modus ponens or the tertium quid as dogmas. This needs to be emphasized because some authors seem to confuse "a priori" with "dogmatic" (e.g., Fishman 2009, p. 814). The same would of course be true if only *some* claims of metaphysics were fallible, whereas *others* would be a priori.

If MN were indeed an epistemology, a procedural protocol, or a set of purely methodological rules, it would be a rather arbitrary choice of a protocol or of a set of rules, because it would not be backed up by a metaphysics. In a realist philosophy, being is prior to knowing. That is, the furniture and structure of the world must make cognition possible in the first place, and they must allow for the successful application of scientific methods. Hence, for a methodology to make any sense and to work successfully, there must be a metaphysics that helps to explain the functioning of this methodology. The methodology of science is therefore based on ON, just as the methodology of Plantinga's "theistic science" is based on supernaturalism.

However, if methodology cannot be separated from metaphysics, science is not religiously neutral. If science adopts ON in the sense of a metaphysical null hypothesis, it is not true that science is neutral on the existence of God, as most defenders of MN maintain (e.g., Scott 1998; Ruse 2001b; Pennock 2009). After all, the null hypothesis about some entity *x* states that *x* does not exist. Thus, science is committed to the "presumption of nonexistence" also with regard to God's existence.

56.6 Methodological and Other Conflicts

The preceding was one long argument to the metaphysical incompatibility of science and religion. It also mentioned several methodological conflicts arising from their disparate metaphysics. It may be helpful to recall them here and add a few further sources of conflict.

We have seen that the successful application of empirical scientific methods and thus the very concept of empirical evidence presuppose ON as a metaphysical null hypothesis. Whoever maintains that science can test supernatural hypotheses must find a way to resolve the paradox that any empirical test of any factual hypothesis presupposes the null assumption that supernatural entities do not exist. Most likely, an attempt at resolving this paradox will consist in some form of noninterventionism, but such an answer should not just consist in coming up with (untestable) ad hoc explanations as to why supernatural entities might refrain from such interventions: it should be a more principled approach, that is, a full theory. And, if scientific rather than philosophical, such a theory about noninterventionism should be independently testable. Yet any such test would in turn presuppose the very non-interventionist assumption….

Assuming for the sake of the argument that this paradox may be resolved, hypotheses involving supernatural entities would be empirically testable only in a limited way, namely, inasmuch as the supernatural is merely overnatural, that is, inasmuch as it has at least some natural properties. Insofar as religious convictions involve transnatural entities, they are untestable. Nonetheless, it is often claimed that even such convictions are testable. However, this often turns out to be terminological trickery, because in the context of religion, "testability" has nothing to do with empirical testability but with some alleged "experiential" or "existential" testability (Rolston 1987). Such "existential testability" is a wholly subjective notion, which is incompatible with the objective testability of science. Indeed, empirical testability undermines religion: "Because religion is an ostensible social relationship, it tends to be nonempirical, since openly testing a social relationship (…) undermines it. Testing therefore may be explicitly prohibited" (Guthrie 1995, p. 202f).

We have also seen that explanations referring to supernatural entities are either omni-explanatory or pseudo-explanatory. They are appeals to ignorance, and they may fill any explanatory gap by positing some supernatural intervention. Such "explanations," however, are arbitrary because any supernatural entity could do the same explanatory work as any other, and we may have no way to distinguish between competing supernaturalist explanations.

An important methodological incompatibility between science and religion is the latter's reliance on particular "methods" of cognition such as intuition, revelation, or religious experience.[41] Their characteristic is that they are inscrutable procedures, hence purely subjective ones. Thus, if such revelations or experiences are contradictory, there is no possibility to decide which of the alternatives is true – unless they yielded some specific factual statements that would be testable independently of the revelation or experience itself. From a methodological point of view then, they are not methods at all. However, whether such procedures are endorsed or not, religionists can always retreat to their faith when they wish to circumvent further rational and critical analysis. The difference between fundamentalist and more liberal religious views only lies at the point when such a retreat to fideism occurs (Bartley 1984; Kitcher 2004; Martin 1990).

Whereas the religionists' faith, i.e., the disregard and disrespect for evidence, is hailed as a virtue in their belief community, scientists are supposed to recognize that personal conviction or psychological certitude is no substitute for cognitive justification. The latter can only be achieved by objective evidence. Now, it may be objected that the history of science indicates that many scientists also stick to their hypotheses in an irrational manner, that they believe in them, and that they try to protect them against negative evidence. Granted. The difference, however, is that critical thinking and cognitive justification by empirical evidence belong to the ideals of the scientific community. If a particular scientist fails to comply with these ideals, he will be blamed by his peers, not praised. And if a hypothesis is not

---

[41] For a defense of religious experience as a valid method, see, e.g., Alston (2004). For critical analyses of the concept of religious experience, see Fales (2004, 2010), Kitcher (2004), Martin (1990), and Proudfoot (1985).

accepted by the scientific community, because there is too much negative evidence counting against it and there are perhaps better alternatives available, it will not enter the fund of scientific knowledge. By contrast, retaining one's faith even under the most averse falsifying conditions is a praiseworthy ideal in religion.

Related to faith is the role of authority in religion. While authority in religion is a methodological category, it is not so in science. Smith (2012) has recently examined the role of authority in science and religion from a mostly cognitive science viewpoint, pointing out that there are parallels between science and religion in how information is passed down from the original authority to colleagues, thence to science or religious teachers, respectively, and finally to students. Even though in science we do learn from authorities, such as colleagues, teachers, textbooks, and papers, because we cannot check every fact ourselves, and even though as individuals we do accept scientific knowledge on the basis of such authority, this is merely a matter of psychology and sociology. The real arbiter in science is evidence cum the current theoretical state of the art. This constitutes the ultimate justification. In religion, by contrast, religious doctrines are justified not by evidence, but because some authority, such as God himself or some spiritual guru, *pronounces* them as true. Justification by fiat and justification by evidence are incompatible methodologies.[42]

It may be objected that in religion "faith" does not mean "acceptance of doctrines on the basis of authority instead of evidence," but rather "trust" or "commitment." In this sense, faith is an aspect of a social relation such as trust in some other person around us. Yet such faith in persons is based on evidence: we trust our family and friends because we have some prior experience that they are trustworthy or worthy of commitment. By contrast, we have no such evidence in regard to supernatural persons, as we do not even have evidence of their very existence. So trust (faith$_2$) in such entities presupposes that we have already accepted the claim of their existence on faith$_1$ (belief without evidence). So even if there are two different concepts of faith, faith$_2$ is based on faith$_1$, so that the notion of faith$_1$ cannot be escaped. And faith$_1$ remains incompatible with science.

A different area of conflict concerns incompatible views about matters of fact. The most well-known case is the evolution/creation controversy. Liberal religionists tend to downplay such conspicuous conflicts because they are restricted to fundamentalist religions or denominations, respectively. However, fundamentalism is widespread in the USA, as well as in the Islamic world. While fundamentalism may have not much intellectual merit, it certainly is a powerful and dangerous social force. The doctrinal incompatibilities between fundamentalist religion and science are well known, so we may focus on the question of whether or not there are remaining conflicts even with respect to more liberal religion.

Apparently, there are no doctrinal conflicts left between science and liberal religion. Many scientific theories such as those in quantum physics, electromagnetism, plate tectonics, or immunology do not pose any problems for liberal religionists.

---

[42] Curiously, Smith (2012, p. 13) appears to realize this difference but he downplays it by saying that "in practice, however, the distinction is less stark." Yet practice is irrelevant: demarcation is first of all a matter of methodology. The cognitive and sociological similarities of learning on the basis of authority in both science and religion cannot attenuate the methodological conflict.

However, a clash between scientific theories and religious beliefs is bound to occur concerning the general cosmological views about man's (and woman's) place and status in the world, such as the evolution of *Homo sapiens*, the nature of mind, the existence of an afterlife, and the origins and social functions of religion. However liberal, religionists cannot admit that evolution has been a purely natural process (Rachels 1991; Plantinga 2011). If consistent, they must adopt at least a minimal teleological viewpoint, that is, they must posit that the evolutionary process has been guided from above and that it has a definite purpose, particularly, to establish a relationship between humans and some supernatural entity, e.g., a deity. Even if this view reduces to the claim that evolution is God's way of creation, it is at odds with evolutionary theory, because the latter makes no reference to supernatural entities and neither does any other scientific theory.

Curiously, Plantinga (2011) claims that evolutionary theory is compatible with theism, because God could have guided the process of evolution and even have caused particular mutations (see also Dennett and Plantinga 2011). Nothing in evolutionary theory would prohibit that. The supernatural is excluded only if evolutionary theory is paired off to naturalism – a union that Plantinga believes to be gratuitous. But this connection is not at all gratuitous because science is not free of metaphysics.[43]

The preceding considerations indicate that, if a religious methodology were applied in science and the scientific methodology in religion, the result would be mutual destruction. Science and religion are not only methodologically different but incompatible. The same holds for the metaphysics and the ethos of science and religion. Finally, insofar as religion makes factual statements about the world, there will also remain some doctrinal incompatibilities between religion and science. Thus, it is plainly false that, at least at a deep level, science and religion are not in conflict (O'Hear 1993). Actually, it is just at the deeper levels where the most conspicuous conflicts arise.

---

[43] Even more curiously, Plantinga (2011) argues that evolutionary theory is incompatible with metaphysical naturalism (see also Dennett and Plantinga 2011). A premise of this counterintuitive claim is that naturalists adopt an instrumentalist view of evolution, according to which natural selection favors at most cognitive faculties adequate for survival, not cognitive faculties furnishing truth, whether absolute or approximate. A purely natural evolution, then, entails that our cognitive faculties are not reliable in the sense of truth tracking. Plantinga is aware of the objection that a frog which manages to catch a fly must have correctly represented some property of its environment. But he claims that, even in the case of humans, the naturalist can talk only of appropriate behavior, not of true beliefs. He supports his case by resorting to antimaterialist arguments from the philosophy of mind, maintaining that any materialist conception of the brain and its functions, whether reductive or emergent, allows at best for appropriate behaviors, never beliefs, let alone true beliefs. True beliefs, so Plantinga's presupposition, can be had only in a nonmaterialist conception of the mind and a nonnaturalist conception of evolution. And the naturalist, who believes in the truth of naturalism, is inconsistent because naturalist evolution does not allow for the very existence of true beliefs. The real conflict, then, is between evolution and naturalism, not theism and evolution or science in general. Yet as evolutionary epistemology shows (Vollmer 2005), which is ignored by Plantinga, the evolution of cognition does lead to approximately true representations of the world (see also Dennett's reply in Dennett and Plantinga 2011). Also, naturalism requires a reconceptualization of concepts such as "knowledge" and "belief," which renders the antimaterialist argument moot (Bunge 1983).

56.7 The Conflict Between Science Education and Religious Education

> Even in his ability to be trained, man surpasses all animals. Mohammedans are trained to pray five times a day with their faces turned to Mecca and never fail to do so. Christians are trained to cross themselves, to bow, and to do other things on certain occasions. Indeed, speaking generally, religion is the chef d'œuvre of training, namely the ability to think; and so, as we know, a beginning in it cannot be made too early. There is no absurdity, however palpable, which cannot be firmly implanted in the minds of all, if only one begins to inculcate it before the early age of six by constantly repeating it to them with an air of great solemnity. For the training of man, like that of animals, is completely successful only at an early age. (Schopenhauer 1974, p. 603)

If science education is expected to inform students not only about facts but also about the philosophical background of science, it will have to address the methodological and metaphysical suppositions of science and maybe even all the world view components of science.[44] Inasmuch as religious education is also concerned with world view aspects, and we may claim that conveying a world view is even its major task, there is bound to be a conflict with the naturalist world view of science. After all, a religious education will have to state that the philosophical view of science is narrow or restricted, whereas the metaphysical and methodological outlook of religion offers so "much more" to discover. Indeed, defenders of religion argue that science and religion can be made compatible by choosing a broader metaphysics than naturalism (Barbour 2000), which entails of course that what science education teaches with respect to its philosophical foundations is inadequate.

The same holds for methodology. Religious education is likely to go against science education by allowing for exceptions concerning the acceptance of beliefs: religious beliefs need not be based on evidence, but may or even must be accepted on faith$_1$. Similarly, while it is a goal of science education to teach that it is appropriate to change one's views in the light of new evidence, religious education is prone to bringing forward a dogmatic mind-set because it teaches that unwavering faith is a good thing (Martin 1997).

Many evolutionary and developmental psychologists maintain that magical and religious thinking comes more natural because it is based on intuition rather than reflection, whereas critical or scientific thinking is something that has to be learned by keeping in check and overcoming our natural inclination towards superstitious thinking.[45]

Reinforcing our natural tendency for magical thinking by religious education thus appears to be antagonistic to the goals of science education. For example, while young children learn to master natural causality, they are at the same time exposed to religious concepts such as prayer, which teaches them that sheer wishing could

---

[44] See Davson-Galle (2004), Irzik and Nola (2009), Matthews (1992, 2009), and Smith and Siegel (2004).

[45] See, e.g., Guthrie (1995), Boyer and Walker (2000), Boyer (2001), Dennett (2007), McCauley (2011), and Shermer (2011). For a different view, see Subbotsky (2000) and Woolley (2000), who consider children's minds as neutral and thus to be filled with either rational or irrational cultural input.

have a physical effect. It seems that children somehow manage to put natural and imaginary causation in different "mental compartments" so as to avoid confusion (Woolley 2000). Even so, we may suspect that this compartmentalization is only partial and thus remains a steady source for ontological confusions, leading to a greater temptation to believe in various supernatural or paranormal claims and theories. Indeed, there is growing evidence that religious believers are more prone to also believing in the paranormal.[46]

If we want to raise responsible citizens who ground both their private and political decisions on scientific rather than illusory information, it is counterproductive to expose them to illusory world views. Worse, they not only learn that it is alright to accept such views as true but also to act according to those illusory beliefs. It comes as no surprise therefore that analytical thinking reduces religious belief (Gervais and Norenzayan 2012), which invites the conclusion that the converse is true too.

It may be objected here that, as the case of religious scientists shows, religion neither impedes scientific understanding nor prevents believers from choosing a career in science (see, e.g., Cobern et al. 2012). However, the empirical situation is not as straightforward.[47] Unsurprisingly, the effects of religious education very much depend on the degree of one's religiosity: the more seriously people take their religion, the worse the effects. For example, Christian fundamentalist students suffer from a lower complexity of thought and thus achieve lower educational attainment (Hunsberger et al. 1996; Sherkat 2007). In general, according to Evans (2011), religious believers take up a scientific career just as often as others. However, both scientific understanding and career choice are reduced when it comes to those scientific fields that interfere with religious belief, such as evolutionary biology and other areas that study human origins. Also, believers tend to deny scientific results if they have the impression that scientists pursue a moral agenda, for example, if scientists make recommendations for political action, as it may occur in the case of climate change. So it appears that orthodox religiosity does not lead to a general hostility towards science, unless the latter competes with central tenets of the given belief system – which shows, however, that there is a conflict with regard to a consistently scientific or else religious world view.

---

[46] See, e.g., Humphrey (1999), Goode (2000), Orenstein (2002), Hergovich et al. (2005), Lindeman and Aarnio (2007), and Eder et al. (2010). Note that the relation between religious belief and belief in the paranormal is not straightforward but depends on many variables such as level of education, gender, church attendance, and even the nature of the paranormal claims. For example, whereas astrology is mostly ruled out by Christians, creationism is not; and regular church attendance seems to prevent belief in the paranormal, presumably because the more frequent contact with official dogma protects from belief in competing paranormal or supernatural claims, respectively.

[47] For example, if science is strongly associated with technology, as in the questionnaire of Cobern et al. (2012), it may not be surprising that even orthodox believers see not much conflict between science and religion, except for ideologically contentious issues such as creationism or embryonic stem cell research. After all, even fundamentalists are glad to reap the benefits of modern technology. More importantly, personal views about the relation of science and religion, or even career choice, do not answer the de jure conflict problem concerning a consistent world view.

That a high level of religiosity may have negative effects is perhaps better seen at the social level. Comparing societal health data of the strongly religious USA with the more secular democracies of Western Europe and Japan, Paul concludes:

> In general, higher rates of belief in and worship of a creator correlate with higher rates of homicide, juvenile and early adult mortality, STD infection rates, teen pregnancy, and abortion in the prosperous democracies (…). The most theistic prosperous democracy, the U.S., […] is almost always the most dysfunctional of the developed democracies, sometimes spectacularly so, and almost always scores poorly. (Paul 2005, p. 7)

Critics have pointed out that, concerning the USA, these correlations are in most cases better explained by its higher level of social inequality rather than its high rate of religious belief (Delamontagne 2010, 2012). Using the Human Development Index (HDI), Delamontagne confirms the finding that high religiosity is accompanied by higher levels of societal dysfunction. However, he does not find a significant difference in HDI scores between moderately religious believers and nonbelievers, where the "moderately religious" are those for whom religion is "somewhat important" and the Bible is not true word by word, and who attend religious services but occasionally. Overall, higher levels of societal dysfunction in the USA are correlated with lower educational attainment, lower income, and race (Delamontagne 2012). While this may be correct sociologically, it is interesting to note from an ethical point of view that the high level of religiosity in the USA does not seem to contribute to decreasing the high level of social inequality – which casts doubt on the self-image of religion as a moral enterprise benefitting society.

It should not go unmentioned that psychological and sociological studies also report some positive effects associated with religiosity. For example, religious students tend to be more sociable, show less substance abuse problems, and tend to be more disciplined with respect to their coursework (Donahue and Nielsen 2005; Sherkat 2007). As the members of many denominations tend to form closer-knit communities, these examples may be seen as beneficial aspects of social embeddedness rather than direct effects of religious education as such. But should we not expect anyway that religious education contributes to a better morality?

Indeed, probably the major argument for religious education is that it is indispensable for moral education, in particular as science is concerned with matters of fact, not values and ethics. However, the alleged connection between religion and morality does not withstand scrutiny. First, empirical studies have shown that, overall, religious people fail to behave more morally than nonreligious people (Spilka et al. 1985; Tan 2006). For example, they neither cheat less in tests nor are they less selfish. Overall, then, religious education has no distinctly positive effect on moral behavior, which we would have to expect if the main function of religion and religious education were an ethical one.

Second, the goals of a modern moral education include acquiring the attitude and the capability of modifying one's moral principles in the light of new experience, knowledge, and insight (Martin 1991). This aim is certainly antagonistic to the religious attitude towards moral norms. If moral norms are God-given, be it by direct command or by a created natural law, they cannot be questioned or modified: they can only be obeyed or disobeyed. Finally, philosophy has amply demonstrated from Plato on that religion cannot be the basis of morality anyway.[48]

A final point, just for the fun of it, so to speak: it appears that religiosity is negatively associated to sense of humor; the more so, the more dogmatic or authoritarian believers are (Saroglou 2002). A possible objection, analogous to the argument from religious scientists, is obvious: we all know religious people with a great sense of humor. But "it is possible that religious people have a good sense of humor *despite* their religiosity; and not necessarily *because* of it" (Saroglou 2002, p. 206).

The quick upshot is this: empirical research on religiosity shows that both people and societies are the better off the less seriously they take the contents of their religious belief systems. The more literal and dogmatic the religious beliefs, the worse; the more abstract and liberal – more bluntly: the fuzzier and emptier – the better. The reason for this is, as we have seen again and again, that science and religion or, if preferred, a scientific and a religious world view are metaphysically, methodologically, and attitudinally incompatible.

Martin Mahner graduated in 1985 at the Free University of Berlin (major: biology, minor: geography). After his second graduation as an A-level teacher in 1987, he obtained his Ph.D. in 1992 (major: zoology; minor: philosophy of science). In 1992, he was awarded a research grant by the Deutsche Forschungsgemeinschaft (DFG) to take up a postdoctoral fellowship with Mario Bunge at the Department of Philosophy at McGill University, Montreal (1993–1996). From 1996 to 1998, he was a free-lance instructor at three universities in Berlin, Germany (zoology, philosophy of science). Since 1999, he has been the executive director of the Center for Inquiry – Europe, near Darmstadt, Germany, a nonprofit educational organization devoted to collecting and disseminating critical information about pseudoscience. Among his publications are *Foundations of Biophilosophy* (with M. Bunge 1997, translated into German, Spanish, and Japanese) and *Über die Natur der Dinge. Materialismus und Wissenschaft* [*On the Nature of Things. Materialism and Science*] (with M. Bunge 2004). He is editor of *Scientific Realism: Selected Essays of Mario Bunge* (2001), and he contributed to the 15-volume *Lexikon der Biologie* [*Dictionary of Biology*] as well as the chapter "Demarcating Science from Non-Science" to the *Handbook of the Philosophy of Science*, vol. 1 (2007).

Part XII
Theoretical Studies: Science Education Research

Chapter 57
Methodological Issues in Science Education Research: A Perspective from the Philosophy of Science

Keith S. Taber

57.1 Introduction

Science education as an academic field occupies an interesting position as there can be something of a tension between its location within one type of academic setting (education, often considered a social science, but also drawing upon the humanities) and its strong links with the disciplines that are the target for that educational activity (i.e. the natural sciences). For one thing, education is primarily about teaching, which is a practical and professional activity, often considered to be as much a craft as a science (Adams 2011; Grimmett and MacKinnon 1992). So education as an academic discipline has strong links with education *as practised* in schools and other institutions 'of' education and seeks to learn about and inform educational activity in such formal learning contexts, as well as increasingly in various informal contexts where learners may be self-taught or learn through informal interactions that may not be primarily intended to bring about teaching.

For the purposes of this chapter, education will be considered to be centrally about the processes of teaching and learning (Pring 2000), acknowledging that the teaching may sometimes be in the form of self-direction of learning (Taber 2009a). So science education is a field that is centrally concerned with the teaching and learning of, and about, science and the scientific disciplines. Science education encompasses both teaching for the general population – science for citizenship, scientific literary – and for the preparation of future professional scientists (Aikenhead 2006; Hodson 2009; Holbrook and Rannikmae 2007; Laugksch 2000; Millar and Osborne 1998).

The nature of the work of teaching has raised interesting issues about the relationship between educational research and practice: issues about outsider versus participant research (Taber 2012b) and about the challenges of translating research

---

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_57,

that is often necessarily framed for the academic community into a form that can inform practitioners (de Jong 2000; Russell and Osborne 1993) – or alternatively, seeking to find ways to draw generalisable findings from local highly contextualised studies (Taber 2000).

In addition, educational research is usually undertaken with human participants and so is subject to ethical considerations that do not apply in the natural sciences (e.g. British Educational Research Association 2004). A common metaphor for science is along the lines of wrestling nature's secrets from her (Pesic 1999), but researchers are discouraged from seeing the collection of educational research data in this way. Indeed, objectifying the learner (or teacher) as a source of data, rather than considering them as a person participating in research, is usually considered inappropriate in educational work. (Ethical issues are considered further later in the chapter.)

These generic issues, which need to be faced by educational researchers wishing to influence educational practice, are often supplemented for science education researchers by questions raised by the juxtaposition of mindsets and commitments of two somewhat different disciplinary backgrounds. Education as an academic subject is often seen as a social science, and research training in education reflects this, with a major focus on the paradigmatic concerns and tensions that operate in social research. (Indeed, this is oversimplistic as some scholarship undertaken within education faculties fits within the behavioural sciences, and some educational scholarship is best seen as located in the humanities.) Yet science education, as a field, tends not to be populated exclusively (or even primarily) by social scientists choosing to focus on science education for their research topic. There is certainly a fair number of those, but many (and in at least some national contexts, most) of those who undertake research in science education have a background in natural sciences and often experience of teaching natural science subjects at school or a higher level.

Even when such a researcher takes on an identity as a social science researcher, this is often secondary to their established identity as scientist and/or science educator (Kind and Taber 2005). Yet, as will be discussed below, research training in the natural sciences is often somewhat different to research training in education and other social sciences. A further complication is that many of those undertaking research in science education who do not have a background of studying and teaching in the natural sciences actually have a background in psychology: a subject that itself straddles the disciplinary divide between natural and social sciences (Barrett 2009). This chapter will explore a range of issues about the nature of educational research (and the consequent implications for methodology), with a particular concern with whether research in science education can be considered scientific.

This focus is of interest for a number of reasons. The question of what can be encompassed within science, the demarcation question, has been of concern to some philosophers of science who have wished to distinguish science from pseudoscience (Lakatos 1970; Popper 1934/1959). The very adoption of the term 'social sciences' reflects an attempt to model disciplines like sociology on the natural sciences, leading to the questions of to what extent and in what ways are social sciences and natural sciences part of a larger ‘science’ (Kagan 2009). In addition are two complications referred to above: the diversity of educational scholarship and the professional identities of science educators.

Within education faculties, research and scholarship may take a wide range of forms, from completely nonempirical philosophical analyses and literary analysis of texts written for children to experimental studies carried out by educational psychologists following established ‘paradigms’ (which, in that context, in effect means an experiment design) and considering participants as interchangeable subjects from particular populations (normal 12-year-olds, dyslexic 9-year-olds, autistic secondary age boys, etc.). In some national contexts, science educators will be working as part of such diverse communities, whereas in other national contexts it is more common for science educators to be working as part of a science faculty – within a physics department, for example. Many science educators move into research in science education with a well-established professional identity as a scientist (or more specifically chemist, etc.) and/or science teacher and therefore bring expectations of what kind of activity ‘research’ is: expectations that will inform their understanding of the particular institutional context in which they are working.

57.1.1 The Programme for This Chapter

The present chapter will first consider the particular nature of educational research and the nature of the field of science education, before considering the question of whether induction into science education research reflects the process of induction into research in the natural sciences. The chapter then considers the logic of developing a research project and how in educational enquiry this involves a justifiable choice of methodology, which may have to be moderated to some extent by ethical considerations and which informs the construction of a specific research design drawing from a range of particular research techniques used in educational work.

The chapter then considers how best to understand the range of methodologies commonly applied in education in terms of the different ontological and epistemological commitments that may apply when enquiring into different kinds of research foci. This leads to the conclusion that science education is unlikely to develop the kinds of neat and somewhat self-contained research traditions often associated with research in the natural sciences, but rather that principled choices from a diverse repertoire of methods are likely to reflect the inherent nature of the research area – and that indeed such choices will be expected to shift as knowledge is developed in any particular area of research.

The chapter finally considers how despite the apparently ‘aparadigmatic’ nature of research in science education, conceptualising research traditions within the field in terms of Lakatosian research programmes is likely to support the research community in organising research in ways that can be seen as scientific, in terms of allowing judgements about progress and offering researchers more heuristic guidance about fruitful directions for research.

57.2 The Nature of Education and Educational Research

The philosopher of education, Richard Pring, has highlighted how educational research should focus on the core activities of education, that is, teaching and learning, suggesting that 'the distinctive focus of educational research must be upon the quality of learning and thereby of teaching' (Pring 2000, p. 27). However, Pring also acknowledged that this would go beyond the immediate classroom context to include research undertaken to 'make sense of the activities, policies and institutions' which were set up to organise learning (p. 17). That is, educational research commonly focuses on classrooms and learners but also encompasses studies exploring the policies that inform classroom teaching and how these are derived, developed and (often imperfectly) enacted. Research may also consider the governance and management of institutions such as schools, as well as the way that education, teaching and learning are understood in particular cultural contexts.

Education is the context for directed learning, and in formal educational institutions (such as schools and colleges), structures are put in place to encourage and channel learning. A key type of activity in such institutions is teaching, which I suggest is best understood as *deliberate actions intended to bring about particular learning* (Taber 2014). The conditional 'intended' is important here, because as the vast literature in science education testifies, what students learn is not necessarily what the teacher intended to teach (Duit 2009) and may sometimes be quite idiosyncratic. Not only is much learning spontaneous, in the sense of occurring without any specific intention to learn, but, as learning is a highly iterative process, it is strongly channelled by existing ways of understanding the world.

There is an interesting question of the relationship between terms such as teaching, pedagogy and Didaktik (Fischler 2011) – the latter being a common term in continental Europe, but used less in the Anglophone countries. Teaching is here used to refer to the activity, where pedagogy can either be used to refer to the general theoretical body of knowledge about how to go about teaching or to refer to a specific strategy adopted in a particular teaching context (an interesting parallel with the way 'methodology' is used both in a general abstract sense and to describe the specific strategy employed in a particular research study).

Learning is here understood as a change in the potential for behaviour, that is, a change in the behavioural repertoire of the learner (Taber 2009b), assumed to be underpinned by changes in the way the learner's experience of the world is represented in some form of cognitive structure. It is widely accepted that 'circuits' within the brain provide the material substrate that supports cognition, although the precise correlation between the synaptic level and experience of 'having an idea' is much less clear. Despite this, it seems that people do represent aspects of their experience of the external world internally and that, as Vygotsky (1934/1986) long ago noted, these representations are organised into structures rather than being like discrete 'peas in a pod'.

The nature (e.g. coherence) and extent of such structuring is a theme of empirical research in science education (Fellows 1994; Ganaras et al. 2008; Taber 2008), and it is clear that the ways individuals relate and integrate their conceptions of the natural world are often quite different from the way concepts are related in professional science or in formal science curricula. However, such conclusions are indirect inferences made in research, because an individual's cognitive structure is not directly observable (Phillips 1983). Rather, we rely on the learner's behaviour in representing their ideas in the 'public space' where it can be observed as the basis for modelling their thinking (Taber 2014). In science education, we are often concerned with developing students' knowledge and understanding (key concepts that are themselves not easy to operationalise in research), so commonly the 'behaviour' we are interested in is of the form of speech or inscriptions – such as are involved in answering a teacher's questions in class or completing a test paper or assignment.

Although some commentators consider informal learning, and the spontaneous mechanisms that support it, to be distinct from learning processes in educational contexts where there is an intention to teach particular things (Laurillard 2012), there is an increasing tendency for contexts for informal science learning (such as museums) to be planned according to pedagogic principles. So although informal science learning may often appear 'haphazard and incoherent' (Stocklmayer et al. 2010, p. 11), the educational work of museums and science centres is informed by similar debates and principles as those informing the design of curriculum and teaching in schools and colleges (Pedretti 2002).

As an academic area, education is something of a recent addition to the academy – despite scholarly periodicals such as *Science Education* (preceded by *General Science Quarterly*, which first appeared in 1916) and *School Science Review* (first appeared 1919) being long established – and this is reflected in the diverse disciplinary backgrounds of many education faculties as noted above. Traditionally education was seen as an applied subject which drew upon four 'foundation' disciplines: philosophy, psychology, sociology and history (McCulloch 2002). However, in recent decades, education has become more firmly established as an academic subject in its own right. There would seem to be a generational effect here, in that the first holders of PhDs 'in education' were necessarily supervised and advised by faculty who themselves originally trained in other disciplines; but that first generation of education PhDs could then start supervising their own research students from within the 'discipline' of education.

57.3 The Nature of Science Education in the Academy

Certainly in science education, this transition occurred within living memory of some of those currently still working in the field, so the most senior professors of science education active today undertook their own postgraduate studies in other subjects. Fensham (2004) has provided a very readable account of the origins of science education through this process. This means that early researchers in the field were trained in research methods of different disciplines, and for those who trained in the natural sciences, their expertise was often not optimal for transferring to a context exploring educational problems.

Some of the early studies in science education adopted methodology that would seem crude and naive to a postgraduate student (and are justified in terms that would be considered inadequate if submitted for publication) today, and there has been much borrowing of techniques from other fields. Such borrowing need not be a bad thing, providing the techniques concerned are not, in the process, decontextualised from the paradigmatic commitments which provided their justification as valid knowledge-seeking tools. To offer a crude analogy: a screwdriver can be used as a chisel, and a chisel can be used as a screwdriver, but in both cases, one is likely to do a poor job and risk the integrity of the tool itself. In the same manner, as will become clear below, research techniques have been designed with particular jobs in mind and may provide a messy outcome when used without due care and attention.

The major journals in science education now publish work not only on a wide range of themes but adopting a broad range of methodologies. Some of these methodologies reflect approaches common in the natural science, but others draw upon approaches less widely employed in the natural sciences, as they are intended to explore aspects of the human experience itself. Whilst the scope of the present chapter does not allow any detailed discussion of specific data collection or analysis techniques, the key considerations that have informed different paradigmatic stances will be considered below.

57.3.1 The Methodological Turn in Science Education

Early researchers in the field of science education were pioneers, and it is perhaps inevitable that some pioneering work seems crude or trite as a field becomes better established. However, recent decades have seen the development of an extensive literature focusing on educational research methodology, and a new researcher entering an educational field such as science education today can be introduced to a varied, if somewhat contested, range of reading, setting out the nature of educational research and how one should go about it. Often educational research is treated as a specialised area within social research (i.e. social science research) more generally, and sometimes it is grouped with other areas that relate to the professions (particularly areas such as social work and nursing). In effect, educational research has developed into a field of activity within education as a subject area, and research methodology has become the subject of primary journals (such as *Educational Research*er, ISSN: 0013-189X; 1935-102X) as well as being an active area of textbook publishing.

This reification of educational research into a subject for study as well as a means to carry out studies has led to much discussion about the diversity of methodological approaches used in educational studies and the relationships between them (Bassey 1992; Clark 2005). Some of these issues are explored later in this chapter. With this specific topics. Rather there will often be several theoretical perspectives that might be relevant to a topic. These might sometimes be seen as based on competing theories, but often they might be better thought of as each illuminating some of the facets of a complex phenomenon.

There are parallels to both of these alternatives in the natural sciences. So we might consider theoretical perspectives as competing in the way that (a) the oxygen theory of combustion competed with the phlogiston theory (Thagard 1992) or (b) the notion that species have an inherent essence that makes them absolutely distinct (as might be expected if each type was originally formed by an act of special creation) is at odds with the idea that all living things derive by descent from a common ancestor (in which case species are not absolute, but current loci of relatively stable forms at a particular historical moment, contingent upon a great many particulars of past events, with temporary salience against a background of constant slow modification and shifts).

But even in the natural sciences, alternative and apparently inconsistent perspectives need not be considered to be in direct competition. An analogy here might be the way interactions between colliding molecules might be conceptualised in terms of different theoretical models. One theoretical perspective that could be applied would be an ideal gas (i.e. kinetic theory) model, where molecules can be considered to behave as spheres that undergo perfectly elastic collisions. Here the molecules are stable entities, and their collective behaviour can be used in explanatory models of bulk behaviour of the gas. Another theoretical perspective that might be applied could be to consider molecules to be complex structures including electronic orbitals with associated energy levels, some of which are occupied and others unoccupied. Here descriptions in terms of potential overlap between occupied orbitals on one molecule and unoccupied orbitals on another may form the basis for explanatory models of reaction mechanisms (at the submicroscopic level) that help explain patterns of chemical reactivity at the bulk level. In this example, we might consider that both of these perspectives are potentially valid and could contribute to a full understanding of gas properties, but that, in relation to a particular scientific problem, one will be more productive than the other. So even within the natural sciences, the application of a concept may involve selecting an appropriate tool for a particular job, from a metaphorical conceptual 'toolkit' (Taber 1995) offering alternatives that all have their own range of application. Indeed, this very feature of science appears to offer a major challenge to many learners, presumably because they often misconstrue the nature of the models presented in the curriculum (Taber 2010c).

The difference between these two types of cases would seem to be whether the different perspectives can meaningfully be considered complementary. Whilst a model of molecules as like tiny billiard balls is clearly incomplete because it does not explain chemical reactions, it remains a useful analogy for some purposes and can complement other models that explain particle behaviour under other circumstances. In other words, the apparently inconsistent models are not competing for the same 'explanatory space' in this example: one perspective explains physical properties that are commonly exhibited by gases and gas mixtures, and the other perspective can explain why chemical change sometimes occurs when gases mix.

diversification of methodological approaches being employed in educational research, it has become increasingly expected that empirical research reports should provide not only a description of the methodology employed but also a justification of the approach used and acknowledgements of limitations inherent in the methodology or the specific design for a study.

These considerations might suggest that there seem to be two related key differences between methodology in education, including science education, and in the natural sciences:

1. Research in science education as a field draws upon a wide menu of available methodological choices, whereas research in most particular fields within the natural sciences is limited to a much more (to mix metaphors) limited palette.
2. Descriptions of research in science education often offer extensive justification of chosen methodology, commonly including explicit discussion of ontological and epistemological commitments underpinning research designs, whereas reports of research in the natural sciences often focus on specific technical details without extensive justification of the overall methodology.

This could be taken to suggest that research in science education, being unlike research in the natural sciences, should not be considered scientific in nature. To consider why these differences exist, it is useful to consider Kuhn's account of how researchers are inducted into the natural sciences.

57.4 Normal Science, Revolutionary Science and Another 'Sort of Scientific Research'

Thomas Kuhn has been highly influential in both science studies and discourse about the nature of work in the social sciences, largely based upon the reaction to his essay on *The Structure of Scientific Revolutions* (Kuhn 1970) and the adoption of the notion of working within a 'paradigm'. In that work, Kuhn argued that scientific revolutions were rare and that most scientists spent their careers doing what he termed 'normal science'. Although key aspects of this work have been much criticised (and some of this criticism will be discussed briefly below), Kuhn's description of how scientists are trained and inducted into traditions of research is especially relevant to the present chapter and is considered here to offer very fruitful insights when considering the way methodology is discussed and understood in educational research.

Kuhn described normal science as working within a paradigm or a 'disciplinary matrix' (Kuhn 1974/1977). In Kuhn's model, most science occurs within an established tradition, and these traditions are occasionally interrupted when a niggling anomaly leads to an individual (a) forming a revolutionary reconceptualisation of the field and then (b) persuading the scientific community to shift allegiance such that a new tradition is formed and the old one abandoned. For Kuhn such a revolution changes both the meaning of terms and ways of seeing and understanding the world to such an extent that those working within the new paradigm should be considered to speak a different language (such that the two paradigms become incommensurable) and in effect work in a different world (Kuhn 1996).

Aspects of this thesis have been widely discussed and critiqued (Masterman 1970; Popper 1994), especially the notion of incommensurability and the potential implication that there can be no objective way of judging progress in science – i.e. it could be argued from Kuhn's analysis that a revolution makes a field different, but not necessarily further advanced – although Kuhn himself argued that his analysis suggests judging progress is problematic rather than impossible (Kuhn 1973/1977).

57.4.1 Induction into Scientific Research

However the aspect of Kuhn's work most relevant for the present chapter is his description of how a new scientist prepares for work in, and becomes accepted within, a research field. For Kuhn, the process of becoming a professional scientist is in effect an induction into a particular tradition (or paradigm, in one of the senses in which Kuhn used the term) through a kind of intellectual apprenticeship. By the completion of this training process, the new scientist has adopted the norms associated with the disciplinary matrix that in effect defines the current state of the particular subfield in which the scientist has completed research training (Kuhn 1996). This disciplinary matrix provides the framework for scientific work 'based firmly upon a settled consensus acquired from scientific education and reinforced by subsequent life in the profession' (Kuhn 1959/1977, p. 227). Kuhn saw each such tradition as ultimately derived from a particular scientific achievement – such as Newton's work on mechanics or Lavoisier's work on chemistry, but other examples might be Darwin's work on natural selection or Crick and colleagues' work on the structure of DNA and the 'central dogma' of molecular biology. Such achievements were revolutionary enough to each initiate a new direction for scientific research; moreover, one which could provide a starting point for developing a whole new approach (Kuhn 1996).

In his work, Kuhn argued strongly that a scientist needed to demonstrate a commitment to the tradition in which he or she was working and that this was equally true for the few who would initiate scientific revolutions of their own, as it was for the majority that would work their entire careers on the 'mopping-up' work of normal science. Kuhn did not imply that such 'mopping-up' work lacked interest or excitement: it was routine in the sense of being within an established tradition and therefore had a strong 'convergent' focus, compared with the divergent nature of the 'discoveries' that initiated the occasional scientific revolutions.

Kuhn recognised the ubiquity of imprecision and anomaly in scientific work and considered that progress in science depended upon scientists being able to have enough commitment to the accepted theory in the field not to be continuously distracted by attempts to explain nonsignificant discrepancies between theoretical predictions and results (Kuhn 1961/1977). Michael Polanyi (1962/1969) also discussed how scientists need to be able to use personal judgement to ignore most of the multitude of apparent anomalies (in effect, prima facie refutations) met in the course of scientific work. Where Polanyi emphasised how such judgement depended upon tacit knowledge (which he related to the way an external reality becomes known through the complexity and subtlety of human perception/cognition), Kuhn stressed how the indoctrinating effect of scientific education could dull the ability to recognise a significant anomaly for what it was.

Whilst identification of a significant anomaly was central to initiating a scientific revolution in Kuhn' account, even the successful revolutionary has to make their argument for a paradigm shift from within the existing tradition – that is, they need to be recognised by others in the community working in the field as being a full legitimate participant (cf. Lave and Wenger 1991) in that particular scientific tradition (Kuhn 1996). This required a 'thoroughgoing commitment' to the existing tradition (Kuhn 1959/1977, p. 235).

The disciplinary matrix in which scientists work, and in which they draw upon the commitments underpinning their scientific work, supports 'relatively unproblematic…professional communication' and allows 'relative unanimity of professional judgment' that is 'comprised of ordered elements of various sorts' (Kuhn 1974/1977, p. 297). These included symbolic generalisations, models and exemplars (the latter providing the derivation of Kuhn's original choice of the term 'paradigm'). For Kuhn, the set of models used within a scientific tradition range from heuristics offering analogical insight to deeply held metaphysical commitments amounting to an ontology (Kuhn 1974/1977). Indeed, within normal science, 'research is directed to the articulation of those phenomena and theories that the paradigm already supplies' (Kuhn 1996, p. 24). Elsewhere, Kuhn refers to how researchers within a shared paradigm 'are committed to the same rules and standards for scientific practice' (Kuhn 1996, p. 11) and how paradigmatic exemplification derives from how scientific practice involves 'law, theory, application, and instrumentation together' (Kuhn 1996, p. 10).

As suggested above, Kuhn's thesis has not been universally accepted. Indeed, whilst it may be welcomed as a useful challenge to models of the nature of science that relied on the logical structure of research and oversold an assumption that in principle sufficient careful research could provide a basis for unambiguously interpreting nature, it arguably encouraged views of science that in turn underplayed the role of logical argument and interrogation of evidence in reaching consensus in science. In particular, the suggestion that normal science is somewhat routine, pedestrian and almost a matter of following algorithms (which has perhaps been taken from Kuhn, rather than offered by him) has been challenged by those who consider controversy to be a common if not constant feature of science, rather than a sign of a rare major shift (Machamer et al. 2000). Indeed, Feyerabend (1988) countered the notion of normal science by claiming that the history of science suggested there was no standard method or set of preferred approaches in science, but rather that scientists were much more pragmatic, adapting and inventing method to meet the needs of the problem at hand.

At first sight, there appears to be a wide gulf here, but perhaps such different accounts of science need not be as inconsistent as may appear initially to be the case. The basis for suggesting this (whilst acknowledging it may partly reflect a personal cognitive style of tending to prefer integration to fragmentation) links to notions of what might be termed 'grain' size in analysing the nature of science. This reading would acknowledge both (i) that controversy is certainly common in science and indeed is probably an important part of the motivation for much research (Machamer et al. 2000), but many controversies concern issues that are not linked to core ontological commitments within a research tradition (and so can be accommodated in something like Kuhn's normal science), and (ii) that innovative techniques for data collection and analysis are indeed common in the history of science when taking the 'long' view, but that again major new approaches (rather than refinements to existing techniques) are relatively rare within the day-to-day career of the working scientist, and that 'standard' techniques do become and remain established within research traditions.

From this view, criticism of Kuhnian normal science as a description of most scientific activity would *not* undermine what Kuhn has to say about the research training of individual new scientists, which generally takes place over a matter of a few years, working in one area of science and often within the context of one or two research teams and laboratories. Typically, then, according to Kuhn, a scientist is trained within a particular research tradition that leads to embracing the research community's commitment to the kinds of phenomena that fall within the scope of the field, the kind of entities that are used in explanations, a theoretical apparatus within which predictions and explanations can be developed, standard forms of representation, and accepted techniques for undertaking research studies. However, despite this characterisation of normal science, Kuhn did not claim that scientific work necessarily *had* to take this form, but rather saw this as the nature of 'mature' sciences.

Indeed, Kuhn (1996, p. 11) acknowledged that in fields that had not achieved such maturity, 'there can be a sort of scientific research without paradigms, or at least without … unequivocal and … binding' paradigms. That is, Kuhn was offering a descriptive account of science based on his historical scholarship, not a prescription for science. His description could be seen as providing demarcation criteria for mature sciences, but not for scientific enquiry per se. In 1983, Gilbert and Watts referred to how research into learning in science was in 'a pre-paradigmatic phase' as there was 'no general agreement on the aims of enquiry, the methods to be used, criteria for appraising data, the use to be made of the outcomes' (p. 61). Arguably, to some extent, this description could still be applied to science education as a field of research some 30 years later, and if we wish to see research in science education as a scientific activity, then we need to consider it as Kuhn's other, less mature, 'sort of scientific research'. However, there is an alternative argument, long recognised by Shulman (1986), for example, that suggests that research into such areas as teaching is unlikely to mature into something like Kuhnian normal science, because the degree of complexity of educational phenomena is such that no single perspective is likely to offer a full enough account of inform effective educational practice.

57.5 Characterising the Educational Research Project

In order to consider whether educational research is, is sometimes, or at least can be, a ‘sort of scientific research’, it is necessary to consider the nature of the work the educational researcher undertakes and to reflect on how and why this might be different from research in the natural sciences.

57.5.1 The Overall ‘Shape’ of a Discrete Research Study

The conceptualisation and development of an educational research project goes through two cycles during each of which there is a kind of expansion phase of exploring options and seeking sources of information, followed by a focusing (Taber 2013). Figure 57.1 uses the lemniscate as a visual metaphor to suggest that a study can be understood to ideally progress through three focal points (indicated on Fig. 57.1):

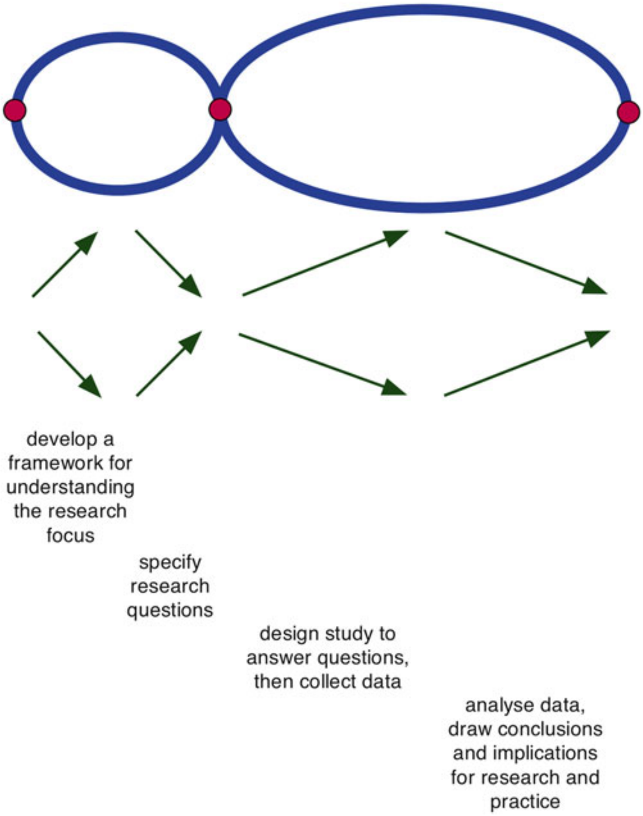

Fig. 57.1 The research process as involving successive phases of expansive and focused thinking

the initial concern or interest, the specific research questions (RQs) and the conclusions. This model assumes, for the moment, that research is largely conceptualised on a study-by-study basis, which is clearly a major simplification (Lakatos 1970).

The origin of the project is some kind of concern, issue or other focus that is seen worth investigating. The first cycle (see below) involves a process of developing the conceptual framework for the study – exploring relevant literature and reviewing previous research that may be pertinent – 'setting the scene' as it were for the new study. That is a phase that can be seen as supported by divergent thinking: allowing the recognition of relevance and forming links across diverse literature. This is followed by the framing of the particular RQ for the study. This latter step involves a focusing in on the specifics of the research (a more convergent process) and setting out how variables and constructs will be understood. Reaching this point will involve identifying any axiological commitments, the values that inform why we do research and so how we should conduct ourselves as researchers, as well as the ontological nature of what is to be researched, and so the epistemological constraints and affordances which will inform the kind of knowledge that it is possible to develop about what we are interested in.

The second 'cycle' of the project (Fig. 57.1) involves another expansive stage, where a research design is developed which can facilitate the answering of the RQ, followed by the collection of data to build up the evidence base needed to answer the RQ. This is followed by a further convergent phase where analysis 'reduces' data to results and leads to conclusions. The overall process therefore calls upon both divergent and convergent thinking: both creative and logical thought (Taber 2011).

57.5.2 *Owning the Research Problem in Science and in Science Education*

Formalising the process in these terms is often important in educational research because of the nature of existing literature. This reflects a difference between the common experiences of new researchers in education and those in natural sciences. A new doctoral student in one of the natural sciences will commonly be set a problem that is part of an ongoing programme within a wider research team in the laboratory and the process of identifying the relevant literature, and so conceptualising the 'gap' in existing knowledge the study is intended to 'fill' may be relatively straightforward. Indeed, it may be quite clear which techniques are to be adopted (perhaps those for which the lab is equipped with specialised apparatus) and how data will need to be analysed to produce knowledge claims acceptable to those working in the relevant field of science.

Arguably, the novice scientific researcher may be scaffolded to such an extent that they are only primarily responsible for the data collection and analysis stages, and much of the decision-making that leads up to this is largely channelled by the induction into an established way of understanding the ontology and epistemology adopted in that subfield of science. This would suggest that much of the thinking which informs such decision-making for a new researcher in education is in effect short circuited in the natural sciences. This is in line with the picture of 'normal' science (see above), described by Kuhn (1996), where the new scientist is inducted into the disciplinary matrix of the field by working through the standard paradigms. The result may often be someone who is very informed about the standard thinking and techniques in a specialised field, whilst having a much more limited knowledge of other fields within the broader discipline.

Yet the experience of a new doctoral student in education may be quite different in a number of ways. Whilst science education is now sufficiently theorised and staffed with expertise to support the natural science model outlined above, it is more likely that the research student will have greater latitude in selecting their project (if only because the apparatuses of research are less specialised and so less likely to be a constraint), and indeed within education the process of developing the project is seen as a key part of the education and training of the researcher. Moreover, whilst it remains important that doctoral supervision provides specialist support in learning about the topic area and acquiring specific skills, the student may find no single clear picture of the research area in the literature that allows an obvious conceptualisation of a 'gap' in the knowledge or a single sensible approach to an issue or problem. The state of knowledge in many educational topics would not fit Kuhn's notion of normal science, with its paradigmatic norms.

Where Kuhn suggests that the primary mode of thinking in normal science is convergent, this is often less true in educational research. Rather than being expected to 'plug' a specific 'hole' assigned by a supervisor, the educational research student is often expected to demonstrate extensive divergent thinking in accessing, evaluating and choosing between alternative potential ways of conceptualising their problem area. Within this context for undertaking research, the transition from an initial topic or issue of interest to the formation of specific RQ normally involves wide reading around a topic to appreciate and consider a range of possible ways of conceptualising the field, perhaps each based upon understanding the topic in quite distinct ways, and so suggesting different notions of how best to enquire into the subject. It is seen as the part of the student's task to develop a conceptualisation of the field and the justification for adopting (and if necessary adapting) a particular theoretical perspective (see below) for supporting the research. To caricature, the educational researcher 'owns' the research problem not because it has been 'given' (assigned) to them by the supervisor or lab director, but because they have 'built' (developed, discovered, constructed) it themselves.

Moreover, because of the lack of a clear disciplinary matrix that sets out particular tools for thinking about and doing research in the field, the research student is expected to learn about a wide range of methodologies so as to be able to comprehend and apply critical judgement to reading literature around the research topic, as it is quite likely that relevant knowledge claims in research journals will derive from a range of data collection and analytical techniques, potentially drawing upon very different (ontological and epistemological) assumptions informing different researchers' work.

The RQs themselves act as the point of transition in the flow of the study (see Fig. 57.1), and just as the RQs should reflect the thinking that has informed their formulation, they should themselves be reflected in what is to follow. A research design must address the RQs and be compatible with ontological assumptions informing the study (in terms of the nature of what is being studied) and epistemological considerations in terms of what it is reasonable to expect to be able to know about that kind of research focus. A methodology should therefore be selected (see below) which is suitable to answer the RQ, taking into account the presumed ontology of what is being studied and the kind of knowledge considered viable for such a focus; and data collection and analysis techniques are then selected which are coherent with that methodology. Data is collected (another 'expansive' stage, see Fig. 57.1) and then analysed to produce findings/results (another phase of concentration and reduction, see Fig. 57.1), developing a logical case for making new knowledge claims.

57.6 Conceptualising the Research Project

Discussions of educational research often make references to such notions as the 'theoretical perspectives' and 'conceptual frameworks' supporting particular research studies. The way these terms are understood, and will be used, in the present chapter (as unfortunately different authors do not always use a common terminology – see the comments below about phenomenography) is represented in Fig. 57.2. As well as 'theoretical perspective' and 'conceptual framework', this figure also includes three other key terms: 'research questions' (as discussed above), 'research design' and 'methodology'.

RQs are the specific questions that a research study is intended to address. These may take the form of a formal hypothesis, but in educational studies, they may instead be much more open ended, and the degree of openness will often depend upon the current state of knowledge in the topic area (as will be discussed further below).

The RQs for a particular study derive from a conceptualisation of the topic area that sets out what is already known and what is not yet known and might be worth finding out. The wording here, 'what is already known', is not intended to suggest absolute knowledge, but rather the set of knowledge claims currently considered robustly supported, and so suitable for taking as a starting point for further research. This conceptualisation, the 'conceptual framework' of a study, is often formalised in the literature review of a research report. The RQs are addressed through a 'research design' that sets out how the required data are to be collected, and how they will be analysed so as to answer the RQ. The essential logic of a research 'design' is such that it should in principle be prepared ahead of the empirical work taking place, and indeed doctoral students are commonly expected to have their research designs scrutinised and approved before commencing their 'fieldwork'. However, as in the natural sciences, research may involve false starts and

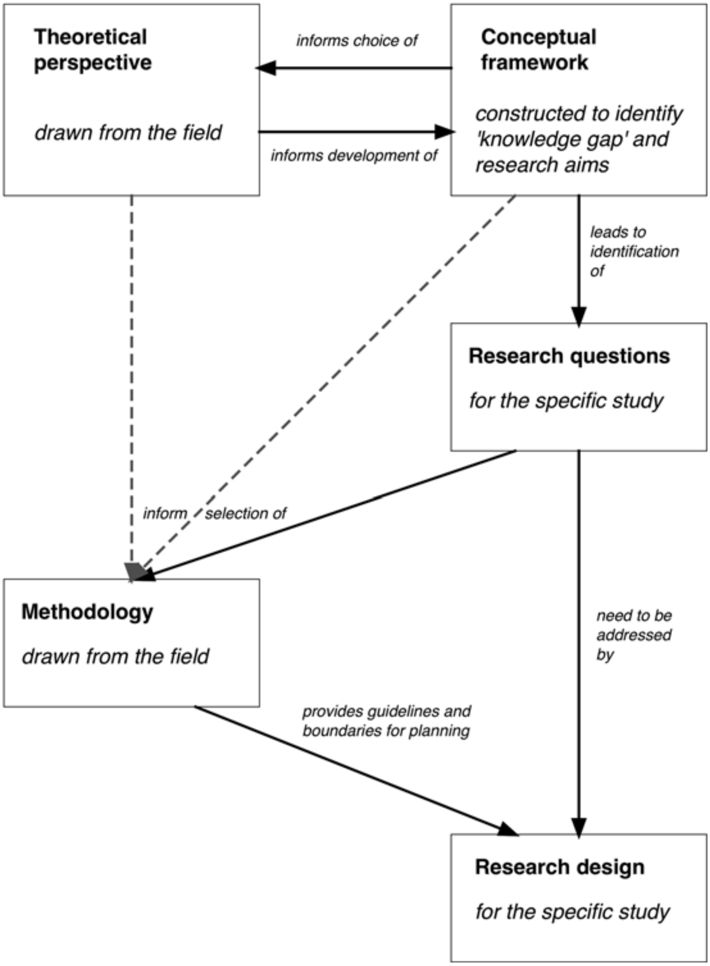

Fig. 57.2 Some key terms used to describe educational research

unproductive 'cul-de-sacs', and the design reported in published reports (and theses submitted for examination) may well – as in the natural sciences (Medawar 1963/1990) – be a rational reconstruction, in the light of experience, of what eventually 'worked'.

In some forms of educational research, the research design might be synonymous with 'experimental design', but, as is discussed below, many educational research designs are not based on experimental methods. Moreover, some research designs are 'emergent' which means that only the initial stages of data collection are firmly established before the research begins, as further detail of the research design will be informed by ongoing data collection. This is a somewhat different issue to the previous point regarding false starts (where a pre-planned approach that it was anticipated would be suitable for answering RQ is later found to be unproductive), as with an emergent design it is recognised in advance that an iterative process will be needed to refine the design.

In a grounded theory study, for example, it would be inappropriate and counterproductive to fully specify the data collection for the entire study in advance (as will be seen from the description later in the chapter, that would undermine the logic of the methodology), whereas in an experiment, it is important to specify data collection and analysis carefully in advance – although the specification that is reported in a formal account may well have been preceded by earlier versions that were abandoned as the research was developed.

Not reporting the outcome of experimental studies because those outcomes are not welcome is unethical, but not reporting studies because they are judged to have methodological failures that undermine the credibility of the results is quite appropriate (and indeed journal referees may well judge studies in these terms even when the researchers consider the procedures employed adequate). Ultimately, it is the researcher's judgement (and so their professional integrity) that has to be relied upon to discriminate between results that go unreported because they are not robustly supported and results that are robust but do not support conclusions the researcher hoped to draw. This issue is familiar enough from work in the natural sciences (Polanyi 1962/1969).

The process of shifting from a conceptual framework to specific RQ and then to a research design is clearly familiar from the natural sciences, although there it is more likely (although not always the case) that research design will imply experimental design and that research designs will be specified in detail (precisely which data to collect, precisely how it will be analysed) before any data collection begins. The argument offered in this chapter is that there are necessary (essential) differences between educational research and research in the natural sciences; but that this need not exclude research in science education from being considered 'scientific'. In particular, the process of designing and justifying research is likely in science education, more (or more often) than natural science, to require *explicit* consideration of ontological, axiological and epistemological considerations.

57.6.1 Theoretical Perspectives

Educational phenomena, teaching and learning and the social institutions intended to support teaching, can (as Shulman 1986 recognised) be very complex, and there are often alternative ways of approaching the conceptualisation of a particular research focus (such as student learning about some science topic). Discussions of educational research often make references to the 'theoretical perspective' informing a study, as something other than the 'conceptual framework' underpinning the study.

Theoretical perspectives can be thought of as well-developed theoretical positions about some aspects of a social or educational phenomenon that can act as starting points for making sense of research topics. An important point is that in science education, there is no 1:1 correspondence between theoretical perspective and

By contrast, the oxygen theory competed with the phlogiston theory to occupy the same explanatory space – of why combustion sometimes (but not always) occurs.

Similarly, descent with modification through natural selection (Darwin 1859/1968), and the notion that organisms are members of a species because of some essence (Mayr 1987) competed (and indeed for some still compete) in the 'explanatory space' for explaining how living things on earth appear to fit into a number of specific types that (although very large) is tiny compared with the number of individual organisms on earth. Theodosius Dobzhansky (1935, p. 345) enquired whether the notion of a species was 'a purely artificial device employed for making the bewildering diversity of living beings intelligible, or corresponds to something tangible in the outside world…[that is, is] the species a part of the 'order of nature', or a part of the order-loving mind?' Indeed, it has been argued that the tendency to retain elements of essentialism long after the general tenets of Darwinian evolution were widely accepted has been a major problem in biology (Hull 1965), amounting to the kind of obstacle to scientific progress discussed by Bachelard (1940/1968).

These examples from the natural sciences give some sense of how theoretical perspectives might be drawn upon in particular research contexts. At first sight, a difference between research in the natural sciences and research in science education is that in education it may not always be so clear whether alternative theoretical perspectives are competing or potentially complementary. This difference reflects the complexity of educational phenomena (discussed further below) and is brought into focus because of the use above of historical examples from the natural science (combustion, particle theory, the origin of species) where we are judging the issue with the benefit of many decades of 'hindsight'.

A wide range of theoretical perspectives have been drawn upon in research in science education, but some illustrative examples would be the following:

Exploring college students' thinking related to the concept of field drawing upon a particular theoretical perspective of the main types of mental representations people use (Greca and Moreira 1997)

Exploring teaching and learning of cell biology in upper secondary school and drawing upon a theoretical perspective based on general system theory (Verhoeff et al. 2008)

Exploring the value of a sociocultural theoretical perspective in thinking about the learning that can occur when people visit science and technology centres (Davidsson and Jakobsson 2008)

57.7 Competing Theoretical Perspectives in Science Education

Space here only allows limited exemplification, but an example of where different theoretical perspectives have competed in science education concerns research into student thinking, understanding and learning in science. Two examples here concern flavours of 'personal constructivism' and the relationship between personal constructivism and sociocultural perspectives on learning.

A very influential theoretical perspective from developmental psychology that informed work in science education was that due to Jean Piaget and his ‘genetic epistemology’ (Piaget 1970/1972). Within that programme of work, Piaget developed a stage theory of cognitive development which saw particular domain general structures of thought as associated with different developmental stages and which put limits on the kind of learning possible for students at each stage (Piaget 1929/1973). Although details of the Piagetian scheme, and how it is understood to relate to education, have faced criticism (Donaldson 1978; Sutherland 1992), this has been a very influential perspective in science education (Bliss 1993, 1995). In particular, Piaget’s work with its focus on structures posited in mind (Gardner 1973) contrasted with work informed by the highly influential behaviourist school (largely in the United States) that had eschewed explanations relying upon non-observable constructs such as states of mind (Watson 1924/1998, 1967).

However, in the 1970s, an alternative perspective was developed in science education that focused less on general structures of thought (the complexity of thinking available to learners) and more on their particular meaning making in different scientific topics, leading eventually to an extensive research effort (Driver et al. 1994; Duit 2009). This research explored students’ own ways of thinking and talking about various natural phenomena and scientific topics, such as force, plant nutrition and heat. The aim here was less to characterise student thinking at particular levels, but to allow teachers to be aware of typical conceptions students brought to (and/or took away from) lessons, and to think about how to support students in developing understanding of the scientific models that were reflected in the school or college curriculum. This work was sometimes labelled as the alternative conceptions movement (ACM).

Both of these perspectives can be understood to be personal constructivist approaches, focused on how the individual comes to iteratively build up personal knowledge in the form of internal representations of the world (as directly experienced and as heard about second hand), but with rather different foci: one domain general (so learning in any topic is constrained by the general stage of development) and one very much on a topic-by-topic basis (where familiarity with a particular domain can lead to areas of relative expertise).

These two perspectives can certainly be seen to have competed for research attention and resources, although arguably they did not compete for the same explanatory space as they focused primarily on rather different aspects of science learning. That the ACM came to dominance within science education – although an important strand of research to inform teaching from the Piagetian perspective continued (Adey 1999) – probably said less about the perceived *validity* of the Piagetian perspective than the greater perceived *fruitfulness* of the ACM for actually informing teaching. It might also be tentatively suggested that the ACM was attractive to many of those setting out on research in science education because the terminology of early work (often conceptualised as being about identifying misconceptions) was more accessible than the rather specialised and perhaps seemingly esoteric language that had been developed within the Piagetian programme. That is not to suggest that the ACM was under-theorised, as that was not so (Driver and Erickson 1983; Gilbert and Watts 1983; Osborne and Wittrock 1985). However, as a research programme developed from within education (rather than the developmental psychology base of the Piagetian work), there was always a strong impetus to report work in terms that would make sense to classroom teachers.

More recently, much discussion and some contention in science education has been focused around the question of whether the adoption of a social constructivist perspective (Roth and Tobin 2006; Smardon 2009) should be seen as complementary to, or a potential replacement for, a personal constructivist perspective. That is, does the acknowledgement of the importance of social interaction in learning (directly through dialogue or indirectly through institutions and cultural artefacts) imply that considering learning as the personal sense making of individuals in order to construct personal knowledge in the form of mental models associated with the minds of individuals (and represented in the physical substrate of that individual's brain) is invalid (or at least, unproductive)? One view would be that the personal constructivist perspective adopts notions of knowing and knowledge that are no longer viable in terms of what is commonly claimed about how learning needs to be understood as socially situated, and how knowledge-in-action depends upon social context (Hennessy 1993).

However, from within the personal constructivist perspective, it can be argued that learning is a very complex phenomenon and that a sensible simplification for many purposes is to understand learning as due to processes that occur within the cognitive system of an individual learner who perceives their environment (in which other people and the signs of culture may be highly salient and relevant to learning); constructs internal models of it, and then acts according to the perceived reality provided by those models (acts that include making public representations of personal knowledge that can be perceived by others); and, where it seems appropriate, adjusts the internal models as indicated by feedback from the environment (including the public reactions of others to that behaviour). It is possible to adopt a more synthetic 'complementary' view of personal and social constructivism as useful perspectives that can both contribute to progressing science education (Taber 2009b): but this is by no means a consensus view in the community.[1]

---

[1] Just as there is a vast literature drawing upon and adopting (labels if not always principles) of constructivism, there has been a range of criticisms of constructivist work in science education. These include criticisms of constructivist approaches that seem to support relativist stances on scientific knowledge (Coll and Taylor 2001; Cromer 1997; Matthews 1993, 1994/2014; Scerri 2003), suggestions that constructivist teaching approaches undermine traditional ecological knowledge in indigenous communities (Bowers 2007), the theoretical basis of constructivism in education (Matthews 2002), the level of empirical support for knowledge claims (Claxton 1993; Kuiper 1994; Solomon 1992), inappropriate focus on individuals (Coll and Taylor 2001; Solomon 1987, 1993b), limited linkage between result findings and implications for teaching (Harlen 1999; Johnstone 2000; Millar 1989; Solomon 1993a), associations with unstructured 'discovery' learning approaches (Cromer 1997; Matthews 2002) and diversion of resources from more productive areas of research (Johnstone 2000; Solomon 1994). An account of these criticisms and possible rebuttals is offered elsewhere (Taber 2009b). Some of these issues reflect a wider debate in education about the nature and relative merits of constructivist and enquiry-based teaching compared with other pedagogies – especially what has been labelled as 'direct instruction' (Kirschner et al. 2006; Klahr 2010; Taber 2010a, b; Tobias and Duffy 2009).

57.8 Selecting a Methodology for a Study

The term ‘methodology’ when used to describe research in education – or the social sciences more widely – is distinguished from ‘methods’, which generally means the specific ‘techniques’ used to collect and analyse data. Methodologies are considered to be broader: to be principled approaches to undertaking research that can provide a framework for selecting particular component techniques. A simple analogy here is that methodology refers to an overall strategy to achieve research aims, within which specific tactics (techniques) may be employed to meet particular subgoals (Taber 2007).

Although one might refer to the specific methodology used in a particular study, methodologies tend to be considered as general-purpose approaches that can be selected according to the nature of the RQ being addressed (as suggested by the analogy with pedagogy and pedagogies above). One common methodology would be the experiment, but educational research commonly also draws on a range of other methodologies such as survey, case study, ethnography and grounded theory. It is worth reflecting briefly on the core characteristics of these common methodologies.

Experiment: The experimental ‘method’ is taken from work in the natural sciences and is used to test a hypothesis by controlling variables to compare two sets of conditions that differ in one accord. In practice, true experiments are seldom possible in education, for reasons discussed later in this chapter.

Survey: A survey is used to find out about the level of association of one type of element with a different type of element. So, for example, a survey could be used to find how many fume cupboards school science laboratories are typically equipped with (i.e. reporting the proportion of such laboratories having no fume cupboard, one fume cupboard, etc.). Commonly surveys are used to seek self-report information from people regarding such matters as their attitudes or behaviours. Surveys may be used to test hypotheses by comparing responses to different survey items – e.g. one could test the hypothesis that a higher proportion of male science teachers than female science teachers expect to be promoted to head of department.

Surveys may be applied within limited populations (e.g. the students in one school), but are commonly used in relation to larger populations (e.g. secondary chemistry teachers in a national context) using sampling techniques and inferential statistics to make inferences about the populations sampled. A survey that all, or nearly all, science teachers responded to could tell us whether or not a higher proportion of male science teachers than female science teachers expect to be promoted to head of department; but in practice a representative sample of modest size is likely to be sought from which inferences can be drawn about the broader population.

Case study is a methodology used to explore a particular instance in detail (Stake 2000; Yin 2003). The instance has to be identifiable as having clear boundaries and could be a lesson, the teaching of a scheme of work in a school department, assessment procedures in a university teaching department, a group visit to a museum by one class of students, etc. For example, Duit and colleagues (Duit et al. 1998) report a classroom episode where one group of students undertakes a discussion task relating to the magnetic pendulum. The authors of the report provide extensive context for making sense of the case in terms of the classroom and curriculum setting of the episode.

Although case study looks at an identifiable instance, it is normally naturalistic, exploring the case in its usual context, rather than attempting to set up a clinical setting – which would often not be viable even if considered useful, as often the case is embedded in its natural context in ways that influence its characteristics (so moving a teacher and a class from their normal setting to a special research classroom in a university, for example, is likely to change behaviours that would be exhibited in the 'natural' setting).

Sometimes (instrumental) cases are chosen because they are considered reasonably typical of a class of instances, where the complexity of what is being studied suggests that more can be learnt by detailed exploration of an instant than surveying a representative sample. Other (intrinsic) cases may be selected because they have been identified as special in some sense, and the researchers want to see if they can find out why: for example, why one teacher facilitates especially impressive learning outcomes.

Ethnography is an approach drawing upon anthropology, which attempts to make sense of a particular culture or group in its own terms, that is, to understand the meaning the individuals in that culture or group assign to certain rituals or cultural practices (Agar 2001; Hammersley and Atkinson 2007). Whilst ethnographies, that is, detailed accounts produced by ethnographic methodology, are relatively rare, if not excluded (Long 2011; Reiss 2000), in science education, studies which draw on ethnographic approaches and perspectives are quite common.

Grounded theory is a set of methods for developing theory using an inductive approach. Developed – or 'discovered' (Glaser and Strauss 1967) – in sociology, grounded theory is an approach which attempts to provide methods to assure scientific rigour when researchers attempt to understand social phenomena and existing conceptual frameworks are considered inadequate. Grounded theory relies on a number of core principles (Taber 2000), including emergent research designs that build upon 'theoretical sampling' (i.e. using the analysis of initial data to inform decisions about the next steps in data collection), 'constant comparison' (an iterative approach to analysis that requires repeated revising of data coding intended to ensure analysis that provides best fit to all the data) and 'theoretical saturation' (i.e. only ceasing data collection when further data adds nothing substantive to the theory being developed).

As this suggests, the complete grounded theory methodology is very demanding and is only viable when researchers are not under strict time pressures to complete a study. Despite this, grounded theory is commonly cited as a referent in educational studies, although often in practice such studies adopt the constant comparison method without substantive theoretical sampling or reaching theoretical saturation.

57.8.1 Other Candidates for Methodology

Sometimes *phenomenography* is considered a distinct methodology, although it is alternatively considered rather to be a particular perspective (e.g. Koballa et al. 2000), an analytical framework (Ebenezer and Erickson 1996) or even a field of enquiry (Marton 1981). Phenomenography seeks to describe, explore and characterise people's experiences.

Approaches such as lesson study and design research may also be considered as methodologies. In lesson study (Allen et al. 2004), an approach to curriculum development that has been especially popular in Japan, a group of teachers work together to plan a lesson, which is then taught by one of the group and observed by others. This allows the lesson plan to be revised, before another member of the group teaches the revised lesson, allowing a further 'trial' and opportunity for further refinement.

Whilst such approaches might seem to be more about 'development' than 'pure' research, if educational research is intended to improve teaching, then such approaches certainly cannot be excluded from consideration. Some commentators on educational research see a major distinction between 'pure' and 'applied' research (Springer 2010), but arguably all 'educational' research (as opposed to, say, psychological research into learning) should potentially have at least distal implications for informing educational activity, and the pure/applied division is not an especially helpful distinction. Arguably this presents a difference between research in science and research in education: perhaps because work exploring educational phenomena that could be considered as 'pure' would be likely to be considered not as educational research but as research in another area such as educational psychology or sociology undertaken within educational contexts. Certainly if we adopt the steer offered by Pring (2000, p. 27), then educational research is always in principle 'applied' research.

Rather, a more significant issue raised here is the role and nature of theory in research and the extent to which curriculum development and lesson design need to be seen as idiographic activities specific to the particular subject matter, curriculum setting, institution and cultural contexts, of teaching and learning. This is an issue where the science education community has not reached a strong consensus (Kortland and Klaassen 2010; Tiberghien 2012). There is an argument that the complexity of teaching and learning is such that iterative processes (such as that used in lesson study) are needed within teaching and should be institutionalised within the profession to make it a 'design science' (Laurillard 2012).

This leads to consider another methodology that is often cited in educational research, i.e. '*action research*' (McNiff 1992). Like many of the descriptors used in discussing education research, action research is understood differently by different authors, but usually means research that is carried out by practitioners to address a problem or issues in their own practice. A key feature of action research is its cyclic nature, with the practitioner-researcher implementing and evaluating an innovation intended to address the concern and then modifying the innovation as indicated by the evaluation. There is then a similarity between the action research cycle and the learning cycle (Marek 2009). The focus of action research is meant to be the improvement of the practical situation, rather than the development of generalisable theoretical knowledge, and so action research often lacks detailed documentation and formal reporting.

That said, published studies are sometimes said to be examples of action research, although generally to be considered worthy of publication, such studies are expected to demonstrate both a level of documentation, and a robustness of argument for knowledge claims, outside the typical characterisation of action research. That is, the logic of action research is that at the end of each cycle, decisions about the next cycle of action are based upon judgements 'on the balance of probability' rather than waiting to accumulate sufficient evidence to support formal knowledge claims that would be robust enough for presentation in an academic research journal.

Arguably, action research is less a methodology as such than a mode of research that is context directed, where the focus is on improving practice within a specific context, rather than developing abstract, generalisable, theoretical knowledge. This is in contrast to academic research that is theory directed, but which might collect data in a limited specific context as a methodological choice (e.g., if a case study seems most appropriate to answer RQ). From this perspective, true (context-directed) action research is unlikely to provide the basis for academic research reports, but there is no 'in principle' reason why *practitioner* research cannot contribute to the academic research literature as long as it is suitably theory directed and not exclusively concerned with addressing an immediate issue embedded within the practice context. Such practitioner research would need to apply suitable methodology to support theory-directed work (i.e. action research per se would not be such a methodology), but could still be initially motivated by a local problem or issue and may well contribute to improving practice, as well as offering a more generalisable contribution. There is therefore a good reason to avoid conflating action research with practitioner research more generally.

The methodologies described here do not exhaust the methodologies claimed in research papers. As well as variations, refined and hybrid versions of the above methodologies, there are also references to quite different methodologies. However, what counts as a distinct methodology is open to debate. It could be argued, for example, that so-called feminist methodologies, such as the feminist ethnography used in a paper reported in *Science Education* (Basu 2008), are conflating a methodology (in this case ethnography) with a theoretical perspective (here, feminism) that is informing both the choice of that methodology and how research is designed based on that strategy (cf. Fig. 57.2). A counter argument would be that the more specific feminist methodology is distinct because it is informed by a particular value position (in this case 'the importance of research having benefit for research participants and their immediate community', p. 256). Whether or not feminist ethnography should be considered a distinct methodology in its own right, ultimately what is important is that methodological choices are carefully explained and justified, and as long as that is so, readers can draw their own conclusions about the worth of knowledge claims made, and the particular labels used as descriptors are secondary.

However, this example raises the important point that methodological decisions in educational research are informed by axiological as well as ontological and epistemological considerations.

57.9 Ethical Considerations and Their Methodological Consequences

All researchers should be informed by professional standards of ethics. In the natural sciences, a focus on research ethics often concerns such issues as not inventing data, not selecting results for reporting based on their level of agreement with preferred ideas and giving full acknowledgement to the work of others. These considerations also apply in educational research, of course, but there are additional ethical complications in educational work that do not tend to arise in most research in natural science. Often these issues are significant enough that methodological considerations may need to be compromised because of the ethical imperative.

57.9.1 The Good

Researchers tend to feel that research is inherently a good thing because it produces knowledge, which allows us a better understanding of some aspect of the world, and so can inform our choices. Even in the natural sciences, such a view might be challenged. Science provided knowledge to allow the development of explosives used in war as well as in engineering applications, poisons used in Nazi gas chambers and the atomic bombs dropped on Hiroshima and Nagasaki. If such applications are considered inherently evil (and few would dispute that at least in the case of the gas chambers used as instruments of genocide), then questions may be raised about the wisdom of the science that provided the technology. However, there is a common argument that knowledge in itself cannot be evil, as it can only inform human actions, where there is a moral choice to be made in how to apply such knowledge.

57.9.2 Costs and Benefits of Research

In areas such as medical science, there may be questions about the costs of the knowledge produced by research. Sometimes new treatments and procedures do more harm than good (as was the case with the use of thalidomide, which led to thousands of serious birth defects): but the medical profession is bound by an imperative to do no harm and so puts in place various safeguards to avoid harming participants in studies. Sometimes there is a recognised substantial risk, and a participant may choose to take that risk in the hope of a possible benefit. In such a situation the notion of informed consent becomes very important: that the person agrees to take the risk based on an understanding of the available knowledge about possible risks and likely benefits of participation. Sometimes participation is altruistic in the sense that the participant may be aware that there is likely to be minimal benefit personally, but that knowledge obtained may contribute to developing treatments to benefit hypothetical others at some future time.

57.9.3 Informed Consent

The medical research scenario offers a strong parallel to the situation regarding much educational research. Educational research may be carried out primarily to develop theories that might be applicable at some point in the future, and such research may potentially inconvenience teachers, learners and others who are asked to contribute through their participation now. We might hope that people would welcome a chance to contribute to the development of educational knowledge through participation in studies, but a researcher cannot require or expect this. Therefore informed consent must be obtained from participants, and the wishes of those potential participants who decline involvement must be respected, regardless of the basis of their decisions, even if this weakens or undermines a research design – such as an experimental design.

There are clearly complications with obtaining informed consent that relate to the ability of – especially young – children to understand what they are being asked to give consent to; regarding when parents as well as learners need to give consent; and about when teachers, acting in *loco parentis*, are able to give consent on behalf of students. Teachers, head teachers (or school principals), area education officers and government ministers may act as ‘gatekeepers’ who decide whether a proposed study can be carried out in particular classrooms and schools. They may well reject requests for research that is judged to have potential for undermining normal order and procedures.

Innovations that seem promising to researchers may be judged to make too heavy demands on potential participants; and even quite straightforward procedures such as administering simple questionnaires to classes may be considered unwelcome by busy teachers. This is often likely to lead to researchers compromising research design based on what might realistically be granted when permission is sought. Experimental designs that look to compare two different teaching and learning conditions can often apply inferential statistics, providing that the learners are randomly assigned to conditions. However, in practice, researchers are usually restricted to working with intact classes, where, at best, whole classes can be randomly assigned to treatments – a much weaker design. Indeed, sometimes the choice of the ‘treatment’ and ‘comparison’ groups depends upon which teacher is prepared to adopt some innovative practice, immediately suggesting that teacher characteristic may well be a confounding factor.

A particular issue that arises is that where some potential participants decline to be involved in a project, this may well bias any attempt at sampling. If a study seeks a representative sample and reasons for granting or declining consent link to the issues being researched, then the final sample may well be skewed.

57.9.4 Openness and Confidentiality

Another key issue that may lead to methodological compromises is the need to respect participants' desire for anonymity in research. Generally, it is considered appropriate to assure potential research participants that their data – and it has been argued that the data is *theirs* to gift to the researcher (Limerick et al. 1996) – will be kept confidential within the research team and that any reports will be written such that individuals (and often institutions) cannot be identified. This is more readily assured in some types of research than others. So reporting detailed case studies, where the expectation is to provide 'thick description' to support reader generalisation (i.e. where the reader makes a judgement about how well the reported context is similar to their own professional context), may be difficult without giving away information that would allow informants to be identified.

Indeed there are examples of research in the science education literature where the published details seem to make it very unlikely more than one person could match the description (see examples disucssed in Taber 2013). Sometimes it is suggested that it is appropriate for researchers to deliberately change some biographical or other details to assure anonymity of participants – but this clearly means providing a report which is known to be false in certain regards and puts the onus on the researchers to know what details can be changed without undermining the authenticity of the published account.

57.9.5 Member Checking and Rights to Withdraw

A further complication of respecting the rights of individuals involved in educational research is that it is often suggested that a participant should have the right to withdraw from a study *at any stage*: 'researchers must recognize the right of any participant to withdraw from the research for any or no reason, and at any time, and they must inform them of this right' (British Educational Research Association 2011, p. 6). This can clearly undermine research designs. In longitudinal studies, it is quite common to experience attrition as participants leave the study for various reasons, and this might modify the balance of participants sampled if decisions to continue participation or withdraw may be linked to issues being explored. To some extent, this might be accommodated by building-in redundancy through enrolling more participants than are required for what is considered likely to be a sufficient data set – but that may well require additional resources.

In an interview study, for example, it is normal to advise participants that they may stop the interview at any time or decline to answer any particular questions. If a sequence of interviews are planned, the participant is invited to continue their participation on each occasion, i.e. the researcher cannot expect them to abide by commitments perhaps made months before. It is commonly also suggested that whilst a study is in progress, participants should not only have the right to decline further participation at any point but also have the right to withdraw any data they have provided *earlier* in the study.

A related point concerns the right to comment on material written about a participant. In some forms of research, particularly interpretive studies claiming to report on the views, ideas and opinions of others, it is recommended that the participants should be invited to read, and comment on, any draft reports relating to their own cases – this is known as member checking. In itself this is as much a methodological as ethical safeguard, as it gives participants the chance to check the researchers' interpretations of their inputs are valid. Any feedback received from such 'member checking' should be treated as additional data that needs to be considered in drawing conclusions. Clearly at this point, there might be potential for a participant to request particular changes (if perhaps they feel their comments are not presented in a favourable light) and seek to withdraw their data from the study otherwise. This has potential to undermine the integrity of a study.

There are clearly circumstances where member checking has less value methodologically. One case would be where students' thinking is analysed in relation to canonical scientific thinking, where it is likely that a student holding an alternative conceptual framework may not be in a strong position to confirm or otherwise the worth of the analysis. In such research, there are techniques that can be adopted as part of interview procedures to ensure the validity of the interpretations being made by researchers during data collection (although it should be noted that further insight into students' thinking may emerge later during analysis): confirming responses by repeating or rephrasing questions; clarifying ideas by asking follow-up questions; paraphrasing what one believes to be the learner's argument, and seeking confirmation; returning to the same point in the same context later in the interview, to see if a consistent response is given by the learner; and approaching the same point through a different context later in the interview, to see if the learner gives consistent responses in the different contexts (Taber 1993). Member checking may also be of limited value in studies looking at shifts in participants' opinions, as participants may not retain a clear and accurate recollection of their earlier stances once their thinking has moved on.

57.9.6 Particular Challenges of Teacher Research

Ethical issues may become especially problematic for teachers and lecturers undertaking research with their own classes (and colleagues). There are a number of complications here compared with research carried out by 'external' researchers.

For one thing, the usual ‘gatekeepers’ who normally need to approve a study before researchers approach students about being potential participants can be bypassed. A second issue concerns obtaining informed consent, as students could feel that they are obliged to help their teacher who will often have a role in writing reports on them or grading their work (Taber 2002). Although the teacher may not seek coercion, safeguards are needed to assure students that participation is entirely voluntary and that nonparticipation carries no penalty in regard of their study. Both of these issues can somewhat be countered by recruiting a suitable senior colleague to act as a nominated person to check on the procedures being employed and informing students that they may refer any concerns to that person.

A difficult issue is to decide when research goes beyond normal teaching practice. The fully professional teacher is expected to be research informed and able to develop their teaching through classroom research (Taber 2013). Teachers are expected to innovate and to collect data so that they know how effective their teaching is. An innovative teacher, trying out new ideas to improve their teaching and collecting classroom data to evaluate their work, would *not* expect to have to seek permission from the learners in the class (and/or their parents for younger learners) nor to offer opportunities for some class members to decline to be involved in any lesson activities based on innovative approaches. Yet, in effect, this kind of evidence-based teaching practice is a form of research. This is indeed an area where it may not be clear when classroom enquiry and innovation should be considered primarily research rather than just good teaching practice.

However, what is clear is that the science education research journals contain many examples of studies based upon data collected and analysed by teachers working with their own classes, where the impression given is that the purpose of data collection was research (rather than as a normal part of teaching) and where often there is no mention of how the research was presented to learners nor whether they were invited to contribute and given the choice to decline. That is, some of these studies are written as though the authors feel that they are entitled to set exercises to collect data without consideration of the way they are using their students as data sources. Perhaps the researchers in such studies did follow appropriate ethical procedures, but if so they did not feel the need to report they had done so.

Increasingly, journals are expecting authors to make a declaration on submitting studies to the effect that appropriate ethical guidelines have been followed: although this relies on the researchers having a good understanding of the issues involved. It is suggested here that there are useful criteria that can be used to decide when evaluations of teaching innovation, or other examples of teacher research, should be considered to need informed consent from students (see Table 57.1). These concern the nature of the activity used to collect data, the purpose of the data collection and the intended use of the results (Taber 2013).

So it is suggested that researchers should (i) seek explicit consent from students they would like to be involved in studies and (ii) acknowledge that informed consent was given in research reports, when the research (a) requires input from students outside of the normal classroom/curriculum schedule and/or (b) is ‘theory directed’ (i.e. looks to answer general questions, where learners involved stand for learners

Table 57.1 Determining when teacher research requires informed consent from learners

	Teacher research should be considered a part of normal classroom practice when	Teacher research requires informed consent from learners when
Activity	It involves normal teaching and learning (including assessment) activities carried out within normal curriculum time	It goes beyond the normal range of teaching and learning (including assessment) activities and/or occurs outside of normal scheduled curriculum time
Purpose	It is intended to help understand better an aspect of the professional context or solve problems arising within that context, i.e. knowledge is sought to inform educational practice in the institutional setting that will benefit the learners involved in the research	It is intended to answer general theoretical questions and support the development of abstract knowledge (i.e. the students' concerned are just a convenient sample considered to represent a broader population of learners)
Dissemination	Research results will inform the teacher-researcher and may be shared will departmental or other colleagues working in the same institutional setting	It is intended that research results will be submitted for publication or disseminated through websites, conferences, networks, etc. (N.b. this would apply to research undertaken for an academic award)

generally) rather than context directed (where the research is aimed at specific issues relating to the teaching and learning in the particular research context) and/or (c) is intended for reporting and dissemination beyond the institutional context where the research is undertaken.

Following these guidelines will protect learners from being treated as research fodder and will protect researchers from suspicion of unethical practice.

57.10 Selecting Techniques in Educational Research

There is not a simple correspondence between methodology and particular techniques, but there are some clear patterns. Experiments require some form of quantification. Surveys tend to involve the use of questionnaires and/or structured observations. Case studies tend to use a range of techniques, commonly including interviews, observation and document analysis.

Interviews can be used as data collection techniques in a range of methodologies, but the *type of* interview used may change from one methodology to another (and this is also true of observational techniques). So an interview in a study employing survey methodology is likely to employ a highly structured schedule of questions (in effect, an oral questionnaire) which the interviewer is not supposed to vary (i.e. to ensure comparability between respondents), whereas in an ethnographic study, interviewing is likely to be based around a much more flexible interview schedule that allows the interviewer to probe for the participants' understandings and perceptions and to use the interactive nature of conversation (Bruner 1987) as a means to check and refine the researcher's interpretations of what they are being told. In effect these types of interview are rather *different techniques*, informed by rather different assumptions about what is methodologically appropriate in a particular study (see below). In the survey interview, it is assumed that (in principle) the interviewer could be replaced by another trained interviewer without influencing the responses of participants. Such objectivity may be more difficult to achieve in an ethnographic study where the sensitivity of the researcher to nuances in responses is much more significant.

A research design should include the ways in which data will be analysed, as well as how they will be collected, and again particular ways of analysing data are linked with particular methodologies. So, for example, formal hypotheses tested through experimental or survey approaches require the deductive use of quantitative methods applying inferential statistics, whereas grounded theory employs the 'constant comparison' method of ensuring theory is developed from data by an inductive approach. In some methodologies, it is expected that triangulation (Oancea 2005) from different data sources, or even different data collection techniques, is used to ensure the 'trustworthiness' of research (Guba and Lincoln 2005). However, this is not considered necessary when research techniques are considered to unambiguously access ontologically clear research foci (as in a well-designed experiment).

Whilst Fig. 57.2 does not show any direct link from the theoretical perspective (or the conceptual framework) to a research design, it is intended to imply that an indirect influence occurs through the RQ. The formulation of RQ involves selecting terms and phrasing that reflect, and imply, particular meanings that have been developed through the formation of the conceptual framework, informed by the theoretical perspective identified as the starting point for building an understanding of a topic.

An interesting question is to what extent the process reflected in Fig. 57. 2 would be recognised as relevant to research in the natural sciences. It is argued in this chapter that *in principle* the same kinds of consideration that apply in educational research also apply in research in the natural sciences, but much more can be taken taken-for-granted within 'normal science'.

57.11 Typologies of Educational Research Methodologies

A key analytical tool used in characterising educational research is a description of several levels at which the research can be described. Commonly three or four levels are posited that shift from a consideration of philosophical commitments underpinning the research to identification of particular techniques to collect and analyse data. For example, one commonly cited model is that used by Crotty (1998), who describes social research at four levels: (i) epistemology, (ii) theoretical perspective, (iii) methodology and (iv) methods. As one example within this scheme, *a questionnaire* (method, i.e. technique) might be used to carry out *a survey* (methodology) from a *positivistic* theoretical perspective drawing upon *objectivist* epistemology.

This is only one of the schemes recommended in textbooks on social and educational research, because it is very difficult to find a common analytical framework that readily fits all different forms of research in education. A somewhat more simplistic model (Taber 2007, 2013) posits three basic levels of analysis understood as philosophical (the level commonly called paradigm in the social sciences), strategic (methodology) and tactical (techniques).

Crotty discusses three epistemologies: objectivism, constructionism and subjectivism – depending on whether meaning is considered to be *inherent in* an object, to *arise from interactions with* an object or to be *imposed upon* an object by a subject. Often in accounts of research such as Crotty's, the impression is given to novice researchers that they are expected to adopt one of these epistemological perspectives as a way of understanding the world. Yet this would seem to imply seeing the world as comprised of objects that at some fundamental level are of the same basic nature, at least in terms of what we might aspire to know about them. Such a perspective may be contrasted with pragmatism (Biesta and Burbules 2003), which is unfortunately (and inappropriately) sometimes presented as having little time for philosophical issues, but rather simply looking for tools to do particular (research) jobs.

Neither the adoption of a blanket epistemology nor of a naive pragmatism offers a justifiable approach for educational researchers when considering methodologies to adopt for particular purposes. The position taken here is that the extent to which researchers can both (a) clarify the ontological status of foci of research; and (b) directly and unambiguously access the foci of research; varies considerably in educational work, and therefore the selection of epistemology must reflect the needs of a particular study. So, for example, it does not make sense to consider that the same assumptions will support research into the provision of Bunsen burners equipping school laboratories, student attitudes to practical work and teacher understandings of socioscientific issues.

57.11.1 Qualitative Versus Quantitative

In a book on research design, Creswell (1994) suggested that once a focus for a study was established, the next step was the choice of paradigm, and he presented two options: the quantitative (or positivist, experimental or empiricist) paradigm and the qualitative (or constructivist or naturalist) paradigm. According to Creswell, particular methodologies (or as he called them methods) were appropriate for each of these paradigms (Table 57.2).

The reference to paradigms here reflects the adoption of the term in the social sciences after the widespread influence of Thomas Kuhn's work (considered above).

Table 57.2 A typology of research methodologies, after Creswell

Quantitative methodologies	Qualitative methodologies
Experiments	Ethnographies
Surveys	Grounded theory
	Case study
	Phenomenological studies

The identification of a paradigm which is considered positivist, experimental or empiricist might seem to some to imply a more 'scientific' paradigm. However, in the present chapter, it is argued rather that a scientific approach involves a choice of methodology that is consistent with the aims of the particular study.

A major problem with the Creswell classification is the prominent use of the terms 'quantitative' and 'qualitative' as major labels, as these terms have come to be used in very different ways in educational research. One common way in which the terms quantitative research and qualitative research are understood is in terms of the type of data being collected and analysed. Certainly there is an important difference between quantitative *data*, which is suitable for certain types of analysis, and qualitative *data*, which needs to be treated with different analytical approaches.

However, even that distinction is not absolute, because there is a spectrum of approaches to the analysis of qualitative data (Robson 2002). So, for example, it may well be that interview transcripts, providing text (qualitative data), may be analysed by counting specific words or phrases to test some hypotheses (i.e. quantitative analysis). It is also common for qualitative data to be initially analysed using interpretive approaches (qualitative analysis), leading to the assignment of coding which then leads to counts of the frequencies of certain codes, which could be the basis of either descriptive statistics or, again, hypothesis testing.

However, in other studies, qualitative data may be treated in much more thematic and narrative ways, with no frequency counts or other quantification. So even when we restrict our focus to data, the quantitative-qualitative distinction is of limited value once we shift beyond the description of the data itself to its analysis. Moreover, if the focus is on the nature of the data itself, then it makes little sense to align methodologies such as case study and grounded theory, which may commonly employ both qualitative *and* quantitative data collection and analysis, under a qualitative paradigm as Creswell does.

Where the focus of qualitative and quantitative is sometimes on the type of data being analysed, the term quantitative research is also sometimes reserved for the use of hypothesis testing approaches, excluding studies that analyse quantitative data to offer purely descriptive statistics. Similarly, some authors limit the use of the term qualitative research to studies that admit the necessity of a subjective element (Piantanida and Garman 2009) and are based on an interpretative approach that does not claim objectivity in the normal scientific sense – because it is argued that some kinds of social phenomena can only be understood through the intersubjectivity formed through establishing researcher-participant rapport and that the kind of detached observer who could claim objectivity would not be able to access suitable data for the study. There are clearly many studies based on the collection and analysis of qualitative data that are not 'qualitative' research in *that* sense.

Table 57.3 Two traditions or paradigms for educational research after Gilbert and Watts (1983, p. 64)

Tradition	*Erklären* tradition: explanation is the goal	*Verstehen* tradition: understanding is the goal
Outlook	Realist – adopting an empirical-inductivist view of knowledge	Relativist – influenced by post-inductivist views of knowledge
Target	Seeking causal mechanisms	Seeking understanding as shown by the individual actors (without the overt pursuit of generalisations)
Characteristics	'Nomothetic': general laws are sought	'Idiographic': relates to the study of individuals
	'Quantitative': suitable sections of a general population are enquired into	'Qualitative': seeks to enquire into phenomena without undue regard to their typicality
	'Prescriptive': outcomes of enquiry are intended to determine future actions	'Descriptive': no overt intention of determining future actions
Approach to phenomena	Reductionist – phenomena are subdivided and the divisions selectively paid attention to	Holistic – phenomena are studied in their entirety
Methodological approaches	'Experimental': controlled situations	'Naturalistic': naturally occurring situations

57.11.2 Two Paradigms for Educational Research?

It seems clear that when used as primary descriptors without further qualification, the terms qualitative and quantitative can be ambiguous and so unhelpful. Gilbert and Watts (1983) also used the descriptors 'quantitative' and 'qualitative', inter alia, when they described two common traditions or paradigms for research that could be employed in science education. However, Gilbert and Watts offered explanations for their uses of the term, in the context of setting out two clusters of characteristics of these two traditions. Their two paradigm descriptions are summarised in Table 57.3, and several of their points will be reflected in the following treatment.

One aspect of the Gilbert and Watts scheme that needs comment is the notion of their 'paradigm 2' (*Verstehen* tradition) being a relativist one. For some commentators, any admission of relativism is seem as antiscientific, and indeed Scerri has attacked the prevalence of 'constructivist' thinking in science (and in particular chemistry) education because of its associations with relativism. Space does not allow this debate to be explored in detail here (see Scerri 2003, 2010, 2012; Taber 2006b, 2010c), except to note it is a rather different proposition to suggest (as a hypothetical example) (a) that the choice between (i) the ancient system of earth, fire, water, air and aether as elements and (ii) the modern periodic system as a basis for scientific progress is all a matter of cultural perspective (a kind of relativism difficult to justify scientifically) than it is to suggest (b) that it is important to investigate and respect learners' alternative conceptual frameworks because of their influence on the individual's *learning of* science.

As suggested above, the research focus on students' ideas in science derived from concerns with the common patterns of conceptual development and the difficulties of learning canonical science, rather than any suggestion that students' ideas offered a viable alternative basis for scientific progress. Indeed it has been noted that common alternative conceptions often share at least superficial similarities with historical scientific models and theories long abandoned (Piaget and Garcia 1989).

Often in education, we are concerned with exploring the personally constructed 'realities' (i.e. the reality as experienced) of individuals because personal sense making is at the heart of the learning process (Glasersfeld 1989). The decision to focus on such 'second-order' perspectives (Marton 1981), i.e. other people's construing of reality, *need not* imply abandoning a belief in an absolute external reality. This can be considered analogous to how the historian of science may use hermeneutic methods to understand how scientists of the past understood scientific concepts because of the value of knowledge of those personal conceptions to our understanding of the history of science, not because anyone is suggesting that such outdated ideas are as valid as current scientific thinking.

The extensive research into student understanding and thinking in science associated with 'constructivism'/the ACM was strongly informed by existing traditions of work which emphasised the importance of a person's existing ways of understanding the world as the basis for how they made sense of experience and so how that interpretation of experience informed their actions in the world (Taber 2009b). In particular, key constructivist thinkers in science (and mathematics) education were informed by the genetic epistemology (Piaget 1970/1972) of Jean Piaget (Driver and Easley 1978; Gilbert and Watts 1983; Glasersfeld 1989) and the personal construct theory (Kelly 1963) of George Kelly (Gilbert and Watts 1983; Pope and Gilbert 1983).

One significant distinction between research methodologies does closely resemble that suggested by Creswell, but is not best distinguished by the labels qualitative and quantitative. Rather, these two types of research are better characterised according to whether the research is intended to test out existing established theory through deductive methods or rather to better understand poorly theorised phenomena to aid the development of new theory (Biddle and Anderson 1986). Developing this idea suggests two clusters of characteristics of research studies, as shown in Fig. 57.3.

This perspective does not set out different methodologies as fundamentally concerned with different research enterprises, but rather reflects how in any area of scientific activity there has to initially be a period of exploring and categorising and 'making sense' of the phenomena of a field – what has been termed the 'natural history' phase (Driver and Erickson 1983) – that can lead to the kinds of theorising, and subsequently bold conjectures (Popper 1989), suitable for formal testing (see Table 57.4).

That much of educational research concerns the former, more exploratory, types of study may be partly related to the relative immaturity of educational research compared with the established natural sciences. However, there are also inherent features of education that channel much research towards the discovery pole. One of these features, noted above, concerns the inherent complexity of educational

Fig. 57.3 Two main types of research in education

Table 57.4 Exploratory and confirmatory research

Paradigmatic commitment	Application	Suitable methodologies
Exploratory	In areas where no clear theoretical picture has emerged, due to limited research or complexity of phenomena	Case study Grounded theory
Confirmatory	To test hypotheses drawn from established theory	Experiments Surveys

Table 57.5 Idiographic and nomothetic research

Paradigmatic commitment	Application	Suitable methodologies
Idiographic	To enquire into educational phenomena where understanding requires detailed engagement with specific instances in their naturalistic context	Case study (to explore individual learners, classes, teachers, etc.) Ethnography (to explore cultures of identifiable groups)
Nomothetic	To enquire into aspects of educational phenomena that may be described in terms of norms and general laws	Experiments Surveys

phenomena, which are often embedded in situations from which they cannot be readily be disembodied whilst retaining their integrity.

This complicates attempts to use experimental method, as there may be myriad potential confounding factors that may be difficult to identify, let alone manipulate to control conditions, or, failing that, to measure so as to attempt to allow for during data analysis. As suggested below, this has encouraged much educational research to be focused on understanding the individual case in depth (see Table 57.5), despite

Table 57.6 Objectivist and constructivist-interpretivist research

Paradigmatic commitment	Application	Suitable methodologies
Objectivist	When dealing with issues where there is consensus ontology (the nature and demarcation of what is being studied) and clear epistemology (agreed means of learning about objects of research)	Experiments Surveys
Constructivist-interpretivist	Where exploring phenomena that are socially constructed and culturally relative or nuanced mental phenomena that can only be communicated through dialogue	Grounded theory (for understanding the central issues in social phenomena and institutions) Case study (to allow detail exploration of an individual or group) Ethnography (to provide immersion in culture to identify emic (insider) perspectives)

the problem of generalising from the individual to the wider 'population' (of teachers, of lessons, of learners, etc.).

Another key issue concerns the nature of teaching and learning as human activities. As such, there is a limit to the extent they can be seen as the subjects of objective study, because humans make personal meaning of and from their experiences, and many of the things we wish to study relate to those meanings (see Table 57.6). So whilst we might be more 'objective' when exploring class size, or curriculum content, or even whether student examination responses match specified features of canonical target knowledge; if we are interested in how a learner understands a concept, or the values they bring to science learning, or their experiences of a new teaching approach, etc., then we need to use ('constructivist'/'interpretivist') methods that can engage with and explore how others make sense of the world.
