Horacio Tignanelli is an astronomer and a graduate of the Universidad Nacional de La Plata (UNLP) in Argentina. He specialized in the history and teaching of astronomy. Since 2000, he has been part of a group of specialists at the National Ministry of Education, where he is developing science education programs (particularly astronomy) for all education levels. Tignanelli is a Professor of Astronomy at the Universidad Nacional del Centro de la Provincia de Buenos Aires (UNICEN) and the Universidad de La Punta (ULP, Provincia San Luis), as well as in different Teacher Training Institutes of the Ciudad Autónoma de Buenos Aires. Previously (1980–2000), he worked for the Buenos Aires Province Commission for Scientific Research (CIC), developing astronomical research and education programs in the Faculty of Astronomy and Geophysics (UNLP).

In addition to journal articles, he has published dozens of astronomy books (textbooks and popular science works) for teachers, students, and for the general public. His historical studies have surveyed part of the astronomical history of his country. At the core of his educational activity are informal education methods, typical of education with art (he has produced and written programs for TV, radio, Internet, and scientific theater).

Yann Benétreau-Dupin is a doctoral student in philosophy at the University of Western Ontario and the Rotman Institute (Canada). He received an MA in Philosophy from Boston University, where he worked on logic and scientific methodology, after studying at Université Paris 1 Panthéon-Sorbonne and Università di Bologna. His main interests are philosophical foundations of physics, methodology in experimental sciences, and particularly questions of confirmation, the role of explanation, and the status of laws in physics (especially contemporary cosmology).

He worked as a research and teaching assistant at Boston University for ITOP (Improving the Teaching of Physics), a graduate program led by BU's School of Education and Department of Physics. Previously, he worked in science education for Planète Sciences, a national educational organization in France, where he developed programs to promote hands-on projects in astronomy in secondary- and higher-level education, and ran an educational astronomical observatory in the Paris region.

Part VII
Pedagogical Studies: Cosmology

Chapter 20
The Science of the Universe: Cosmology and Science Education

Helge Kragh

20.1 Introduction

Whether majoring in science or not, students at high school and undergraduate university level are confronted with issues of cosmology, a subject which has only attracted a limited amount of attention in the context of science education (Kragh 2011a). It is important that when students are introduced to cosmology, this is done correctly not only in the technical sense but also in a conceptual sense. As shown by several studies, misconceptions abound in both areas. They include some of the philosophical aspects that are so closely intertwined with cosmology in the wider sense and to which a large part of cosmology's popular appeal can be attributed. These aspects need to be addressed and coordinated with the more standard, scientific aspects. In this respect it is often an advantage to refer not only to the modern big bang theory but also to older developments that may illuminate modern problems in cosmology in a simple and instructive manner.

Following a brief discussion of the development of cosmology as a science, the article focuses on various conceptual misunderstandings that are commonly found in students' ideas about modern cosmology. Some of these misconceptions are of a philosophical nature, for example, related to the concept of the universe and its supposed birth in a big bang. By taking issues of this kind seriously, students will hopefully be brought to reflect on the limits of science and adopt a critical attitude to what scientific cosmology can tell us about the universe.

20.2 Early Cosmology: Lessons for Science Education

According to the view of most physicists and astronomers and also according to some historians of science (Brush 1992), cosmology became a science only in the twentieth century. Some will say that the supposed turn from 'philosophical' to truly scientific cosmology only occurred with the discovery of the cosmic microwave background radiation in 1965, while others date the turn to Edwin Hubble's insight in the late 1920s of the cosmological significance of the galactic redshifts. Others again suggest that the turning point is to be found in Albert Einstein's cosmological model of 1917 based on his general theory of relativity.

The widely held opinion that there was no scientific cosmology – scientific in more or less the modern sense of the term – before Einstein and Hubble entered the stage is reflected in most introductory textbooks in physics and astronomy. The general structure of these books is to start with the solar system and then proceed to stars and galaxies, ending with the universe as a whole. The chapters on cosmology are usually restricted to post-1920 developments (Krauskopf and Beiser 2000). Although earlier developments are sometimes included, then it occurs in sections that appear separate from the account of modern cosmology and are typically placed in the beginning of the book. For example, the epic confrontation between the Aristotelian-Ptolemaic universe and the heliocentric world system during the so-called Copernican revolution is a classic theme in the teaching of physics and astronomy, where it is often presented as a methodological case study. On the other hand, textbooks and similar teaching materials rarely refer to other parts of the rich history of cosmological thought, for which teachers and students must look up the literature written by historians of science (North 1994; Kragh 2007). The exception to this state of affairs is Olbers' famous paradox of the dark night sky, dating from 1826 but with roots back to Johannes Kepler, which can be found in most textbooks.

Although modern cosmology dates in most respects from the early part of the twentieth century, it does not follow that earlier theories about the universe were not scientific. The cosmos of the ancient Greeks was very different from ours, yet Ptolemy's cosmology was basically scientific in so far that it was a mathematical model that rested on observations and had testable consequences. At any rate, there are good reasons to include aspects of pre-Einsteinian cosmology also in the context of science education. For one thing, students should be aware of this earlier development for general cultural reasons. Moreover, the earlier history of cosmology provides many more examples of educational relevance than just the one of the Copernican revolution. Although Michael Crowe's two books on theories of the universe are not ordinary textbooks, they are based on his very extensive experience with teaching history of astronomy and cosmology at the University of Notre Dame (Crowe 1990, 1994). They are of value to the teacher of introductory astronomy courses because they include a large amount of primary sources from Ptolemy to Hubble that can be easily used in the classroom. Moreover, Crowe (1994) includes laboratory exercises related to the studies of the nebulae by William Herschel in the late eighteenth century and by William Parsons, the Earl of Rosse, in the mid nineteenth century.

To illustrate the relevance of earlier cosmological thought in science education, consider the discussion in the thirteenth century concerning the possibility of an eternal yet created universe. The discussion was abstract and philosophical, not scientific, but it is nonetheless of relevance to problems of modern cosmology because it led Thomas Aquinas and other scholastic thinkers to scrutinize the concept of creation in a sophisticated way that went beyond the identification of creation with temporal beginning (Carroll 1998, see also below). As another example one might point to the difficult problem of spatial and material infinity as it turned up in Isaac Newton's correspondence with Richard Bentley in the early 1690s. Both Bentley and Edmund Halley mistakenly believed that in an infinite stellar universe each star would be attracted by equal forces in any direction and therefore be in a state of equilibrium. The belief is intuitively convincing and probably shared by most students, but Newton knew better. As he pointed out, two infinities do not cancel. The case is well suited to discuss with students the tricky problems of infinities that appear no less prominently in modern cosmology than they did in the past.

Students should also be aware that the fundamental distinction between realism and instrumentalism, an important issue in the discussion of the nature of science (Campbell 1998), does not turn up only in microphysics but also in cosmology. After all, the universe is no less unobservable than are quarks and superstrings. No one has ever observed the universe and no one will ever do so, so how can we know that the universe exists? The realist will claim that 'the universe' designates an entity that exists independently of all cosmological enquiry, while the instrumentalist considers it a concept that can be ascribed a meaning only in a pragmatic sense, as it is a construct of cosmological theory. The tension between the two opposite views can be followed through much of the history of cosmology, from Ptolemy's world system to the modern multiverse, and from a teaching point of view, it may sometimes be an advantage to refer to older sources rather than to modern examples. To illustrate cosmological or astronomical antirealism with regard to theories, one may read passages of Stephen Hawking (a positivist and instrumentalist), but the same point is brought home, and with greater clarity, by Andreas Osiander's notorious preface to Nicolaus Copernicus' *De Revolutionibus*.

20.3 Patterns in the Development of Modern Cosmology

To the extent that practicing scientists are familiar with philosophical theories of science, the theories are often limited to the views of Karl Popper and Thomas Kuhn. The ideas of these two philosophers are also likely to be the only ones that students will meet, either explicitly or implicitly, in physics and astronomy courses.

While historians agree that Kuhn's theory of scientific revolutions does not in general fit very well with the actual history of science, the history of cosmology yields some support for the notion of paradigm-governed science and revolutionary changes, if not in the radical sense originally proposed by Kuhn (Kragh 2007, pp. 243–245). In both the older and the modern history, there are several cases of beliefs and traditions that formed the nearly unquestioned framework of cosmological thinking and hence had the character of paradigm. Thus, until about 1910, it was generally believed that the stellar universe was limited to the Milky Way. As the astronomy writer Agnes Clerke asserted, ‘No competent thinker, with the whole of the available evidence before him, can now, it is safe to say, maintain any single nebula to be a star system of coordinate rank with the Milky Way’ (Clerke 1890, p. 368). She added: ‘With the infinite possibilities beyond, science has no concern’.

Likewise, until 1930, the static nature of the universe as a whole was taken for granted. Current cosmology is solidly founded on Einstein’s theory of general relativity and some kind of big bang scenario, elements that are largely beyond discussion and conceived as defining features of cosmological theory. Yet, although it may be tempting to characterize these beliefs as paradigmatic, they are so in a different sense from what Kuhn spoke of in his classical work of 1962, *The Structure of Scientific Revolutions*. First of all, there is no indication of radical incommensurability gaps in the development that led from the static Milky Way universe to the current standard model of big bang cosmology.

The applicability of the Kuhnian model to the case of modern cosmology has been investigated by Copp (1985) from a sociological perspective and by Marx and Bornmann (2010) using bibliometric methods. Marx and Bornmann examine what they misleadingly call ‘the transition from the static view of the universe to the big bang in cosmology’, a process that supposedly occurred in the mid-1960s when the steady state model was abandoned in favour of the hot big bang model. (In reality, the transition from a static to a dynamic universe occurred in the early 1930s and was unrelated to ideas about a big bang.) As indicated by bibliometric data, the emergence of the victorious big bang model in the 1960s marked a drastic change in cosmology, if not a sudden revolution.[1] Based on citation analysis, the two authors suggest that if there were a paradigm shift, it was a slow process ranging from about 1917 to 1965 – which cannot reasonably be called a paradigm shift in Kuhn’s sense.

Shipman (2000) found that nearly half of his sample of astronomers had never heard of Kuhn and that an additional third was only vaguely familiar with him. Of those who were aware of Kuhn’s philosophy, several responded that it informed their teaching and consequently was of value in the classroom. One respondent said: ‘I think changing paradigms are so obvious in astronomical history that it goes almost without saying that his work is interesting to an astronomer, but I never thought to actually make a big deal of it in class’ (Shipman 2000, p. 165). Whereas some astronomers found Kuhn’s model to be helpful in understanding the development of the astronomical sciences, none of them thought it was relevant to their research or had an impact on modern astronomy and cosmology. As one astronomer responded, ‘Kuhn … has no effect on the way science is done’ (p. 169).

---

[1] The number of publications on cosmology grew dramatically in the 1960s, apparently an indication of the revolutionary effect caused by the standard big bang theory (Kaiser 2006, p. 447; Marx and Bornmann 2010, p. 543). However, the growth is in some respect illusory, as the number of publications in the physical and astronomical sciences as a whole grew even more rapidly. While cosmology in 1950 made up 0.4 % of the physics research papers, in 1970 the percentage had shrunk to a little less than 0.3 % (Ryan and Shepley 1976). Numerical data can be presented in many ways, sometimes resulting in opposite messages.

In this respect, the case of Popper is rather different as his falsificationist philosophy of science has exerted a strong and documented influence on the astronomical and cosmological sciences and continues to do so (Sovacool 2005; Kragh 2013). Although most cosmologists are only superficially acquainted with Popper's ideas, which they tend to use in a simplified folklore version, they often invoke them as a guide for constructing and evaluating theories. This is evident from the modern controversy over the multiverse, and it was just as evident in the past, when Popperian standards played an important role in the debate between the steady state theory and the class of relativistic evolution theories (Kragh 1996, pp. 244–246). Hawking has in general little respect for philosophy, but in his best-selling *A Brief History of Time*, he nonetheless pays allegiance to the views of Popper:

> Any physical theory is always provisional, in the sense that it is only a hypothesis: you can never prove it. … On the other hand, you can disprove a theory by finding even a single observation that disagrees with the predictions of the theory. As philosopher of science Karl Popper has emphasized, a good theory is characterized by the fact that it makes a number of predictions that could in principle be disproved or falsified by observation (Hawking 1989, p. 11).

Influential as Popperianism as in cosmological circles, the influence is mostly limited to the popular literature and general discussions of a methodological nature. As it is the case with Kuhn, Popper's name very rarely appears in research papers. Perhaps more surprisingly, the same seems to hold for elementary textbooks in astronomy and cosmology. On the other hand, the influence of a philosopher may be visible even though his or her name is missing. Thus, in a brief methodological section, astronomy author Karl Kuhn writes: 'A theory of science must be able to be shown to be wrong. A theory must be testable. Every theory must be regarded as tentative, as being only the best theory we have at present. It must contain within itself its own possibility of destruction' (Kuhn 1998, p. 557). It is then up to the teacher whether Popper should be named or not.

20.4 Conceptions and Misconceptions of Cosmology

Most of the misconceptions about cosmology commonly found among students concern the two fundamental concepts of the expanding universe and the big bang. The two concepts are closely connected, but the precise connection between them is often misconceived.

20.4.1 The Expanding Universe

The standard tradition in introductory astronomy and physics textbooks dealing with cosmology is understandably characterized by an emphasis on observations rather than theory. Observations are used as arguments for new concepts and often presented in a historical context. Expositions typically start with two important and connected observations from the early decades of the twentieth century, Vesto Melvin Slipher's discovery in the 1910s of galactic redshifts and Hubble's conclusion from 1929 of a linear relationship between the redshifts and the distances of the galaxies. Both of these historical cases are easily comprehended and can, moreover, be turned into students' exercises by providing the students with the data used by the two astronomers or by using the students' own data found with a 'simulated telescope' (Marschall et al. 2000). From the Hubble relation, there is but a small step to the expanding universe. Almost without exception, textbooks and popular expositions illustrate the expansion of space by means of the inflating-balloon analogy, which may also be used to introduce the notion of curved space such as applied in relativistic cosmology. This standard and very useful analogy – to 'imagine the nebulæ to be embedded in the surface of a rubber balloon which is being inflated' – was first suggested by Arthur Eddington in (1931), shortly after the expansion of the universe had been recognized (Eddington 1931). It also figured prominently in Fred Hoyle's *The Nature of the Universe* from 1950, a classic in the popular astronomy and cosmology literature.

Although there may be but a small step from the Hubble relation to the expanding universe, the step is real and should not be ignored. Students may be told that the expansion of the universe is an observational fact, but this is not quite the case. We do not *observe* the expansion, which does not follow from the data of either Hubble or later observers. As Hubble was keenly aware of, it takes theoretical assumptions (such that the redshifts are due to a Doppler effect) to translate the measured redshifts into an expansion of the universe. It is quite possible to accept the redshift-distance relation and, at the same time, maintaining that the universe is static, such as many scientists did in the 1930s and a few still do. In fact, Hubble, a cautious empiricist, never concluded that the universe is in a state of expansion. What is 'commonly known' and stated in many textbooks and articles, namely, that 'The expansion of the universe was discovered by Edwin Hubble in 1929' (Lightman and Miller 1989, p. 135), is just wrong. Hubble did not discover the expansion of the universe, and he never claimed that he did (Kragh and Smith 2003).

There is a tendency in textbooks, perhaps understandable from a pedagogical perspective, to simplify and dramatize discoveries. For example, one textbook presents Hubble's discovery of the redshift-distance relation as follows: 'The law was published in a 1929 paper on the expansion of the universe. It sent shock waves through the astronomical community' (Kuhn 1998, p. 512). However, it is only in retrospect that Hubble's paper was about the expansion of the universe, and it did not initially create a stir in either the astronomical or the physical community. According to the *Web of Science*, in the years 1929–1930, it received only three citations in scientific journals.

A much better candidate for the discoverer of the expanding cosmos is the Belgian pioneer cosmologist Georges Lemaître, who in a work of 1927 clearly argued that the universe was expanding and even calculated the quantity that came to be known as the Hubble constant (Holder and Mitton 2012). Contrary to Hubble, Lemaître was fully aware that the measured galactic redshifts are not due to a Doppler effect of galaxies flying through space but must be interpreted as the stretching of standing waves due to the expansion of space, that is, as a relativistic effect. As he explained, if light was emitted when the radius of curvature of the closed universe was R_1 and received when it had increased to R_2, the 'apparent Doppler effect' would be given by $\Delta\lambda/\lambda = R_2/R_1 - 1$. The important difference between the Doppler explanation and the relativistic expanding-space explanation can be illustrated in a simple way by means of the balloon analogy (Lotze 1995). One should distinguish between the expansion of space and the expansion of the material universe, such as most textbooks do. It is much easier to comprehend galaxies moving apart, as were they flying through space, but it is more correct to conceive space as expanding and the galaxies changing their relative positions because of the expansion of space. The counterintuitive notion of an expanding empty space, such as implied by the model first studied by Dutch astronomer Willem de Sitter in 1917, illustrates the difference between the two explanations.

As documented by many studies, the expansion of the universe is not well understood, if understood at all, by either the general public or general science students. Comins (2001) discusses a large number of astronomical and cosmological misconceptions, why they are held and how to correct them.[2] Unfortunately, when it comes to the history of cosmology, he expresses several misconceptions of his own, including that Einstein, because he included the cosmological constant in his 1917 cosmological model, 'missed the opportunity to predict that the universe expands' (p. 162). This common misunderstanding is easily seen to be unfounded, for other reasons because the cosmological constant was part of Lemaître's expanding model of 1927 based on Einstein's equations. Moreover, Einstein did not introduce the cosmological constant to keep his universe from expanding but to keep it from collapsing. In short, a cosmological model may describe an expanding universe whether or not it includes a non-zero cosmological constant.

Asked whether the universe is systematically changing in size or remaining about the same size, nearly 60 % of 1,111 interviewed American adults offered the last response. According to the survey conducted by Lightman and Miller (1989), only 24 % of the respondents said that the universe is expanding. Later large-scale surveys of students following introductory astronomy courses confirm that they have difficulties with the expanding universe and other concepts of modern cosmology. Only a minority of the students revealed a reasonably correct understanding of the meaning of the 'expansion of the universe', and a sizeable minority denied that the universe is increasing in size. Instead they suggested that the phrase was a metaphor for how our knowledge of the universe has increased over time (Wallace et al. 2012). One student answered that the expanding universe is an expression for stars and planets moving away from a central area in the universe, if not necessarily from the Earth (Wallace et al. 2011).

---

[2] See also Comins' website on 'Heavenly Errors' that includes nearly 1,700 common misconceptions that students and other people have about astronomy and cosmology. Among them are that the universe has stopped expanding, that there is a centre of the universe and that all galaxies are moving away from the Earth (http://www.umephy.maine.edu/ncomins/).

Another question that often causes confusion is *what* takes part in the expansion. Although the expansion is 'universal', it does not refer to everything. Objects that are held together by other forces than gravity, such as electromagnetic and nuclear forces, remain at a fixed physical size as the universe swells around them. Likewise, objects in which the gravitational force is dominant also resist the expansion: planets, stars and galaxies are bound so strongly by gravitational forces that they are not expanding with the rest of the universe. There is no reason to fear that the distance of the Earth from the Sun will increase because of the cosmic expansion, although worries of this kind are not uncommon (Lightman and Miller 1989). In the survey conducted by Prather and colleagues (2003), 10 % of the students thought that the expansion of the universe has terrestrial consequences, including the separation of the continental plates that is a central part of the geological theory of plate tectonics. Nor is our Local Group of galaxies expanding. The Andromeda Galaxy, for example, is actually approaching the Milky Way, causing a blueshift rather than a redshift. (In 1913, Slipher concluded that the Andromeda Galaxy approached the Sun, only subsequently to realize that it was an exception to the general pattern of galactic redshifts.) On the other hand, on a cosmological scale, all matter is rushing apart from all other matter at a speed described by Hubble's law, $v = Hr$, where H denotes the Hubble parameter or 'constant'. Since the Hubble time $1/H$ is an expression of the age of the universe, H, it is not really a constant but a slowly decreasing quantity.

There are other and more complex ways in which the expansion of the universe can be misconceived, some of them relating to the magical limit of the recession velocity apparently given by the speed of light c (Davis and Lineweaver 2004; Ellis 2007, pp. 1214–1216). Students learn that nothing can move faster than the speed of light, which is a fundamental postulate of the theory of relativity. But according to Hubble's law, the recession velocity keeps increasing with distance, implying that beyond the Hubble distance c/H, the velocity will exceed the speed of light. Can receding galaxies really cross this limit? If they do, will they then become invisible because their redshifts become infinite? In spite of the apparent contradiction with Einstein's postulate, superluminal recession velocities do not violate the theory of relativity. As Lemaître emphasized in 1927, the recession velocity is not caused by motion *through* space but by the expansion *of* space. According to general relativity theory, redshifts do not relate to velocities, as they do in the Doppler description (both classically and in special relativity), and the redshifts of galaxies on the Hubble sphere of radius c/H will not be infinite.

Not only can the universe, or space, expand faster than the speed of light, we can also observe objects that recede from us with speeds greater than this limit. Students may believe that since the universe came into being 13.8 billion years ago, the most distant objects are 13.8 billion light years away, but in that case they think in terms of a static universe. Since distances between faraway galaxies increase while light travels, the observability of galaxies is given by the look-back time, which is the time in the past at which light now being received from a distant object was emitted. As a result of the expansion, the farthest object we can see is currently about 46 billion light years away from us, receding with more than six times the speed of light, even though the universe is only 13.8 billion years old. The size of the observable universe is not given by the Hubble sphere but by the cosmic particle horizon beyond which we cannot receive light or other electromagnetic signals from the galaxies.

20.4.2 The Big Bang

Having digested the notion of expanding space, the next crucial concept that students need to be introduced to, the idea of the big bang, is often presented as a simple consequence of the cosmic expansion.[3] After all, if the distances between galaxies (or rather galactic clusters) increase monotonically, apparently there must have been a time in the past when all galaxies were lumped together. This inference is facilitated by the balloon analogy, where the airless balloon corresponds to the original universe before expansion. However, the inference is more seductive than correct. The argument from expansion to big bang may be pedagogically convincing, but it is not supported by either logic or the history of science. If there were such a necessary connection, how is it that while the majority of astronomers in the 1930s accepted the expansion of the universe, practically no one accepted the idea of an explosive origin?

In the version of the 'primeval atom' hypothesis, the idea of a big bang was first suggested by Lemaître in 1931 – not in his 1927 paper, as is often stated – but it took many years until the hypothesis was taken seriously. The hypothesis was independently revived and much improved by George Gamow and his collaborators in the late 1940s, but even then it failed to win much recognition (Kragh 1996, pp. 135–141). Remarkably, from 1954 to 1963, only a single research paper was published on the big bang theory. During most of the period from about 1930 to 1960, the favoured theory of the evolution of the universe was the Lemaître-Eddington model according to which the universe had evolved asymptotically from a static Einstein state an infinity of time ago. This kind of model is ever expanding but with no big bang and no definite age.

Teachers presumably want their students to accept the big bang theory, but not to do it by faith or authority. To convince students that the big bang really happened, they need to provide good reasons to believe in it, which primarily means observational and other empirical evidence. In this respect, the students may be compared to the majority of astronomers and physicists who still in the 1950s resisted the idea of a big bang, basically because they lacked solid empirical evidence for the hypothesis. As the sceptics pointed out, quite reasonably, if our current universe has evolved from a very small and extremely dense and hot state several billion years ago, there

---

[3] The undignified name 'big bang' was coined by Fred Hoyle in a BBC radio programme of 1949, but neither Hoyle nor other scientists used it widely until the late 1960s. Contrary to what is often said (e.g. Marx and Bornmann 2010, p. 454), the phrase did not catch on either among supporters or opponents of the exploding universe. Hoyle belonged to the latter category, and it generally thought that he coined the name as a way of ridiculing the theory, but this is hardly the case. The first scientific paper with 'big bang' in its title appeared only in 1966.

must presumably still be some traces or fossils from it. If no such traces can be found, we have no reason to believe in the big bang and nor is there any possibility of testing the hypothesis.

An additional reason for the cool reception of the big bang theory was that according to most of the models, the calculated age of the universe came out embarrassingly small, much smaller than the age of the stars and smaller than even the age of the Earth, in the 1930s estimated to be about three billion years. A universe that is younger than its constituent parts is of course ruled out for logical reasons. The age problem is mentioned in some astronomy textbooks but not always historically correct. According to Arny (2004, p. 517), the age of Lemaître's primeval-atom universe was 2/3 times the inverse Hubble constant, which at the time, when Hubble's value $H = 500$ km/s/Mpc was generally accepted, corresponded to only 1.2 billion years. The reference should be to the Einstein-de Sitter model of 1932, which assumed a flat space and a zero cosmological constant. Lemaître, on the other hand, assumed a positive cosmological constant by means of which he was able to avoid the age problem and assign to his universe an age of 20 billion years or more.

It is all important that some kind of fossil is left over from the cosmic past, which otherwise would be inaccessible to us and therefore just a postulate one can believe in or not. It would have the same questionable ontological status as other universes in modern multiverse theories. In evidence-based courses in physics and astronomy, students come to understand and accept the big bang picture by means of empirical evidence such as the cosmic microwave radiation and the abundance of helium in the universe. What matters is not so much the right scientific belief as it is to be able to justify these beliefs and distinguish them from ideas that are not adequately supported by evidence (Brickhouse and colleagues 2000, 2002). Students learn that a theory must necessarily be supported by evidence and also that evidence depends on and is only meaningful in relation to the theory in question. The way students learn to accept the big bang corresponds to some extent to the historical situation in the period from about 1948 to 1965.

The celebrated discovery of the cosmic microwave background killed the already weakened rival steady state theory and turned the big bang theory into a successful standard theory of the universe.[4] Although the best known of the cosmic fossils, the microwave background is not the only one and nor was it the most important in the historical development of cosmology. It may be less well known that the distribution of matter in the universe provides us with another and more easily accessible fossil. None of the 219 students questioned by Bailey and associates (2012) referred to the chemical composition of the universe as evidence for the big bang, while 32 mentioned the expansion and three the cosmic microwave background as evidence.

---

[4] The classical steady state theory was abandoned half a century ago and for this reason is mainly of historical interest. On the other hand, from a methodological and also an educational point of view, it is an instructive example of how an attractive theory with great predictive power was eventually shot down by new observations. In addition, it illustrates the aesthetic and emotional appeal of a cosmological theory, a phenomenon which is not restricted to the past. While Kuhn (1998, p. 555) covers the essence of the steady state theory, other textbook authors choose to ignore it (Krauskopf and Beiser 2000).

The hypothesis that the distribution of matter reflects the cosmic past was first proposed in the late 1930s, when the first reliable data of the cosmic abundance of chemical elements appeared. The general idea in this line of reasoning is that the nuclear species, or at least some of them, are the products of nuclear processes in the early phase of the universe. This was the guiding philosophy of Gamow and his associates Ralph Alpher and Robert Herman, who in the late 1940s developed it into a research programme sometimes known as 'nuclear archaeology' (Kragh 1996, pp. 122–132). The apt phrase underlines the methodological similarity between this area of physical cosmology and ordinary historical archaeology. It refers to attempts to reconstruct the history of the universe by means of hypothetical cosmic or stellar processes and to test these by the resulting pattern of element abundances. Gamow was unable to account in this way for the heavier elements, but in collaboration with Alpher and Herman, he succeeded in calculating the amount of helium in the universe to about 30 % by weight, in reasonable agreement with observations. This early success of the big bang hypothesis was later much improved and extended to other light isotopes such as deuterium.

What matters is that by the late 1960s there was solid empirical evidence for the hot big bang, primarily in the form of the microwave background and the abundance of helium. This does not amount to a 'proof' of the big bang, but it does provide convincing evidence that makes it rational to accept the big bang picture (which does not imply that it is irrational not to accept it). Alternative cosmological models must, as a minimum, reproduce the empirical successes of the standard big bang model and do it without assumptions of an ad hoc nature. To do so on the basis of non-big bang assumptions turns out to be exceedingly difficult. It was the main reason why the steady state model of the universe was abandoned in the late 1960s. The lack of successful rival models is yet another reason to have confidence in the big bang, if by no means to accept it as true.

Whether students follow an evidence-based approach that corresponds to the historical development or not, it is not enough that they can justify their belief in the big bang picture in terms of evidence for it. They also need to know what this picture is, more exactly. If not the students will believe in the big bang, knowing why they believe it but not knowing what they believe in. Several studies show that students have quite different views of the nature of the origin and evolution of the universe. According to a study of Swedish upper-secondary students of age 18–19 years, they conceive the big bang in a variety of ways:

> For example, there are students saying that the universe has always existed in some way. Others talk about a beginning with the Big Bang, but show that they do not view this as an absolute beginning of the universe. … In addition to the view ascribed above where the Big Bang is viewed as something happening to the whole of the universe, there are also some students who talk about the Big Bang as the origin of the earth and/or the sun (Hansson and Redfors 2006, p. 359).

One of the students described the big bang as an event 'where an explosion made gases and particles spread out in space and then they attracted each other and formed suns' (p. 366). Studies show consistently that the most common misconception of the big bang is to associate it with an explosion of pre-existing matter into empty space (Prather and colleagues 2003; Wallace and colleagues 2012; Bailey and colleagues 2012). Perhaps more surprisingly, only relatively few students connect the big bang to the beginning of the cosmic expansion, and very few think of it as an explosion from nothing.

Although it is hard not to think of the big bang as some kind of explosion of pre-existing matter, it is important to make the students understand that this is at best a somewhat flawed metaphor. Lemaître used the metaphor as early as 1931, when he spoke of his new big bang model as a 'fireworks theory', thereby trying to visualize what happened in the cosmic past. Fireworks explode into the surrounding air, but there is nothing 'outside' that the universe can explode into. While an explosion occurs at some location, the bang of the past did not happen somewhere in the universe. It was the entire universe that 'exploded' and thus the big bang happened everywhere. If this is hard to visualize, it is because it cannot be visualized.

It is also important to be aware that the qualitative meaning of the big bang is that long ago all distances, as given by the scale factor $R(t)$, were nearly zero, after which $R(t)$ increased rapidly. For some 14 billion years ago, the universe was very compact, very hot and, in a sense, very small. The essence of the big bang is not a claim of an absolute beginning in some 'singularity' at $t=0$ but a claim of a state of the universe, much earlier than and very different from the present state, that has evolved into the one we now observe. Another way of putting it is that the presently observed expansion started at some finite time ago in the cosmic past, so that the expanding universe can be ascribed a finite age. Note that this does not necessarily imply that the universe has a finite age. Creation in an absolute and therefore metaphysical sense is not – and fortunately not – a part of the big bang scenario, just as little as an absolute origin of life is a necessary part of the neo-Darwinian evolution scenario.

20.5 The Concept of the Universe

Although cosmology has undoubtedly developed into a proper and impressive physical science since the 1960s, it is not just another branch of physics or astronomy. Nor is it just astrophysics extended from the stars to the universe at large. No, it is a very special and potentially problematic science in which questions of a philosophical (and sometimes religious) nature cannot be clearly separated from scientific questions relating to observation and theory. To present cosmology to students without taking into regard its special nature is to present them with a narrow and distorted picture of the fascinating science of the universe. Questions of a philosophical nature are part and parcel of what cosmology is about, and they should be given due consideration also in educational contexts, if not at the expense of the scientific issues. This is a major reason why modern cosmology, including aspects of its history, should have a prominent role in science teaching and why it enters significantly in many courses for students not majoring in physics or astronomy.

20.5.1 The Cosmological Principle

Much of cosmology's special and potentially problematic nature is independent not only of the big bang but also of the expansion of the universe. Indeed, being basically of a conceptual nature, it is largely independent of modern scientific discoveries. A key problem, no less important today than it was in the time of Aristotle, is simply the unique domain of cosmology, this most peculiar concept of *the universe*. The standard definition of cosmology is something like 'the science of the universe', yet it is far from obvious that such a frightening concept as the universe can be the subject of scientific study. The relatively recent recognition that this can be done, and that even the universe at large is not foreign land to science, is one of the marvels of the modern physical sciences.

Among the epistemic problems that face a science of the universe is that cosmological knowledge seems to be conditioned by certain principles or assumptions that are completely unverifiable and for this reason may appear to be metaphysical rather than physical (Ellis 1984). The best known of these principles is the so-called cosmological principle, namely, the generally held assumption that the universe is homogeneous and isotropic on a very large scale. It is sometimes referred to as the extended Copernican principle, a rather unfortunate name given that Copernicus' universe had the Sun as its fixed and unique centre. First explicitly formulated in 1932, the cosmological principle lies at the heart of all relativistic standard models, but it is not restricted to models governed by the general theory of relativity. Indeed, when British cosmologist Edward Arthur Milne introduced it in 1932, it was in connection with his own theory of the expanding universe which was entirely different from the theory governed by general relativity. The principle assumes that the vast ocean of unobservable regions of the universe is similar to the region we have empirical access to, a region that may well be an infinitesimal part of the entire universe. What is the epistemic status of the cosmological principle? Is it a necessary precondition for cosmology, or is it merely a convenience that may be accepted or not?

The cosmological principle does have an empirical basis in so far that it roughly agrees with observations, but observations can say nothing about the structure of the universe far beyond the Hubble region, not to mention the cosmic horizon. Extrapolations much beyond this scale are necessarily hypothetical as they rest on an assumption of global uniformity that can never be verified. One might also say that they rest on 'faith', although the faith in the global validity of the cosmological principle is supported by local observations and therefore quite different from 'blind faith'. If cosmology rests on an unverifiable and perhaps metaphysical principle, can it still claim to be scientific? This is not to suggest that the cosmological principle is in fact metaphysical but to suggest that it is worth contemplating the status of the principle and to discuss it also in a teaching context rather than merely present it as a reasonable if unprovable assumption (Kuhn 1998, p. 551).

The instinct of many students majoring in science is to react with hostility and distrust to terms such as 'faith' and 'metaphysics'. (For students not majoring in science, see Shipman and colleagues 2002.) Yet, because something is ultimately a matter of faith, it does not imply that it is irrational, unscientific or arbitrary. There is an element of belief in most scientific ideas. It is important to recognize that unverifiability is not a great methodological sin that automatically deprives a theory or field its scientific status. In fact, students are well aware of high-status scientific theories that cannot be verified, although they may never have thought of them as theories that, in a manner of speaking, rest on belief.

Several of our commonly accepted laws of physics can be said to be cosmological in nature in so far that they are claimed to be true all over the universe and in any patch of cosmic space-time. Newton's law of gravitation speaks of the attractive force between any two masses in the universe, and the law of energy conservation is valid for all processes at any time in the universe. They can reasonably be considered statements relating to the universe at large and for this reason implicitly of a cosmological nature. Of course, neither these two laws nor other similar laws can be verified experimentally. The moral is that students have no reason to fear unverifiability in cosmology, since we have to live with this feature anyway. On the other hand, unfalsifiability is a different matter.

Contrary to what some philosophers have argued (Munitz 1986), the cosmological uniformity principle and similar principles are not of an a priori nature, that is, true by necessity. The cosmological principle is a simplifying assumption that could be proved wrong by observation. In that case it would have to be abandoned, but this would not make cosmology impossible, only more complicated. There are plenty of theoretical cosmological models that do not presuppose homogeneity or isotropy. The case exemplifies the important distinction between verifiability and falsifiability that is a central message in Popperian philosophy of science. That global uniformity principles of this kind are indeed falsifiable is further illustrated by the 'perfect cosmological principle' upon which the now defunct steady state theory was based. This principle extended the cosmological principle to the temporal dimension, namely, by claiming that there is no privileged time in the history of the universe any more than there is a privileged position. When the steady state theory was put in the grave in the 1960s, so was the perfect cosmological principle.

20.5.2 The Uniqueness of the Universe

The universe does not only stretch beyond the observable region; it is also, at least according to the ordinary meaning of the term, a unique concept (Ellis 1999). If the universe by definition comprises everything of a physical nature, space and time included, there can only be one universe. Contrary to ordinary physics, which operates with objects and phenomena which are local and of which there are many, the universe is not a member or instance of a class of objects. Newton could establish his inverse-square law of gravitation because there are many bodies that gravitate. By observing and experimenting with different initial conditions, he and later physicists could confirm the validity of the law, but not so with respect to the universe, where the initial conditions are fixed and unchangeable. We cannot rerun the universe with the same or altered conditions to see what would happen if they were different. It seems to follow that we cannot establish proper cosmological laws *of* the universe comparable to the ordinary laws of physics, for we cannot test any such proposed law except in terms of being consistent with a singular ‘object’, the observed universe.

Since we use laws to explain things, such as explaining the falling apple as an instance of the law of gravity or the energy generated by the Sun as an instance of the laws of quantum physics, it may seem that the domain of cosmology is beyond explanation in the causal-nomological sense normally used in physics. To put it differently, whereas in local physics law-governed and contingent properties can be distinguished, this may not be possible in cosmology. Does it follow that the universe – the domain of cosmology – is beyond explanation? The question was discussed by René Descartes and his contemporaries in the seventeenth century, and it has continued to attract attention from both philosophers and cosmologists. According to Descartes, the divine mechanical laws guaranteed that the original chaos, whatever its structure and initial conditions, would evolve into our universe or one indistinguishable from it. Newton, on the other hand, insisted that the universe cannot be fully understood by the laws of mechanics alone. Descartes’ ‘indifference principle’ continues to play a role in modern cosmology, except that the laws are no longer seen as mechanical only (McMullin 1993).

There are ways to avoid the pessimistic conclusion that the universe is beyond explanation. One strategy is simply to deny the uniqueness of the universe by postulating the existence of many others. Another solution is to recall that there are other forms of explanation than those used in the standard deductive-nomological scheme. Because cosmology is a non-nomological science, it does not follow that it is impossible to account for the present state of the universe. Thus, to explain the fact that the present temperature of the microwave background is about 2.7 K, we do not need a law of the universe or an ensemble of universes we can compare ours with. We can and do offer an explanation – not a causal one, but a historical or genetic explanation – by accounting for how the background radiation cooled with the expansion of the universe.

20.6 Unfinished Businesses

Cosmology of the twenty-first century is in some respects an unfinished business that may provide students with a rare insight in science in vivo. Not only are there important scientific questions that are not solved yet, most notably the nature of dark matter and dark energy, there are also questions of old vintage that may belong as much to philosophy as to science and about which we do not even know whether they are answerable or not. Many students are naturally curious about the kind of borderline questions that cosmology present us with, and teachers should do what they can to satisfy their curiosity. Students should be confronted with problems of this kind and be stimulated to think about them in a critical and rational way.

They should not be dissuaded from asking questions even though these may appear to be naïve – maybe they are not so naïve after all. Modern physical cosmology is a wonderful resource for enlightenment and discussion of questions that relate to the limits of science. Contrary to what is the case in most other sciences, such questions are integrated parts of the science of the universe understood broadly. In general science courses dealing with cosmology, it will be natural to introduce at least some of the issues.

20.6.1 Many Universes?

A typical textbook definition is that 'the visible universe is the largest astronomical structure of which we have any knowledge' (Arny 2004, p. 9). This is a reasonable and operational definition, but why restrict cosmology to the study of the visible universe? There surely is something behind it. In the more general and ambitious sense adopted by some cosmologists, the universe is taken to be 'everything that exists'. If so, it makes no sense to speak of other universes. Nonetheless, this is what several theoretical cosmologists do nowadays, where the question of the definition of the universe has been reconsidered as part of the controversy over the 'multiverse', the hypothesis that there is a multitude of different universes of which the one we observe is only a single member (Carr and Ellis 2008; Kragh 2011b, pp. 255–290). This ongoing controversy has many interesting aspects, not least that critics have questioned the scientific nature of the multiverse hypothesis and thus reopened the old question of whether cosmology, or some versions of cosmology, belongs to physics or metaphysics. On the other hand, advocates of the multiverse argue that it is a scientific idea and that it follows from, or is strongly suggested by, recent developments within string theory and inflation cosmology. Although the multiverse cannot be tested directly, they claim that it leads to testable consequences.

The existence of a cosmic horizon beyond which we will never be able to see or otherwise get information from, not even in principle, is not a new insight. As early as (1931), Eddington pointed out that the accelerated expansion of the closed Lemaître-Eddington universe would eventually lead to 'a number of disconnected universes no longer bearing any physical relation to one another' (Eddington 1931, p. 415). This kind of multiverse is relatively innocent, since the different universes, although causally separated, inhabit the same space-time. More extreme and more speculative is the modern idea of a huge number of disparate universes, each of them with its own physical laws, number of space dimensions and constants of nature (and with ours being perhaps the only one with intelligent life). We obviously cannot have empirically based knowledge about the content and properties of these other worlds, nor can we establish their existence observationally. The numerous other worlds may exist or not, but if the question cannot be decided by means of experiment and observation, does it belong to science?

The recent controversy over the universe may well be used in the teaching of introductory cosmology as it does not rely on advanced theories but is essentially of a qualitative and philosophical nature. A recommendable source, most relevant also for the purpose of teaching, can be found in a discussion between George Ellis and Bernard Carr in the journal *Astronomy & Geophysics* (Carr and Ellis 2008). This illuminating source has for some years been used in courses in philosophy of science for undergraduate science students at Aarhus University, and with considerable success. It works very well and provokes much good discussion among the students.

20.6.2 Infinite Space

The problem of the spatial extension of the universe is another of those cosmological questions that have been discussed since Greek antiquity and that we still do not know the answer to. While Einstein's original universe of 1917 was positively curved and with a definite volume, corresponding to a curvature radius of only about ten million light years, the expanding Einstein-de Sitter model of 1932 assumed a flat and therefore infinite space. The same was the case of the steady state universe, where a zero curvature parameter $k = 0$ follows from the perfect cosmological principle. Indirect and model-dependent measurements of the curvature of cosmic space did not lead to a definite answer, but the present consensus model (including inflation and dark energy) strongly favours a flat universe of infinite extent. Assuming the cosmological principle, this implies a universe with an infinite number of objects in it, whether these being electrons or galactic clusters.

Students may tend to think of infinity as just an excessively large number, but (as Newton was well aware of) there is a world of difference between the extremely large and the infinitely large. Actual infinities are notoriously problematic, leading to all kinds of highly bizarre and possibly contradictory consequences. The general attitude of modern cosmologists is to ignore the troublesome philosophical problems of actual infinities and speak of the infinite universe as just an indefinitely large universe, not unlike the students' intuition. Only rarely do they reflect on the weird consequences of the actual infinite – but perhaps they should. Ellis is one of the relatively few cosmologists who take the infinite cosmos seriously, suggesting that the infinities may not be real after all, indeed cannot be real. Ellis and his collaborators argue that physical quantities cannot be truly infinite and that infinite sets of astronomical objects have no place in cosmology. If such quantities formally turn up in a theory or model, it almost certainly means that the theory is wrong. Infinity, they emphasize, 'is not the sort of property that can be physically realized in an entity, an object, or a system, like a definite number can' (Stoeger et al. 2008, p. 17).

Although an infinite universe follows from some cosmological models, we will never know whether the universe is in fact infinite. Observations and theory indicate a flat space, but observations are limited to the visible universe. It is only by assuming the cosmological uniformity principle that we can extrapolate to the universe at large. Moreover, we can never know observationally whether $k = 0$ precisely, only that k varies between the limits $\pm \Delta k$ corresponding to the inevitable observational uncertainties. This observational asymmetry between flat and curved space was pointed out by the Russian mathematician Nikolai Lobachevsky as early as 1829, a century before the expanding universe. It is worth noticing that although the idea of curved space only was adopted by physicists and astronomers with Einstein's general theory of relativity, as a mathematical idea it goes back to the first half of the nineteenth century.

20.6.3 The Enigma of Creation

The traditional version of the big bang theory inevitably invites questions of a philosophical and to some extent religious nature concerning the origin of everything. Although the big bang model is not really a model of absolute beginning or creation, but a cosmic evolutionary scenario, it would be artificial to ignore these questions and simply dismiss them as unscientific. Unscientific they may be, but they are no less natural and fascinating for that. Teachers can keep them out of astronomy and general science courses, but that would be to betray the curiosity and natural instincts of the students. Moreover, questions concerning cosmic creation have a long and glorious history which makes interesting connections between the history of science and the history of ideas, philosophy and religious thought. Whether one likes it or not, the creation of the physical universe is part of the world view of most cultures, and for this reason alone, it should not be ignored in science courses. Fortunately, there is a rich literature on philosophical, political and religious world views and their place in science education (Poole 1995; Matthews 2009).

The problem with creation in a cosmological context is that if we conceive the big bang as an absolute beginning at $t=0$, then a causal scientific explanation of the creation event is impossible. After all, a cause must come before the effect, and there is no 'before'. Current cosmology has traced the history of the universe back in time to the inflationary period which is supposed to have occurred at $t=10^{-34}$ s or thereabout. It is often assumed that the cosmic past can be traced even farther back to the Planck time at $t=10^{-43}$ s (and there are even speculative pre-Planck theories). But however close calculations may bring us to the magical moment $t=0$, it seems in principle impossible to account for the creation event itself. To say that the universe was created in a space-time singularity is a mere play with words, since the singularity is a mathematical abstraction devoid of physical content. Physics did not exist at $t=0$ and it makes no sense to speak of physical mechanisms where even the concepts of cause and effect cannot be defined.

In spite of the rhetoric of some cosmologists, there are no scientific theories that explain the origin of the universe from 'nothing', and there never will be such theories. The concept of nothingness or absolute void has a rich history (Genz 1999) that recently has become relevant to science, not least after the discovery of the dark energy that is generally identified with the vacuum energy density as given by the cosmological constant and interpreted in terms of quantum mechanics. However, the modern quantum vacuum is entirely different from absolute nothingness.

There cannot possibly be a scientific answer to what nothingness is, and yet it does not therefore follow that the concept is meaningless.

A major reason why big bang cosmology has been and to some extent still is controversial in the eyes of the public is that it may be seen as a scientific version of Genesis or at least to provide scientific justification for a divinely created world. This misguided view was endorsed by Pope Pius XII in 1951 (Kragh 1996, pp. 256–259) and is still popular in some circles. Although this is not the place to discuss the complex relations between cosmology and religion (Halvorsen and Kragh 2010), it appears that some of these questions are suited for discussions with and among students and should not necessarily be kept out of the physics classroom. Courses that aim to establish a dialogue between science and religion have existed for some time, and in some of them cosmology enters prominently (Shipman and colleagues 2002). The issue is also mentioned in Kuhn (1998), a textbook which includes a brief and admirably clear exposition of the relationship between cosmology and religious faith:

> If we use God as an explanation for the big bang, there would be no reason to look further for a natural explanation. Use of supernatural explanations would shut down science. … If science relied on a creator to explain the inexplicable, there would be nowhere to go, no way to prove that explanation wrong. The question would have already been settled. … Science does not deny the existence of God. God is simply outside its realm (Kuhn 1998, p. 557).

While much attention is paid to the origin of the universe, the other end of the cosmic time scale is rarely considered a question of great importance. And yet Einstein’s equations of relativistic cosmology are symmetric in time, telling us not only about the distant past but also about the remote future. Will the universe ever come to an end? If so, what kind of end? In the late nineteenth century, these questions were eagerly discussed in relation to the so-called heat death supposedly caused by the increase of entropy in the universe, and recently they have been reconsidered within the framework of modern physics and cosmology. The new subfield known as ‘physical eschatology’ is concerned, among other things, with the final state of life and everything else (Kragh 2011b, pp. 325–353). Parts of physical eschatology are controversial and highly speculative, yet it is a subject that is likely to appeal to many students and that they should know about. As the birth of the universe relates to religious dogmas, so does its death.

20.6.4 A Universe Without a Beginning

In his last book, *The Demon-Haunted World*, the prominent astronomer and science popularizer and educator Carl Sagan pointed out that science might conceivably demonstrate the universe to be infinitely old. He suggested that ‘this is the one conceivable finding of science that could disprove a Creator – because an infinitely old universe would never have been created’ (Sagan 1997, p. 265). On the face of it, Sagan’s assertion may appear convincing, perhaps even self-evident, but it is based on a misunderstanding that conflates the scientific notion of ‘finite age’ with the theological notion of ‘creation’. Theologians and Christian philosophers agree that even an infinitely old universe would have to be created, in the sense of being continuously sustained, and that it would in no way pose problems for faith. Even if the universe had existed in an infinity of time, we could still ask for the reason of its existence or why it was created.

We have very good reason to believe in the big bang, but we have no good reason to believe that this is how the universe ultimately came into being. Concepts such as cosmic origin and time are difficult, not only conceptually but also for semantic reasons. Thus, we would presumably think that whereas the steady state universe of Hoyle and others had always existed, this is not the case with the finite-age big bang universe. The two statements ‘the universe has a finite age’ and ‘the universe has always existed’ appear to be contradictory, but in reality they may both be true. To say that the universe has always existed is to say that it existed whenever time existed. The word ‘always’ is a temporal term that presupposes time. Since it is hard to imagine time without a universe – much harder than imagining a universe without time – it makes sense to speak of a big bang universe which has always existed. The phrase ‘the universe has always existed’ reduces to a tautology. This observation is more than just a philosophical nicety, as illustrated by one of the questions posed to students in a questionnaire: ‘Does the universe have an age, or has it always existed’ (Bailey and associates 2012). Several of the students, we are told, ‘gave a contradictory response, such as “the universe has always existed: it is billions of years old”’. As argued, the answer is not really contradictory.

Until recently, it was taken for granted that a universe of finite age implies an absolute cosmic beginning of some kind. The traditional answer to the supposedly naïve question of what there was before the beginning in the big bang has been to dismiss or ridicule it as an illegitimate and meaningless question. For how can there be something ‘before’ the beginning of time? But there is no reason to ridicule the question if it is recognized that the big bang event at $t=0$ did not necessarily mark the beginning of time.

During the last two decades, an increasing number of cosmologists have argued that the big bang picture does not preclude a past eternity in the form of, for example, one or more earlier universes. Most theories of quantum gravity operate with a non-singular smallest volume, which makes it possible to extend cosmic time through the $t=0$ barrier at least in a formal sense.[5] There exists presently a handful of such theories, which are all speculative to varying degrees but nonetheless are considered serious scientific hypotheses. To mention but one example, according to so-called loop quantum cosmology, the universe was not created a finite time ago but exists eternally. There was a big bang, of course, but in the form of a well-described transition of the universe from a contracting to an expanding phase. The space of loop

---

[5] It is far from obvious that the symbol t, as it appears in the equations describing the very early universe near or before the Planck time $t=10^{-43}$ s, can be ascribed a well-defined physical meaning (Rugh and Zinkernagel 2009). The meaning of time is even less clear in theories of quantum cosmology describing the hypothetical universe before $t=0$. The claim that there was a universe ‘before’ ours seems to presuppose a common measure of time in the two universes.

quantum cosmology is discrete on a very small scale (meaning volumes of the order 10^{-100} cm^3), which has the observable consequence that photons of very high energy should travel faster than those of low energy.

Did the universe have an absolute beginning in time or not? The most honest answer is probably that we do not know and perhaps cannot ever know. It may be one of those questions about which we cannot even tell whether it is meaningful or not or whether it belongs to science or not.

20.7 Conclusion

The cosmological world view of the twenty-first century, largely identical to the standard big bang theory, is to a considerable extent what the Copernican world system was in the seventeenth century. Just as this system was not only a new theory of astronomy but also carried with it wider implications related to philosophy, religion and social order, so the modern picture of the universe cannot be easily separated from extra-scientific considerations. Such considerations, be they of a philosophical, conceptual or religious nature, should to some extent appear also in the teaching of science and do it in a qualified and critical manner.

One of the important aims of science education is to bring home the lesson that although science provides us with reliable and privileged knowledge of nature, it does not answer all questions that are worth asking. This lesson emerges with particular force from the study of cosmology. It may be expressed more poetically with a famous quotation from Shakespeare's *Hamlet*: 'There are more things in heaven and Earth, Horatio, than are dreamt of in your philosophy'. Recall that at the time of Shakespeare, the term 'philosophy' had a meaning corresponding to our 'science'.

Part VIII
Pedagogical Studies: Mathematics

Chapter 21
History of Mathematics in Mathematics Education

Michael N. Fried

21.1 Introduction

On the face of it, with so many good essays on the history of science in science education, a separate chapter on mathematics education might well be thought unnecessary. Considerations regarding history of mathematics in mathematics education, it is true, are similar to those regarding history of science in science education. Similar benefits, for example, have been cited in both cases, including humanizing subject matter, adding variety to teaching, showing alternative approaches to scientific ideas, analyzing students' understandings and misunderstanding, and deepening a sense of the nature of the discipline. For both, too, there are similar difficulties.[1] For one, both must confront mundane but no less worrying problems, such as finding time for history and fitting historical material into an already crowded curriculum; but also they must confront deeper problems arising from the tension between anachronism and relevance and between useful rational reconstruction and faithful historical analysis.

The case of mathematics education, however, differs from that of science education as mathematics itself differs from the natural sciences. That difference, of course, is subtle and cannot be reduced simply to whether one or the other is more empirical or more cumulative. Indeed, it is precisely historical and philosophical studies that have made clear the extent to which science can develop according to nonempirical theoretical issues, while mathematics can take on an empirical or quasi-empirical character, as Lakatos liked to put it (e.g., Lakatos 1986). Still differences do exist along these lines. In arguing his own theory of mathematical

---

change, Kitcher (1984), for example, points out that "…mathematics often resolves threats of competition [between opposing theories] by reinterpretation, thus giving a greater impression of cumulative development than the natural sciences" (p. 159).

Leaving aside whether or not it is justified, this impression that Kitcher refers to, combined with a Platonist tendency to see mathematical objects as given, typically translates into a sense that somehow the mathematics of the past is as valid now as it was in its own time, as opposed to the science of the past, which one easily (often *too* easily) takes to be obsolete or inadequate from the perspective of modern science. Consequently, the historical character of mathematics is often more problematic for students and teachers than the historical character of the natural sciences: it is more difficult, that is, for students and teachers to see mathematics of the past truly *being* of the past, truly different from the mathematics of the present. The benefits and difficulties of incorporating history of mathematics into mathematics education are, in their turn, all colored by this sense of the historical character of the discipline. So, despite striking similarities between questions connected with history of science in science education and history of mathematics in mathematics education, there is good reason to take a closer look at the latter independently of the former. This then is the purpose of the present chapter.

We shall proceed according to the following plan. Part 1 will take a brief look at several early instances of using historical mathematical material for learning. As we shall see, many of the justifications for incorporating history of mathematics in mathematics education proposed today are prefigured in this educational history, and this will give the entire chapter a spiral character. The discussion in this first part will also hint at the question of what it means to have a historical approach in the first place. The reader should be warned, however, that this part in no way presumes to be a thorough history of the subject in any sense of the word; indeed, that history needs one day to be written!

Part 2 will examine three central themes associated with more recent attempts to bring history of mathematics into mathematics education: the motivational theme, the curricular theme, and the cultural theme. Inevitably, these themes, to a greater or lesser degree, rest on presuppositions concerning the nature of mathematics, history of mathematics, and mathematics education itself.

Part 3 then looks more closely at these presuppositions by considering them in light of how historical inquiry in general is understood. It is this part that most directly addresses how the historical character of one's approach in bringing history of mathematics into mathematics education relates to its benefits and difficulties. It asks, at bottom, in what sense do students gain historical *knowledge* of mathematics or an historical outlook regarding mathematics? Tensions between frameworks based on the curricular theme and those based on the cultural theme, in particular, are revealed by this line of thinking. Responding to these tensions may demand reconceiving what mathematics education is about. The use of original sources is examined in this context and is discussed in this part together with some empirical findings.

21.2 Some Early Instances of Using Historical Material in Mathematics Education

In the 1970s, the idea that history of mathematics could play a part in mathematics education began to take root broadly in the mathematics education community. More importantly, in those years, educational interest in history of mathematics became organized at national and international levels, especially, with the establishment of the *International Study Group on the Relations between the History and Pedagogy of Mathematics* (ISGHPM or, as it is now known in its abbreviated form, HPM). The many conferences, books, and international cooperation that arose from the HPM and other organizations tempt one to think that before the 1970s, interest in using the history of mathematics in mathematics education was rare at best, and concrete instances of such use were thin on the ground if existing at all. In fact, historical material has almost always been present, one way or another, in mathematics education, in one form or another.

The qualifications in the last sentence are necessary because of the variety of ways one can treat historical materials and conceive one's relationship to the mathematics of the past and, at the same time, because of the variety of settings for learning mathematics and ways of understanding what it means to be mathematically educated. Notions of what it means to learn mathematics and where mathematics learning takes place are connected to the history of mathematics education proper, which has been an area of active interest on its own in recent years (observe, e.g., the existence of the *International Journal for the History of Mathematics Education* edited by Gert Schubring). But by taking into account the variety of ways of treating history and defining one's relation to the past, the present discussion becomes connected as much, or even more, to historiography. Indeed, although we shall speak of this in more depth later in the third part of this chapter, it is important to keep in mind now that in thinking about how history of mathematics comes into the learning of mathematics, it is impossible to separate considerations of the nature of history itself and of the telling of history from its use in teaching.

The blurred borders between doing and learning mathematics and history and historiography of mathematics are particularly apparent when one tries to understand mathematics education of the ancient classical period. Education in the ancient world is, altogether, a topic difficult to give an account of in plain and simple terms. The key notion is that of *paideia*. This Greek word has been translated variously as "culture," "civilization," "tradition," or, simply, "education"; more tellingly, its typical Latin translation is *humanitas*. The course in *paideia* is the *enkyklios paideia* from which we derive the word "encyclopedia," and yet the acquiring of *paideia* was not considered the acquisition of encyclopedic knowledge. The immense difficulty of the idea of *paideia* is evident in the mere fact that the great classical scholar Werner Jaeger needed three thick volumes to describe it (Jaeger 1945). One can say this though, that *paideia* entailed knowledge of a certain corpus of literature as well as the possession of skills and a presence of mind to think, speak, and act in an intelligent manner, one might say in a *cultured* way.

The emphasis on thinking, speaking, and writing is one reason why rhetorical training was so central in classical education and why some of our best accounts of classical education of the time are specifically of rhetorical education (see, for example, Kennedy 2003). The nature of mathematics education is much less clearly laid out, and there seems to be a large gap between accounts of very elementary education (discussed by Mueller 1991) and the more advanced mathematics education leading to the work of figures like Archimedes and Euclid (Fried and Bernard 2008). One key to understanding classical education, whether it be rhetoric or mathematics, is that such education was pursued for a lifetime; *paideia* had always to be cultivated. The speeches of the fourth century BCE rhetorician, Isocrates, therefore, were explicitly not only speeches as such but also models for himself and his students – production, teaching, and learning, for him, flowed seamlessly into one another.

This makes Marrou's referring to ancient "textbooks" in mathematics, meaning books such as Euclid's *Elements* (Marrou 1982, pp. 177ff) as plausible as it is deceiving. For, on the one hand, even though the *Elements* was used as a school textbook almost into modern times, it was in its own time the work of a mature mathematician addressed to mature mathematical audiences for whom "elements" meant something much more than "elementary" (Fried and Unguru 2001, pp. 58–61). On the other hand, as we noted regarding Isocrates' speeches, the perfecting of one's own *paideia* could include teaching and learning from the *Elements*. In that light, it is quite natural that Proclus, writing both as a philosopher and as the head of the Platonic Academy in the fifth century CE, should produce a commentary on just the first book of the *Elements* and refer often to its effect upon students. And, by the latter, it is perfectly clear Proclus includes himself as well as those younger than him.

Proclus' *Commentary on the First Book of Euclid's Elements* (Morrow 1970; Friedlein 1873) is also one of the important sources we have for the history of mathematics. Proclus refers often to the historical development of mathematics and, by giving his own principal source, Eudemus of Rhodes (fourth century BCE), he also tells us much about one of the early histories of mathematics, Eudemus' no-longer-extant *History of Geometry*. From Proclus, and elsewhere, we know that Eudemus' approach to history involved pointing out and discussing the first discovers of a given result, the *prōtoiheuretai* (see Zhmud 2006). The verb *heurein*, from which we derive the English word *heuristic*, means actually "to find" or "to invent." In the rhetorical educational tradition, *heuresis* is an extremely important term, for while the students, the *manthanontas* (i.e., those who engage in *mathēsis*, learning), learn by imitation, by studying texts, they must simultaneously learn to invent, to engage in *heurēsis* (Kennedy 2003; Fried and Bernard 2008); in rhetoric this means by studying speeches of masters, they learn to invent their own speeches. It is not unreasonable then to assume an educational principle in Proclus' attention to history and in the work of his historian predecessor Eudemus: through learning about the first inventors of mathematical ideas, students discover their own powers to invent. As we shall see shortly, this has remained, *mutatis mutandis*, a motive for introducing historical elements into mathematics education.

It can be argued that although Proclus engages with mathematics and mathematicians of the past, he does not treat these historically. His relationship to earlier mathematicians is one of colleagues, despite the great span of time separating them. But as I have outlined elsewhere, there is a broad spectrum of possible relationships to the mathematics of the past, including that of "colleagues"(Fried 2011, where a sample of eight relationships was described). There are, for example, "treasure hunters," who try and bring up gems lost in the past; "conquerors," like Descartes, who refer to the past to show the superiority of the present; "privileged observers," like H. G. Zeuthen, who think their modern mathematical knowledge privileges them to interpret the past; and "historical historians of mathematics," who view the past as fundamentally different from the present and see the treatment of the past demanding more than present mathematical knowledge. These kinds of relationships do not necessarily correspond to historical periods. For example, regarding "colleagues," even in modern times, Hardy quotes Littlewood as having said the Greek mathematicians were merely "Fellows of another college" (quoted in Hardy 1992, p. 81). Whether or not these relationships are properly historical is just the sort of historiographical question I referred to above and it is far from settled. But one must accept that these relationships are *in some sense* historical; more importantly, they allow us a way of seeing how mathematics of the past, at least in some general way, has entered mathematics teaching and learning.

A "colleague" relationship to mathematics of the past, for example, can be discerned in the use of Euclid's *Elements* and other classic works as texts for teaching geometry from the Middle Ages to the nineteenth century. Howson (1982) points out that in England during the nineteenth century, an enormous number of new editions of Euclid for use in schools were produced and that "Many of these editions were, in fact, Euclid pure and simple; additional notes were often included, but no exercises, for the student was expected to memorise not to act" (p. 131). The study of geometry, in this respect, was identified with the study of a certain historical text. Yet it was not its historical character alone that was behind its use: similar to what I have suggested regarding Proclus, the use of Euclid's *Elements* was justified by its ability to train rigorous logical thinking, as good then as now. Interestingly enough, Howson (1982) makes very clear, the reform of mathematics education in England in the second half of the nineteenth century centered on the rejection of Euclid as a text (see also Carson and Rowlands 2000). It could be said that the whole argument surrounding Euclid's *Elements* stemmed from its being regarded on the same terms as a modern text, that is, as if it were a text written by a colleague. Yet, it cannot be discounted from the present discussion, for one, because there are still proposals for using history of mathematics whose claim to being history comes down to the fact only that a historic text is being used (and the counterargument is often the same as that against Euclid, namely, that it is not modern or not pedagogically sound!). Furthermore, the claim for using Euclid in the mathematics classroom is in line with a common claim for using historical texts in general, namely, that they often present accounts of mathematical ideas that are particularly clear, probing, or challenging.

But more explicitly historical views of the mathematics of the past can also be found in educational materials for teaching mathematics from the same time and before. A relatively early case was the classic 1654 text by the Jesuit Andreas

Tacquet (1612–1660) *Elementageometriaeplanae ac solidae* (Tacquet 1761), originally produced for students studying mathematics in the Jesuit colleges. It opens with a long "historical narrative of the origin and progress of the mathematical sciences" (*historiconarratio de ortu & progressumatheseos*) that students might know to what science the wisest figures of past times had dedicated themselves. In other words, Tacquet was telling his students, in effect, that in order to understand its importance, their study of mathematics must be pursued against the background of its history. He was not the first to hold this position; he himself refers to Ramus (1515–1572) as preceding him in this regard.

In a more formal way, and somewhat closer to the way we imagine history of mathematics entering education, we find in the late eighteenth century, in Poland, a very early interest in history of mathematics as a component of mathematics education – earlier, in fact, than a professional interest in history of mathematics in Poland. Domoradski and Pwlikowska-Brożek (2002) tell us that "The first Ministry of Education in Europe – *Komisja Edukacji Narodowej* (Commission on National Education) (1773–1794) – hoping to improve and broaden mathematics knowledge, recommended that students be acquainted with the history of mathematics beginning from antiquity" (p. 199). The case of Poland is remarkable when one considers that something like national curricula for education were almost nonexistent before the eighteenth century, so that history of mathematics, here, came into the mathematics curriculum almost at the same time the mathematics curriculum, in the modern sense of the word, itself was coming into being.

As for the next century, especially towards its end, one finds clear instances of an interest in the history of mathematics and science in education in French education and educational policy. From around 1869, for instance, questions concerning "the historical method" in science and mathematics began to appear in official "agrégation" examination for teachers of science (Hulin 2005). Somewhat later, Paul Tannery (1843–1904), who falls somewhere between what I called above the "privileged observer" type and the "historical historian of mathematics," developed a course of studies for the history of science to make clear "the order of ideas, true or false, that dominate each of the sciences" (Hulin 2005, p. 393, my translation), and he taught a course in the history of mathematics in the Paris Faculty of Science from 1884 to1886 (Hulin 2005; Peiffer 2002).

An interest in the role of history of science generally continued into the twentieth century in France, culminating perhaps in the activities of IREM (Institut de Recherche sur l'Enseignement des Mathematiques) at the end of the century. But at the start of the century, we have Ernest Lebon, then minister of public instruction, expressing the desire that history of science be made part of secondary school teaching and a sanctioned part of the baccalaureate examination (Hulin p. 389).[2] This interest took in mathematics as well, though at times the justifications for history of science were different than those for mathematics. The physicist Paul Langevin, for example, in the first quarter of the twentieth century was a strong advocate for history of science as a way for combating dogmatism

---

[2] Lebon's remarks were made as a delegate to the Congrès' histoire comparée in 1900.

(Bensaude-Vincent 2009, p. 16), which was not a common theme if at all for history of mathematics in mathematics education.

Significant efforts were made to introduce history of mathematics into mathematics education and teacher education in the United States, where ironically, as Robert Hughes has remarked, "Americans love to invoke the idea of American newness" (Hughes 1997).[3] In the period between the last years of the nineteenth and the first quarter of the twentieth centuries, two figures stand out in this and other aspects of American mathematics education. These are Florian Cajori (1859–1930) and David Eugene Smith (1860–1944).

D. E. Smith was an excellent historian of mathematics, but he also made great contributions to mathematics education in America and on the International scene.[4] That history of mathematics, in his view, was not separate from mathematics education is clear from his classic book, *The Teaching of Elementary Mathematics* (Smith 1904), which contains three entirely historical chapters and several others in which history has a part. And at the Michigan State Normal School in Ypsilanti, where D. E. Smith held the mathematics chair, he designed a course on the history of mathematics for teachers that "…became the foremost distinguishing characteristic of Smith's program: the importance of a historical perspective" (Donoghue 2006, p. 562). It is no surprise then that Smith was on the committee that prepared the 1923 report by the *National Committee on Mathematical Requirements* written under the auspices of the *Mathematical Association of America* in which cultural aims of mathematical education, in general, were highlighted, including "…the role that mathematics and abstract thinking, in general, have played in the development of civilization" (in Bidwell and Clason 1970, p. 394).[5]

Looking back across the ocean for a minute, I should mention that the cultural motive described in the 1923 report was also evident in Felix Klein's enthusiasm for a historical component in mathematics education. Historical sections appear in parts I and II of his *Elementary Mathematics from an Advanced Standpoint* (Klein 1908/1939). In the geometry part (part II), Klein states quite explicitly that "…I shall draw attention, more than is usually done…to the *historical development of the science*, to the accomplishments of its great pioneers. I hope, by discussions

---

[3] In the same place just cited (Hughes 1997), Hughes, whose focus is art in America, also refers to an American "worship of origins": the tension between old and new seems to be very much part of the American psyche.

[4] It was Smith who suggested the formation of an international society for mathematics education in a paper in 1905 published in *L'Enseignement Mathématique*. This became the *International Commission on Mathematics Instruction*, the ICMI established in Rome in 1908.

[5] Bidwell and Clason correctly point out (p. 394, note 3) that the ideas in this section of the report parallel closely views in other writings by Smith, for example, his "Religio Matematici" published in the *American Mathematical Monthly* (vol. 28, pp. 339–349) in 1921. The latter, I should say, is not strictly speaking about history of mathematics per se; it is piece written on the model of Thomas Browne's *Religio Medici* and tells what the belief is of a mathematician. Nevertheless, one of the articles of faith is that "Mathematics is a vast storehouse of the discoveries of the human intellect. We cannot afford to discard this material" meant to parallel to the claim that "Religion is a vast storehouse of the discoveries of the human spirit. We cannot afford to discard this material" (Smith 1921, p. 348).

of this sort, to further, as I like to say, your general *mathematical culture*: alongside of knowledge of details, as these are supplied by the special lectures, there should be a grasp of subject-matter and of historical relationship [emphases in the original]" (Klein 1908/1939, II, p. 2). Incidentally, this work by Klein was published in the same year as the founding of *International Commission on Mathematics Instruction* (ICMI), initiated by Smith and headed by Klein as its first president. But let us return to America and Florian Cajori.

Cajori's first historical work was published by the US Bureau of Education and was entitled *The Teaching and History of Mathematics* (1890). As Dauben (2002) points out, "…Cajori was the first in a continuing American tradition of mathematicians interested in the history of mathematics due to its perceived value in teaching" (p. 265). Three years later, Cajori wrote a textbook for the history of mathematics, underlining his interest that this be used by students, rather than other mathematicians or professional historians of mathematics. Cajori's next book *A History of Elementary Mathematics with Hints on Methods of Teaching* (1896) makes the educational motive for his endeavors into the history of mathematics even more explicit. He opens the preface with a quotation from Herbert Spencer in which the following principle is stated: "The education of the child must accord both in mode and arrangement with the education of mankind as considered historically; or, in other words, the genesis of knowledge in the individual must follow the same course as the genesis of knowledge in the race".[6] Cajori then uses this to justify his own use of history of mathematics for mathematics teaching:

> If this principle, held also by Pestalozzi and Froebel, be correct, then it would seem as if the knowledge of the history of a science must be an effectual aid in teaching that science. Be this doctrine true or false, certainly the experience of many instructors establishes the importance of mathematical history in teaching. (p. v)

It is interesting to note that these works of Cajori were carried out before he carried out serious historical work on mathematics under the instigation of no less than Moritz Cantor. (Dauben 2002, p. 266) In other words, Cajori's interests in history of mathematics, as an independent field of inquiry, came *after* his interests in it as an adjunct to teaching.

The principle adduced by Cajori to justify his own historical approach is one of the most persistent and in some ways the most serious reasons given for using history of mathematics in mathematics education. The principle is called variously the genetic principle, the biogenetic law, the principle of parallelism, or the recapitulation principle, after the famous biological principle associated with Ernst Haeckel (1834–1919) that ontogeny, the development of an individual, recapitulates the development of the species, phylogeny (see Schubring 2011; Furinghetti and

---

[6] Cajori continues the quotation in which Spencer attributes this principle to Auguste Comte insisting at the same time that the principle can be accepted without accepting Comte's entire theory of knowledge. That Cajori leaves this in the quotation may be a sign that he too had reservations about Comte's theories taken as a whole. Still he, like Spencer, accepts the general genetic principle as a principle for guiding education. The quotation is from the second chapter, "Intellectual Education," of Spencer's *Education: Intellectual, Moral, and Physical* first published in 1861 (Spencer 1949/1861).

Radford 2008).[7] Important figures in the early development of modern mathematics education were adherents to the principle. Thus, calling on the biological principle as his model, Poincaré wrote in 1899 in, that "The educators' task is to make children follow the path that was followed by their fathers, passing quickly through certain stages without eliminating any of them. In this way, the history of science has to be our guide" (*L'Enseignement Mathématique,* quoted in Furinghetti and Radford 2008, p. 633). Felix Klein too, as Schubring (2011) points out, "decisively promoted the genetic principle" (p. 82), even though Klein, as described above, also saw studying history of mathematics in conjunction with mathematics as a matter of general mathematical culture.

The strength of the principle as a guiding principle for mathematics education can be judged by the fact that in 1908[8] an entire book on mathematics education – one of the very earliest books entirely dedicated to the subject – was published by Benchara Branford (1867–1944) in which the genetic principle played a central role.[9] In fact the frontispiece of Branford's *A Study of Mathematical Education* (Branford 1908, see the Fig. 21.1 below) is a "Diagram of the Development of Mathematical Experience in the Race and in the Individual": it is graphic representation of the entire theory, with stages of human history and various occupations such as geodesy and physics as well as what Branford calls primary and derivative occupations (such as miner, shepherd, and scribe, among others, corresponding to "infancy") listed along the left margin; the development of mathematical subjects together with an indication of the degree of "sense activity" and "thought activity" in the center; and the periods of an individual's life – embryonic (!), infancy, childhood, school, college – listed in the right margin. Referring to the diagram, Branford summarizes the educational implication, saying, "Thus, for each age of the individual life infancy, childhood, school, college may be selected from the racial history [i.e. history of the human race] the most appropriate form in which mathematical experience can be assimilated" (p. 245). It is worth noting that later in the work (p. 326), Branford cites exactly the same passage from Herbert Spencer's *Education* quoted by Cajori.

---

[7] Although those who use these various terms may see some shades of difference between them, here we shall commit the minor sin of lumping them together into a single perspective, one asserting that historical development can *in some way* provide a guide for individual intellectual development or course of learning.

[8] According to Scott (2009), Branford began the work in 1896.

[9] Schubring (2011) denies that Branford should be taken as the "classical advocate and propagator of that parallelism [the biogenetic principle grafted onto psychology] for the purposes of education" (p. 83). Yet, the fact that Branford took the genetic principle as a guide to his thinking about mathematics education and a "scientific" principle to ground research is certainly clear, and Schubring himself points out that "The merit of Branford's book…lies in his reflections and differentiations concerning the notion of the biogenetic law" (p. 83). Moreover, although Schubring says that too much weight has been placed on the frontispiece of the book, one must consider that that diagram was nevertheless chosen *as* the frontispiece and, therefore, meant to set the stage for the book. Furthermore, it is not merely an illustration presented and forgotten: an entire chapter is dedicated to the interpretation of the figure (Chap. 16), and many of the other chapters follow its structure.

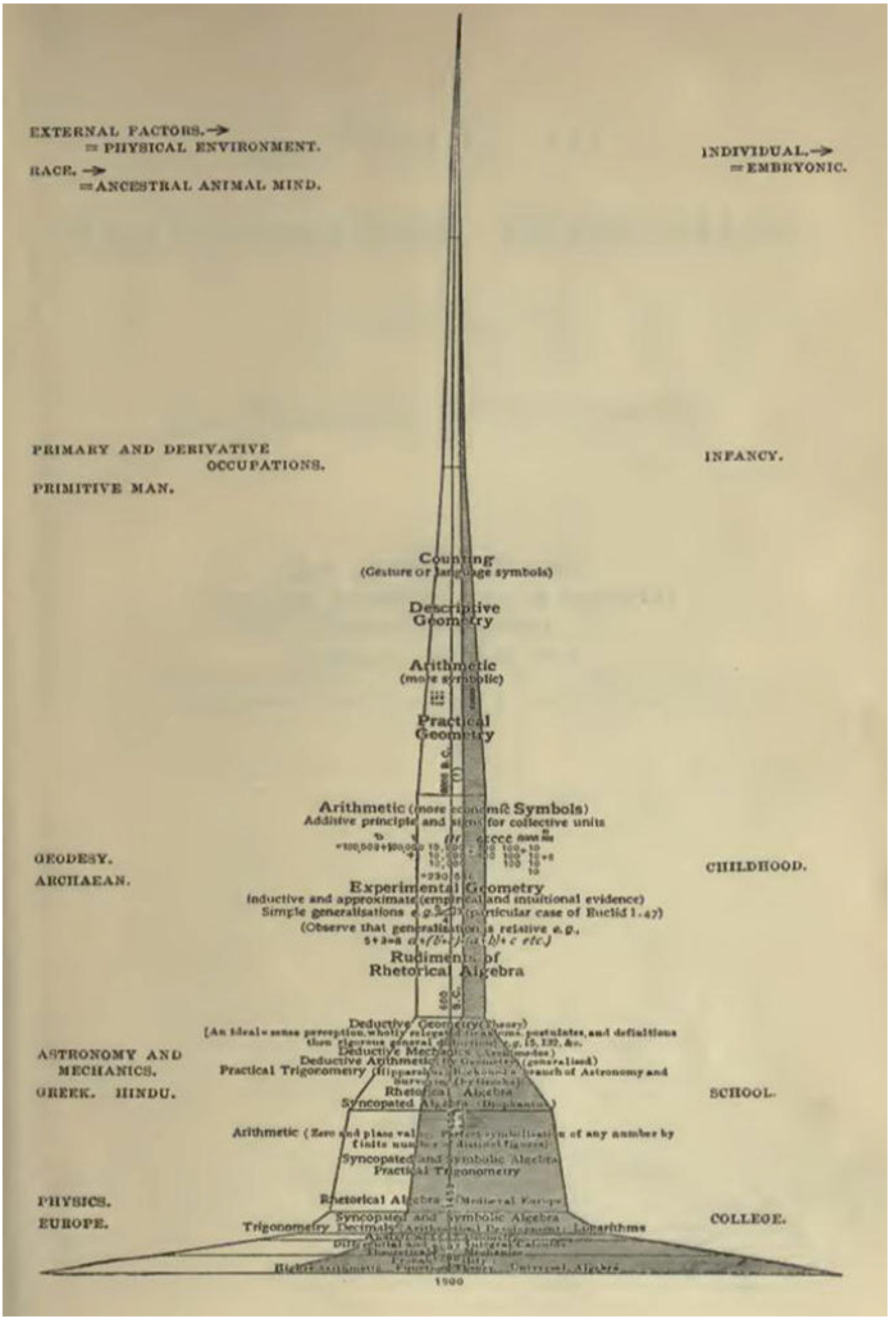

Fig. 21.1 Frontispiece of Benchara Branford’s *A Study of Mathematical Education*

Probably the most famous instance of the genetic approach taken up practically was Otto Toeplitz's (1881–1940) course in calculus according to the genetic methodology, published posthumously in 1949 as *Die Entwicklung der Infinitesimalrechnung: Eine Einleitung in die Infinitesimalrechnung nach der genetischen Methode* republished in English in 1963 as *The Calculus: A Genetic Approach* (Toeplitz 1963). Toeplitz distinguishes between the direct and indirect genetic approach (Toeplitz 1927). In the direct genetic approach, the historical development is presented to the student as a way of presenting mathematical concepts themselves – an approach that should have an effect because of the basic assumption of the genetic principle. It is this direct approach that most characterizes Toeplitz's 1949 work. Thus, he begins his text with a chapter, "The nature of the infinite process," and continues according to the following sequence: "The beginning of Greek speculation on infinitesimals," "the Greek theory of proportions," "the exhaustion method of the Greeks," "the modern number concept," "Archimedes' measurements of the circle and the sine tables," "the infinite geometric series," "continuous compound interest," "periodic decimal fractions," "convergence and limit," and "infinite series." Overall, like most calculus textbooks, he aims towards the idea of limit, but his path to that concept is guided by historical precedents and examples rather than strictly logical considerations.[10]

In the indirect approach teachers use the historical development to draw conclusions about teaching mathematical concepts, which subsequently need not be historical. As Toeplitz puts it, the indirect approach consists of a "Clarification of didactic difficulties, I should say, didactical diagnosis and therapy (didaktische Diagnose und Therapie) on the basis of a historical analysis…" (Toeplitz 1927, p. 99, my translation). About this, Schubring (2011) says "Toeplitz's indirect approach looks not so much on knowledge, but on meta-knowledge, and his main focus is on how to provide future teachers in their training with such a meta-knowledge about mathematics" (p. 9). But Schubring also says that Toeplitz could never really free himself from a teleological viewpoint, from the notion that mathematical development is continuous and cumulative so that "his own notion of an indirect approach could not become fruitful" (p. 10).

Yet, that "teleological" viewpoint seems almost unavoidable if one adopts the genetic point of view. To assume that an individual's mathematical development follows the historical development of mathematics means that the historical development is somehow as natural and directed as that of an organism. It is thus not surprising that in his biography of Toeplitz in the *Dictionary of Scientific Biography*, Abraham Robinson should point out that Toeplitz "…held that only a mathematician of stature is qualified to be a historian of mathematics" (Robinson 2008, p. 428). The genetic point of view suggests a position towards the past that I categorized above as that of a "privileged observer."

---

[10] One only has to think of Edmund Landau's famous calculus text (Landau 1965) to grasp the contrast.

21.3 Three Themes in Our Own Time

In these older instances of using history or adopting a historical orientation in mathematics education, one can see the presence and emergence of themes still at work in current discussions of the subject.[11] History of mathematics as part of students' cultural education, a theme recognizing the enterprise of mathematical inquiry as part of students' cultural heritage in general as well as in the specific context of the sciences, has become all the more important as we recognize the centrality and formative power of culture altogether. And it ought to be emphasized here that in recognizing mathematics as a part of culture, one also adopts a view of the nature of mathematics. Let us call this, then, the *cultural theme*, keeping in mind that it is both a reflection on general culture as including mathematics and also on mathematics as being cultural. Besides this theme, which we saw in connection with Felix Klein and D. E. Smith, we also noted the suggestion that history of mathematics can help clarify or deepen the understanding of mathematical ideas: this theme, which could already be found in Proclus and certainly in Toeplitz, continues to be a potent reason for turning to the history of mathematics in mathematics education. Let us call it the *curricular theme*: it includes then both arguments claiming historical treatments of mathematical topics, such as that of Euclid, have great pedagogical power either in themselves or by offering a contrast to modern approaches, as well as the genetic argument and its variations. A third theme, which we did not encounter in our brief survey above, is what we should call the *motivational theme*.[12] We shall begin with this last.

21.3.1 The Motivational Theme

The motivational theme is that history of mathematics makes mathematics teaching less threatening, more human, less formal, and more interesting; the motivational theme introduces an affective consideration into the question of history of mathematics in mathematics education. Ironically, the objection to Euclid in the nineteenth century was partly on the grounds that it was dull![13] In a well-known

---

[11] Besides discussions in the context of meetings connected with the HPM mentioned above, other recent forums include those at the CERME meetings. See, for example, Kjeldsen (2011) and Tzanakis and Thomaidis (2012).

[12] Another theme one might suggest is an epistemological theme concerning the possibility that knowing the history of mathematics is knowing mathematics: but this is included in both the cultural and curricular themes together.

[13] That Euclid should be made more colorful was taken up literally by Oliver Byrne who produced a version of Euclid using a system of colors in place of Euclid's lettered diagrams and corresponding text. The book was meant to make Euclid more approachable, as advertized in the full title: *The first six books of the Elements of Euclid in which coloured diagrams and symbols are used instead of letters for the greater ease of learners* (Byrne 1847).

textbook meant to reform the teaching of geometry by replacing Euclid, the author James M. Wilson wrote that:

> We put a boy down to his Euclid; and he reasons for the first time…but we make him reason in iron fetters…we make the study of Geometry unnecessarily stiff, obscure, tedious and barren….And the result is, as everyone knows, that boys may have worked at Euclid for years, and may yet know next to nothing of Geometry (Wilson 1868, pp. vi–vii)

But today, the motivational theme is quite often called upon to justify a historical approach (see Gulikers and Blom 2001, who also refer to "motivational arguments" for history of mathematics). This was certainly the case with Perkins (1991), who saw history as a vehicle for making classroom teaching more interesting and, in so doing, a vehicle for improving students' achievement. A more recent example comes from a Turkish study (Kaygin et al. 2011) in which the authors say, "Thanks to the vast culture and wide knowledge held within the history of mathematics, it becomes easier to understand the abstract concepts of mathematics which is thus [no] longer a subject arousing fear and concern" (p. 961).

A clear statement of the motivational theme can be found in a paper by Po-HungLiu (2003) addressed to teachers and asking, "Do teachers need to incorporate the history of mathematics in their teaching?" Liu's answers include in fact all three of the themes that I have mentioned, but he begins with the motivational theme. He writes:

> As sometimes taught, mathematics has a reputation as a "dull drill" subject, and relevant studies report a steady decline in students' attitudes toward the subject through high school. The idea of eliciting students' interest and developing positive attitudes toward learning mathematics by using history has drawn considerable attention. Many mathematics education researchers and mathematics teachers believe that mathematics can be made more interesting by revealing mathematicians' personalities and that historical problems may awaken and maintain interest in the subject (p. 416)

Pursuing this theme sometimes reduces to light storytelling as in Lightner's "Mathematicians are human too" (Lightner 2000), where Lightner tells a series of humorous anecdotes about mathematicians so that students learn that "…mathematicians were all human beings with peculiar foibles and personality quirks just like the rest of us" (p. 699). For example, Lightner tells us how Norbert Wiener was so absentminded he habitually forgot not only where he parked his car but also which car he drove, and so, after a seminar, he would wait patiently until every car left the parking lot but one, his![14]

As a justification in mathematics education, one should not be completely dismissive of the motivational theme. Getting students to want to learn mathematics is a natural and important goal for mathematics educators, especially when so much emotional baggage truly gets in the way of students' learning mathematics – ranging from distaste and a sense of mathematics as dry and rigid, to frustration and fear.

---

[14] Theodore Eisenberg has asked elsewhere (Eisenberg 2008) whether we also ought to tell some of the less amusing stories about mathematicians, about their occasional racism and association with Nazis.

So it is not for nothing that much serious research in mathematics education has looked at affect and its relation to mathematics learning and achievement (e.g. Goldin 2009; McLeod 1994). However, while the educational motive behind the motivational theme may be serious, as a theme connected with the incorporation of history into mathematics education, it is problematic. First, it supposes, not always consciously, that mathematical content alone, unembellished with stories, anecdotes, or colorful characters, cannot itself be made sufficiently interesting to hold students' attention. History is presented as something *to add* to mathematics lessons to "enliven" teaching, teaching that, one must assume, would *otherwise* be dull and dry. Second, history as a body of knowledge to learn and to take seriously is put aside and turned into a mere ploy for drawing students into learning the mathematics their teachers are required to teach. Put baldly, if a good story will keep students from falling asleep in class, tell it; whether or not the story is true, informative, or deep is pertinent, but it is secondary to its being entertaining. And like the story about Norbert Wiener, it does not even have to be, strictly speaking, about mathematics. The motivational theme, accordingly, ends up doing justice neither to history nor to mathematics itself. That said, it must be underlined that similar difficulties exist, albeit more subtly, in other cases where history is brought into the mathematics classroom. The main problem is that history in such cases is superadded to mathematics education, with the particular identity of history as a form of knowledge being lost in the process.

21.3.2 The Curricular Theme

The curricular theme as a focus for introducing history of mathematics into mathematics education must be taken much more seriously, for there is a genuine attempt in this case to see mathematical *ideas* in the light of history. For this reason, it is right that Gulikers and Blom (2001), in their survey of recent literature on history in geometrical education, refer to what I am calling the "curricular theme" as the category of "conceptual arguments." Yet it must be kept in mind that whatever concepts are spoken of here, they are not so much drawn out from the history, but – like the concepts of function, number, and equation – are given in advance, as if from a set curriculum and, only subsequently, discussed historically.

It is in the curricular theme, then, that one sees most clearly the tendency described in my introduction, namely, the tendency to treat the mathematics of the past, though perhaps incomplete, to be as valid now as in its own time. So, for example, even if Euclid did not have group theoretical tools for geometry, he did have theorems on congruence and similarity – and, to that extent, we can use Euclid's work as a basis for our own teaching. Or, in this view, we can take ideas that, from a modern standpoint, are "implicit" in historic texts and translate them into a modern idiom, for example, translating Apollonius' principal properties for conic sections – what he called their *symptōmata* – into equations for conic sections. History of mathematics from the perspective of the curricular theme, as the name implies, makes the least demands from the point of view of the curriculum, for historical treatments of mathematics can be adapted in such a way that they are consistent with a modern program of studies. It is not surprising then that when one looks at Gulikers and Blom's tables of articles in various subject categories of geometry that of the 36 articles in which resources are cited, 24 either have a "written guide with modern exercises," or a "written guide with 'old' problems translated into modern mathematical language" (Gulikers and Blom 2001, Appendix A).

I might point out that this theme could be interpreted as a motivational theme, but in the deeper sense of motivating an idea or a position, an answer to the question, why should we study subject X in chapter Y of the curriculum? This is Fauvel's approach when he discusses the history of logarithms (Fauvel 1995): the paper attempts to provide an answer to a friend who, when hearing Fauvel was thinking about how to teach logarithms, asks "Whatever for?" (p. 39). Fauvel goes on to show in the paper that by considering the history of logarithms, one sees how considerations of this tool, which may be used little nowadays, lead one to important mathematical ideas[15] and ideas about mathematics. The curricular theme, in this light, provides a different nexus for mathematical ideas than would a "logical" approach[16]: providing a motivation for a mathematical idea shows in a way different from pure logic why one idea follows another.

Often the curricular theme is pursued by just taking a problem from the past that allows students to exercise and develop mathematical thinking and skills relevant to their school studies. For example, Kronfellner (2000) uses the problem of duplicating the cube[17] as a means to study topics such as irrational numbers, series, nonlinear analytical geometry, and curves – and he says explicitly that this is one strategy for introducing history into mathematics teaching, namely, "…to offer suitable tasks in which a traditional curriculum topic is connected with history." Swetz's (1995) "Historical Example of Mathematical Modeling: the Trajectory of a Cannonball" is another good instance where a historical problem becomes an opportunity to use and deepen mathematics studied in the classroom. As Swetz puts it: "Contemporary secondary school students can explore a variety of problem-solving situations involving trajectories and use their knowledge of geometry, algebra, trigonometry, vectors, calculus and even computer programming" (p. 101).

In a recent special issue of *Mathematics in School*, Elizabeth Boag's article on the "Dandelin Spheres" (Boag 2010) is a good example of how a historical topic can suggest not just a problem but also an approach to a school subject, in this

---

[15] Toeplitz similarly saw the logarithm as an entrance to important mathematical ideas and discusses it prominently in the chapter of his genetic approach concerning the fundamental theorem of the calculus (Toeplitz 1963, Chap. III).

[16] We shall soon encounter the "logical approach" again in connection with the 1962 Memorandum by Morris Kline and associates (Memorandum 1962).

[17] The classic problem is to find the side of a cube whose volume is twice that of a given one. The ancient interpretation was to find two mean proportionals between a line and its double, that is, two lines A and B satisfying the proportion: M:A::A:B::B:2 M. The modern translation is to construct the cube root of 2.

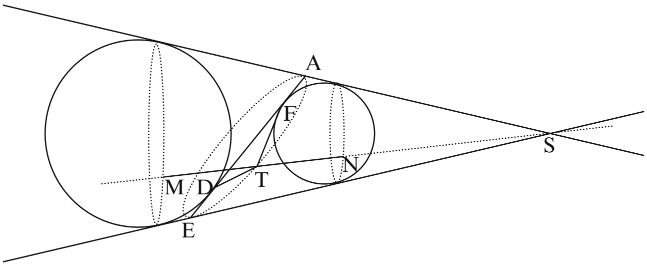

Fig. 21.2 Dandelin spheres for the case of the ellipse

case, the focal properties of conic sections. Just to remind the reader, what G. P Dandelin (1794–1847) showed in the course of his work, "Mémoire sur quelques propriétés remarquables de la focale parabolique"(Dandelin 1822), was that the focal properties of the conic sections, say of the ellipse, could be conceived strictly in terms of the cone. Consider the property that the sum of the lines from a point on an ellipse to the foci is constant: suppose a right cone is cut by a plane such as that containing the line AE and let two spheres be inserted in the cone, tangent to generating lines of the cone and to the cutting plane.[18] As for the latter, let them be tangent to the plane at points D and F (see Fig. 21.2) – these, it turns out, are the foci of the ellipse produced by the cutting plane.

Let T be a point on the ellipse produced by the cutting plane and let SNTM be the generating line of the cone that passes through T. Then since TM and TD are tangents from T to the sphere, MT = DT. Similarly, TN = TF. Therefore, DT + TF = MT + TN = MN, which is constant.

The Dandelin spheres illustrate well how a mathematical development grounded in a historical text can be enlightening and useful in a classroom presentation. But how far can one say that this grounding in history is the essential element in the mathematical presentation? What really is the role of the historical context? Having shown the basic idea of the Dandelin spheres, Boag says, "Before continuing with the mathematics, I will give a brief biography of Dandelin" (p. 35). Three short paragraphs follow providing a few biographical details, the name of Dandelin's paper on the Dandelin spheres and where it was published, and then some further work by Dandelin following the 1822 paper. What I want to stress is not that Boag should have given more historical information – for the paper, in many ways a very good one, was meant to be short from the start – rather, it is that the historical background and mathematical content are taken as separable. The mathematics is stopped and then continued after the history; it is not continued into the history, nor is the history continued into the mathematics. If the Dandelin spheres were presented to a reader of Boag's article without ever

---

[18] Dandelin's diagram shows a planar section, with no perspective and no variation of line types, as I have done here; however, the lettering is consistent with Dandelin's. In her paper, Boag gives Dandelin's original diagram in facsimile as well as her own.

mentioning Germinal Pierre Dandelin, they would possess no less explanatory power and probably no less charm.[19]

In the examples of the curricular theme so far, the position assumed with relation to the past is very similar to that of "the treasure-hunter" described above: one dips into the past to pull out some beautiful example or approach, like the Dandelin spheres, which one can then use in the classroom. It is a completely legitimate way of using history, and it is legitimate to call it a historical approach, *if*, paradoxically, one accepts that there is a mathematical content that can be set off from all considerations of time, culture, and place: the gold one digs up may come in the form of unfamiliar coins, but it is gold nonetheless.

The genetic approach, which we have also included within the curricular theme, is much more subtle and places historical development at the center of its attention since it is there it finds its key to how students understand mathematical ideas and how they can learn to understand mathematical ideas better. As we said above, a teleological viewpoint is almost unavoidable in the genetic approach, and it is for this reason that the same mathematical ideas as those comprised in a modern curriculum can be assumed to exist, at least implicitly, in historical texts; this, in turn, proves the relevance of historical texts to the modern classroom. Again, the relation to the past implied by the genetic approach tends towards that of the "privileged observer."

To see how the genetic idea is expressed in current ideas about history of mathematics in mathematics education, however, we shall have to take a fairly general definition of it: we shall include in it any position that sees historical development as providing light on educational processes, students' learning and understanding, by somehow running parallel to these.[20] It will become apparent, though, that the genetic idea, viewed loosely as I intend to do, leads easily into the cultural theme, which undeniably tends away from a teleological viewpoint.

One year before Toeplitz's *The Calculus: A Genetic Approach* (Toeplitz 1963) appeared in English, the genetic approach appeared explicitly in a famous memorandum published in *The Mathematics Teacher* and *The American Mathematical Monthly* (Memorandum 1962). The memorandum was signed by 64 mathematicians but was, apparently, mainly the work of Lipman Bers, Morris Kline, George Pólya, and Max Schiffer, and, of those, mainly, Morris Kline (Roberts 2004). The paper was a thinly veiled attack on the curricular reforms forming the "new math" movement,

---

[19] The point, I must emphasize, is not that the Dandelin spheres have no historical interest. They do! As one of the anonymous reviewers of this chapter emphasized, correctly, Dandelin's ideas are indicative of the atmosphere created by Gaspard Monge's teaching at the École Polytechnique, where Dandelin was a student. This may provide a hint as to why Dandelin's spheres had to wait until the 19th century to be born. My point here is that these matters played no crucial role in the article which I have discussed, nor, *given the general orientation of the article*, did they have to.

[20] In this way I am allowing the views of Sfard (1995), Dubinsky et al. (2005), and others inspired by Piaget's ideas in *Genetic Epistemology* (1971) to come within range of genetic approaches, even if Schubring (2011) claims, with some justice, that Sfard, for example, misunderstands Piaget in this connection and adopts only a primitive form of parallelism.

chief among them the *School Mathematics Study Group* (SMSG), headed by Edward Begle. The writers warned that it would "be a tragedy if the curriculum reform should be misdirected and the golden opportunity wasted" (p. 189), and, therefore, they would set out "fundamental principles and practical guidelines."

The paper then goes on to discuss seven guidelines of which the fifth is "genetic method." For Kline and the others, the genetic method furnished the ground for a direct attack on the thinking behind the "new math," namely, that when it comes to teaching and designing a curriculum history is a more dependable guide than the logic of an axiomatic system. Thus the memorandum states:

> This genetic principle may safeguard us from a common confusion: If A is logically prior to B in a certain system, B may still justifiable precede A in teaching, especially if B has preceded A in history. On the whole, we may expect greater success by following suggestions from the genetic principle than from the purely formal approach to mathematics. (pp. 190–191)

It is hardly surprising then that when Edward Begle responded to the memorandum (Begle 1962), he was conciliatory on most points *except* for the genetic principle. About that, he said it would "…require children to learn to compute with Egyptian, Babylonian, Greek and Roman numerals before being introduced to the historically later but far more efficient place value decimal system" (p. 426).

It is worth noting, too, that this exchange, in which the genetic approach was endorsed on the one side and rejected on the other, happened to be between one group of prominent mathematicians and another. For although it is not wrong to refer to the SMSG, and "new math" movement in general, as "mathematician-dominated" (see Amit and Fried 2008), it is important to realize that in a historical framework for education guided by the genetic principle, one finds a framework as congenial to the modern mathematician as the formal-axiomatic one. Kline, it should be kept in mind, was himself a research mathematician, and he well understood that, logically, the ideas of sequence, limit, and convergence precede derivative and integral; yet, when he wrote his own calculus textbook (Kline 1977), he had no qualms about beginning with the derivative.

For education, naturally, the attractiveness of the kind of parallelism represented by the genetic approach lies in its potential to provide clear concrete models for teaching and for understanding students' learning. This potential, so clearly assumed in the 1962 memorandum, is still adduced, albeit in a more qualified tone. Thus following Victor Katz's paper on the development of algebra in the special issue on history of mathematics in *Educational Studies in Mathematics* (volume 66, number 2),[21] Bill Barton writes in his "Commentary from a mathematics educator" that "To the extent that the ontogenetic argument is useful in mathematics education, this reflection should cause us to rethink some current trends" (Katz and Barton 2007, p. 198). In that same issue, Yannis Thomaidis and Constantinos Tzanakis take up the theme in a more focused way in their paper, "The Notion of Historical 'Parallelism'

---

[21] I mention the special issue explicitly since it was one of the few instances that history of mathematics was given such broad attention in a leading research journal for mathematics education.

Revisited: Historical Evolution and Students' Conceptions of the Order Relation on the Number Line" (Thomaidis and Tzanakis 2007). Thomaidis and Tzanakis offer there what they see as empirical evidence both that students produce solutions to problems analogous to historical solutions and that they encounter difficulties which also follow a historical pattern.

That students' conceptual difficulties or epistemological obstacles[22] run parallel to conceptual difficulties in history has been taken up before (e.g., Katz et al. 2000; Bartolini Bussi and Sierpinska 2000; Herscovics 1989). Dorier (1998), for instance, uses history to identify students' problems with notions from linear algebra such as dependence. Among other things, he shows how Euler's notion of "inclusive dependence," as Dorier refers to it, the implicit redundancy of equations, is similar to students' conceptions and is what students need to overcome in order to arrive at more general notion of linear dependence: "Their concept of (in)dependence is, like Euler's, that of inclusive dependence and not linear dependence," he says (Dorier 1998, p. 150, see also Katz et al. 2000, p. 150). Plainly, this is a weaker application of the genetic principle than the traditional one in which students' learning of mathematical ideas actually recapitulates the historical development of those ideas; but it is also one much easier to swallow. That may be simply because these conceptual difficulties are truly difficulties, and one must contend with them whenever one faces them. On the other hand, is it not arguable that the compelling need to face these difficulties in the first place is a sign of their constant reoccurrence, strengthening the recapitulation theme? This is one possibility. But it is also possible that the reoccurrence of conceptual difficulties or any of a range of mathematical ideas is not because history and individual development proceed along parallel tracks, but because individual development is actually a *function* of historically conditioned ideas. In other words, the reoccurrence of mathematical ideas in individual development might be because those ideas and their mode of development are embedded in the culture in which children's mathematics education is situated.

21.3.3 The Cultural Theme

While one might strain to turn this latter possibility into a variant of the genetic position having a distinctive mechanism for individual development, it is more clearly a position directly opposed to a genetic position. Thus, Luis Radford and Luis Puig (Radford and Puig 2007) (see also Furinghetti and Radford 2008), who call this position, appropriately, the "embedment principle," write:

> Biological or natural developments unavoidably become *affected* by and *entangled* with the historical-cultural one as individuals use signs and other cultural artifacts, such as language. In fact, the merging of natural and historical developments constitutes the actual line of

---

[22] This term stems from Bachelard's work on the history of science (Bachelard 1938) and then adapted for mathematics education prominently by Brouseau (see Brousseau 1997, pp. 98ff).

> growth of the individual. Given that it is impossible to untie the merging of the cultural and the natural lines of development, the conceptual growth of each individual cannot *reproduce* a historical-social conceptual formation process. In short, phylogenesis cannot recapitulate ontogenesis. (pp. 147–148)

Radford and Puig's embedment principle, which sees our thinking in mathematics as "…related in a crucial manner, to a historical conceptual dimension ineluctably embedded in our social practices and in the signs and artifacts that mediate them" (Radford and Puig 2007, p. 148) brings us squarely into what we called above the cultural theme. One sees immediately how the entrance into that theme is accompanied by the introduction of new subthemes, specifically, ones connected to semiotics, language, and social practices. Radford, for example, draws together these subthemes and their relationship to an historical approach in, among other places, his "On the epistemological limits of language: mathematical language and social practice during the renaissance" (Radford 2003). Even linguistic theorists such as Ferdinand de Saussure (1857–1913), one of the founders of modern semiotics, begin to have relevance in thinking about history of mathematics in mathematics education. Indeed, the idea of language as a semiotic system with both synchronic and diachronic aspect can be shown to be a good model for thinking about the seemingly fixed structure of mathematics and its simultaneous existence as a culturally engendered system changing over time (see Fried 2008, 2009).

Whether or not one takes the cultural theme as far as Radford and others have into the world of semiotics, the theme always carries a sense that mathematics and culture are inseparable, and this means that mathematics and history are inseparable. In a certain sense, this is no more than a very conscious recognition that mathematics is a human enterprise. Accordingly, in his paper, "The necessity of history in teaching mathematics" (Rickey 1996), Fred Rickey tells us that the point he wants to argue is that,

> …Mathematics is the work of individuals. It is a discipline that has been developed by many people over the ages, some making great contributions, some making minor contributions, with the cumulative effect that mathematics has developed into a rich field that has had a significant impact on the way people view their world.
>
> As teachers of mathematics, and even more so as historians of mathematics, we arethe carriers of the mathematical culture. It is our solemn responsibility to transmit this culture to our students. (p. 252)

This aim to humanize mathematics admittedly comes dangerously close to the trivial storytelling we have seen in Lightner's (2000) "Mathematicians are human too," but whereas "humanizing mathematics" there only meant making mathematics less formidable so students might not feel threatened by it and shun it as somehow inhuman, "humanizing mathematics," here, it means seeing mathematics as an *essentially* human activity, that is, as part of the *nature* of mathematics. It becomes a human science almost in the sense of Dilthey's *Geisteswissenschaft*, and, in this sense, the history of mathematics no longer functions only as a means used to promote motivation or interest but as something at the core of mathematics and, accordingly, of what it means to learn mathematics.

As an expression of culture, one's perspective on mathematics changes radically. For it brings to mathematics a conception foreign to the usual one in which mathematical objects and relations are eternal, ideal Platonic entities, everywhere viewed in the same way and everywhere given the same weight, ideas with no geography and no past. Such a change in perspective does not mean necessarily that relativism becomes the philosophy of mathematics, but it does invite a pluralistic view in which one does not assume that mathematics always and in all places means the same thing and is directed towards the same phenomena (needless to say, this is not a claim that everyone is always right and no one is ever wrong!).

With this in mind, one can see how the history of mathematics in mathematics education finds much in common with the still-developing subfield of mathematics education known asethnomathematics (e.g. D'Ambrosio 2006). Thus in their paper for the ICMI study volume on history in mathematics education (Fauvel and van Maanen 2000), Lucia Grugnetti and Leo Rogers (2000) emphasize mutual relations between history of mathematics and multicultural issues. In particular, in their view, the history of mathematics helps the student acquire a sense of diversity, of the many different ways people can think about and approach the world:

> Multiculturalism then, in the sense that we have tried to convey here, is the identification and celebration of diversity, the respecting and valuing of the work of others, the recognition of different contexts, needs and purposes, and the realisation that each society makes and has made important contributions to the body of knowledge that we call mathematics. (p. 51)

The idea of diversity is not only a central idea in all cultural studies, it is also a central notion in all historical studies, mathematical or not. In this way, the cultural theme comes closest to a historical approach to mathematics education that is truly historical. Yet, as we shall see shortly, this brings us into a difficulty when we consider history of mathematics in the context of other legitimate goals in mathematics education. To see this we shall have to get a better sense for what it means to be historical – and *non*-historical.

21.4 History of Mathematics as History and What That Implies for History of Mathematics in Mathematics Education

Although there is no complete agreement on what history is and what is at the heart of the historian's craft, still, there are undeniable commonalities.[23] Of these, a keen awareness of the tension between past and present or, at very least, the need to confront the question of past and present, stands out most clearly. For while it is impossible to think of history without reference to the past, history is not solely about the past; it is also about the present. To start, one must refer to the present to the extent

---

[23] Much of this section is based on a plenary talk (Fried 2010) at the ESU-6, HPM conference in Vienna, July, 2010.

historians' materials, their objects of study, are things having made their way into the present. With this in mind, Geoffrey Elton (1967) defined history as being "… concerned with all those human sayings, thoughts, deeds and sufferings which occurred in the past and have left present deposit; and it deals with them from the point of view of happening, change, and the particular" (p. 23).

The qualification in Elton's statement emphasizes also that it is not just past or present that is essential but how these are treated, namely, "from the point of view of happening, change, and the particular." The historical mode of thinking demands treating these "survivals" from the past, as Michael Oakeshott calls them (see Oakeshott 1999), precisely *as* survivals, survivals from another world. One interrogates them to understand where they came from – for theirs is a world not conditioned by the existence of ours, yet it is one out of which ours has grown.

History, viewed in this way, is a kind of vicarious experience of the past through what has made its way into the present. Oakeshott, whom I have just mentioned, views history for this reason as a mode of experience, and, for him, to experience the past in the present *as history,* one must view the past *unconditionally*. The historical past is a kind of past, but there are other kinds of past as well. To describe a relationship to the past that depends on the present, in other words, that sees the past in terms of present values, needs, and ideas, Oakeshott uses the term "practical past." The historical past is defined in opposition to the practical past; it is a past understood in terms of its separateness from the present.

Accordingly, in his chapter on historical experience in *Experience and Its Modes* (Oakeshott 1933), Oakeshott sets out the historian's task as follows:

> What the historian is interested in is a dead past; a past unlike the present. The *differentia* [emphasis in the original] of the historical past lies in its very disparity from what is contemporary. The historian does not set out to discover a past where the same beliefs, the same actions, the same intentions obtain as those which occupy his own world. His business is to elucidate a past independent of the present, and he is never (as an historian) tempted to subsume past events under general rules. He is concerned with a particular past. It is true, of course, that the historian postulates a general similarity between the historical past and the present, because he assumes the possibility of understanding what belongs to the historical past. But his particular business lies, not with this bare and general similarity, but with the detailed dissimilarity of past and present. He is concerned with the past as past, and with each moment of the past in so far as it is unlike any other moment. (p. 106)

So even though historical experience is an experience in the present and one belonging to a living and breathing historian, the historian must live by the desideratum to view the past in its particularity. Historians' rule to avoid anachronism is an easy corollary to this desideratum. However, it is not an easy rule to obey, since we are beings who live in the present and whose immediate experience is not that of the historical subjects we study. The struggle with anachronism is at the heart of the tension between past and present, with which I began this section. It might be said, indeed, that the historical art is one that aims to keep that struggle alive.

The dangers of submitting to anachronism and the subtle ways in which it can subvert history were discussed most trenchantly and colorfully by Herbert Butterfield in his classic, *The Whig Interpretation of History* (Butterfield 1931/1951). The term "Whiggism" has subsequently entered the vocabulary of standard historiography.

The tendency it refers to is the distorting of the past not only by reading modern intentions and conceptions into the doings and writings of thinkers in the past, which is anachronism in its most direct form, but also by forcing the past through a sieve that bars ideas foreign to a modern way of looking at things and permits those adaptable to modern interests. For example, in reading Proclus' *Commentary on Book I of Euclid's Elements*, a Whig historian would leave out Proclus' arguments in the "first prologue" about the nature of mathematical being and role of mathematics in the moral education of the soul while emphasizing Proclus' comments on logical difficulties, missing cases, and alternative proofs connected with the familiar geometrical propositions in the *Elements*. These things are truly to be found in Proclus, but a Whig historian would give the impression that they are the *only* things in Proclus, or the only things of any worth in Proclus.

Whig history is indeed particularly seductive when it comes to mathematics. This is because, as we have remarked before, mathematics is easily taken to be a constant component of thought not only in the modern world, but also in all parts of the world and at all other times. Left unchallenged, that view of mathematics makes Whiggism almost inescapable: present mathematical knowledge, short of logical errors, is mathematical knowledge *tout court*; past mathematical knowledge, to be understood, has merely to be translated into a modern idiom. So one can feel fully justified in treating mathematicians of the past as Littlewood famously said of the Greek mathematicians, that they are only, "Fellows of another college" (quoted in Hardy 1992, p. 81); mathematicians of the past, like one's colleagues, are useful for gaining insights into one's present mathematical research. The past, for Whig historians, is thus almost *by definition* a "practical past," adopting Oakeshott's term: they seek in the past what is useful for the present.

Clifford Truesdell (1919–2000) is a good example of a Whig historian. He is a good example, not because his historical work was false or inaccurate or superficial, but precisely because he was tremendously learned and serious; his work was thorough and in some ways deep. The problem is only how his history was oriented, and how much *historical* understanding we gain from it. For him, history of mathematics was unabashedly dedicated to a "practical past": "One of the main functions [the history of mathematical science] should fulfill is to help scientists understand some aspects of specific areas of mathematics about which they still don't fully know" (in Giusti 2003, p. 21). What one learns from the history of mathematics, in its Whiggish form, is, in short, mathematics.

By now it should be apparent that this view of mathematical past as a "practical past" lies close to the foundations of the curricular theme. The very fact that history, in the curricular spirit, is seen as something *to use* in order to promote modern mathematical knowledge brings it into line with the practical past and the Whig interpretation of history. It must be made clear that the problem is not that proposals according to the curricular theme have no good effect for learning mathematics; it is its historical character that is in question. For to the extent that mathematics is continuous over time and place, a universal body of content, it is really ahistorical and noncultural, or, at best, its peculiarly historical and cultural aspects involve only trivial matters of form. Besides this kind of history being thus non-history, by using the present to determine what is useful for the present, one finally forfeits *learning* from the past. It is this that Butterfield found so wrong about Whig history. More specifically, he writes:

> If we turn our present into an absolute to which all other generations are merely relative, we are in any case losing the truer vision of ourselves which history is able to give; we fail to realise those things in which we too are merely relative, and we lose a chance of discovering where, in the stream of the centuries, we ourselves, and our ideas and prejudices, stand. In other words we fail to see how we ourselves are, in our turn, not quite autonomous or unconditioned, but a part of the great historical process; not pioneers merely, but also passengers in the movement of things" (p. 63)

By contrast, history of mathematics in mathematics education according to the cultural theme with its interest in difference and the essential human imprint in mathematical thought is consistent with a truly historical mode of thinking and assumes that one can learn something from history as such. Indeed, it assumes one can learn about ourselves as beings for whom mathematics is part and parcel of our cultural identity,[24] and, as Butterfield warned, we shall fail in this if we too easily adopt a history guided by the present. Put in different terms, ones inspired by Anna Sfard's work on "meta-discursive rules" and "commognition"[25] (Sfard 2008), Kjeldsen and Blomhøj (2011) have stated the case thus:

> As active learners, students can become aware of their own meta-discursive rules by identifying the meta-rules that governed the mathematics of the past and comparing them with meta-discursive rules governing the mathematics of their textbook and instruction. In this way, opportunities for students to experience commognitive conflicts are provide and proper changes can be initiated. (pp. 4–5)

But even in these different terms, Kjeldsen and Blomhøj are fully aware that what stands opposed to these opportunities is Butterfield's Whig history, as they immediately point out (p. 5):

> If one's reading and interpretation of historical sources are constrained by the way mathematics is perceived and conceptualized in the present, the historical text cannot play the role of an "interlocutor" that can be used to create commognitive conflicts, as explained above, when students communicate with the text, since differences in the way of communicating in the past and in the present will have been "washed away" by the whig interpretation. (p. 5)

The conclusion seems to be clear. In order to have a historical approach in mathematics education in which history is taken seriously *as a form of knowledge*, we ought to embrace an approach along the lines of the cultural theme and reject the Whiggish proposals derived from the curricular theme. But there is a difficulty here. For one cannot forget that mathematics educators are not historians and have other legitimate concerns. So while the history of mathematics can bracket the present in order to understand the past, mathematics education typically justifies itself precisely by the power and

---

[24] One recalls in this connection Collingwood's claim that this kind of self-knowledge is the entire point of history (e.g., Collingwood 1939).

[25] In creating this term – a fusion of the words "communication" and "cognition" – Sfard tried, in a Vygotskian spirit, to capture the way thinking is entangled with discourse.

necessity of mathematics in *modern* contexts, in science, engineering, economics, and industry. This is certainly consistent with the spirit of the American *Principles and Standards for School Mathematics* (NCTM 2000). There, we read:

> The level of mathematical thinking and problem solving needed in the workplace has increased dramatically.
>
> In such a world, those who understand and can do mathematics will have opportunities that others do not. Mathematical competence opens doors to productive futures. A lack of mathematical competence closes those doors.
>
> …More students pursue educational paths that prepare them for lifelong work as mathematicians, statisticians, engineers, and scientists.
>
> …Today, many students are not learning the mathematics they need. In some instances, students do not have the opportunity to learn significant mathematics. In others, students lack commitment or are not engaged by existing curricula. (NCTM 2000, Introduction)

One cannot belittle this emphasis on modern mathematics: the ideas and methods of modern mathematics are undeniably profound and powerful, and there is no reason they should not be pursued and taught. But accepting this kind of emphasis also means that mathematics educators *cannot* bracket the present, as historians can and must. Thus, when mathematics educators – even those with real historical sensitivity and knowledge – confront a chapter in the history of mathematics they must heed, to some extent at least, the counterweight of their obligation to teach mathematics in a modern spirit. They must consider how relevant the chapter is to the modern mathematical ideas they need to convey, how well it fits the subjects required by their curriculum. Seemingly practical considerations of time and scheduling are, in fact, signs that history of mathematics in the classroom must be subordinated to such standards as those in the NCTM document.[26]

Naturally, there may be some historical topics for which a happy medium can be found, some cases where a chapter in the history of mathematics fits comfortably in the curriculum without demanding too great a compromise as to its historical character. While this may be, it is not the point. The point is that when mathematics education emphasizes mathematics as it is understood and practiced today, as it is needed in science and engineering, it will be necessarily predisposed to treat the history of mathematics in a Whiggish spirit, separating relevant from irrelevant ideas according to the needs of the modern curriculum. This predisposition is not an injunction to be Whiggish; it is, rather, a kind of ineluctable internal pressure at work in any attempt to introduce history of mathematics into mathematics education, where the latter is directed, as it generally is,[27] towards modern mathematics.

---

[26] One might also cite European standards as well, even the Danish competence-oriented mathematics education, KOM-project (see Niss and Højgaard 2011). The latter, however, includes competencies that invite a broader view of what it means to be mathematically educated (see Jankvist and Kjeldsen's (2011) paper and also the discussion below).

[27] There are, of course, exceptions. One of the anonymous reviewers of this chapter made me aware of the Ross School and Institute in New York State, USA, whose program, among other things, stresses cultural history. Describing their "spiral curriculum," they write: "Teaching the humanities and sciences in the context in which they historically emerged makes for a naturally integrated approach" (http://rossinstitute.org/#/The-Ross-Model/Spiral-Curriculum, accessed April, 2012).

Mathematics educators, in this way, are placed in a very different position from the historian of mathematics who must struggle with the problem of anachronism. For the historian, engaging in that struggle is part of what it means to do the history of mathematics: historians who do not live in the tension between past and present are not true historians. But in the case of mathematics education, the problem is one of conflicting demands and commitments, presenting the mathematics educator with a dilemma: maintain modern mathematics as one's main end and thus subordinate history of mathematics serve modern ideas and needs, that is, adopt a Whig version of history of mathematics, or insist that history of mathematics be history and put aside the perfectly legitimate emphases of programs seeking to help students use and understand the modern mathematics essential for all the pure and applied sciences (see Fried 2001, 2007 for further discussion and additional examples).

Of course the force of the dilemma derives from accepting prescribed ends like those described in the example of the NCTM. And one must emphasize that built as they are on the power of modern mathematics to address societal and scientific needs, those ends are anything but inconsequential and easily dismissed; however, they are not absolute. What it means to teach mathematics and what it means to be mathematically educated can be defined in accord with a different set of ends, ones more cultural and humanistic and less utilitarian. Mathematics education may not be so determined that it must follow the standards set out in the NCTM Principles and Standards (NCTM 2000) or similar documents (e.g., European Mathematical Society 2001). Mathematics education can be reconceived so that it promotes an educational approach shaped by history of mathematics as a form of knowledge rather than one that only uses history of mathematics in the service of ends not necessarily in line with those of history, "history as a goal" rather than "history as a tool," as Uffe Jankvist has aptly put it (Jankvist 2009).

Reconceiving mathematics education in this way does not mean turning it into what has derogatorily (and somewhat unfairly) been called "mathematics for poets"[28]: it can be rigorous and, yes, mathematical. Although there is no single scheme for this, it is clear that, one way or another, the presence of original sources will be essential. This is because, as Elton (1967) made plain in the passage quoted above, at the heart of the historical enterprise are those thoughts – in our case mathematical thoughts – "…which occurred in the past and have left present deposit…" (p. 23) In the case of the history of mathematics, as with all history of ideas, the present deposit consists, maybe not exclusively, but certainly chiefly of written texts. For while written texts in general history are crucial *as accounts* of happenings in the past, in the history of thought, texts are, one might say, the thought itself. Original mathematical texts are also the chief expression of how mathematicians have sought to engage other mathematicians in their thought; they represent communicated thought. And that, bringing us back to the cultural theme, places original texts at the center of what we should call mathematical culture and tradition.

---

[28] Poets can have a deep knowledge of mathematics. The mathematical knowledge of the great French poet, Paul Valéry, for example, could hardly be called superficial or soft.

Tradition is too often misunderstood as something rusty and dogmatic. With Eva Brann, “By *the tradition* I mean neither the old customs nor the recent routines, neither the sedimentary wisdom nor the petrified habits of communities. I mean, to begin with, *a collection of books*” (Brann 1979, p.64). And as Brann also points out, the origin of the word “tradition,” the Latin verb “tradere” means both to pass on and to betray (p. 67). In other words, tradition implies not only what one remembers and respects but also the platform from which one changes and develops. It is in this sense, then, that one should understand tradition when it comes into the arguments of those who promote the use of original sources in teaching mathematics. For example, Laubenbacher, Pengelley, and Siddoway (1994)[29] write this in defense of using original texts:

> For a novelist, poet, painter or philosopher such observations would be old news, since their disciplines have long recognized the importance of studying the original work, techniques and perspectives of classical masters. And in so doing, they are never removed from an understanding of how people have struggled, and have created works of art. Young artists thus see themselves as part of a creative tradition. Unfortunately, we have lost this sense of tradition in our discipline, and, ironically, we can perhaps blame much of this loss on the dazzling explosion of mathematics in this century. It is time we step back from our accomplishments and recapture a historical perspective.

The picture of mathematics education, or rather of becoming educated mathematically, that begins to emerge is not so much one that concentrates on the mastery of certain techniques in mathematics or even certain concepts in mathematics such as a function or derivative, but on the reading and learning to read a body of mathematical texts. Which texts to be included and which not, aside from certain texts, such as Euclid’s *Elements*, could no doubt be debated; even courses on Shakespeare vary as to which play or sonnet is discussed, alluded to, or left unmentioned. And mentioning literature is not by accident: reading of texts, following authors’ modes of presentation and their points of attention, weighing the cultural context of works, and so on would make mathematics education into a kind of literary education. And yet it *is* mathematics, as one quickly finds out working through Euclid’s *Elements*, Descartes’ *Géométrie*, or Euler’s *Introductio*.

But using original texts is only a condition for a mathematics education for which history is a goal; one must know how to use original texts. While this involves theoretical considerations concerning the role of original source material, it also involves considerations arising from empirical studies. As Furinghetti et al. (2006) point out, “An important development in recent years is that more empirical research studies on the integration of original sources are being done, many of which include a large number of students” (p. 1288).

---

[29] Laubenbacher and Pengelley have promoted the use of original sources indefatigably for over twenty years with such works as (Laubenbacher and Pengelley 1999). In the latter, for example, they treat analysis by looking closely at the transitions of ideas connected with the calculation of areas and volumes, and do so via texts from Archimedes,Cavalieri, Leibniz, Cauchy, and Abraham Robinson. An overview of their work can be found at the website: http://math.nmsu.edu/~history/

One good example of this sort of empirical study is that by Jankvist and Kjeldsen (2011) (also described in Kjeldsen and Blomhøj (2011)). This research was carried out against the background of Danish competence-oriented KOM-project report, which emphasized history of mathematics in what it termed “overview and judgment,” competences referring to “mathematics as a discipline” (Niss and Højgaard 2011, pp. 118–120).[30] In the course of the study, high school students worked on problem-based mathematical projects over the course of a semester with close attention to history via original sources (in translation) such as Johann Bernoulli’s 1691 “solution of the cable problem” as well as more modern works, such as Hamming’s 1950 “Error Detecting and Error Correcting Codes,” treated in a historical spirit. By assuming a problem-based approach, Jankvist and Kjeldsen tried to achieve a situation in which close attention to written texts and sensitivity to history as history, attention “meta-issues,” was “anchored” in the “in-issues” of mathematics, as they put it. Although there was a risk of making the in-issues *the* issues, and, therefore, descending into Whiggism, they could avoid that and keep “history as a goal” partly through this close attention to texts and partly through the constant interaction with historically knowledgeable supervisors.

The genetic principle is an obvious and in some ways natural basis for using original texts. Because the principle assumes that history follows a course towards a given modern topic that mirrors the course of students’ own of understanding, it is reasonable, on that basis, to present texts one after another in historical sequence. Michael Glaubitz (2010) obtained empirical data on this point by comparing the genetic approach and a conventional nonhistorical approach. His experiment centered on 175 students using the quadratic equation and formula as his topic and works by Al Khwarizmi, for example, as his texts. Even with respect to interest, Glaubitz’s results were disappointing. He summarizes them as follows: “…this teaching did not work. The students rather got confused and appeared very displeased in the end” (p. 8). Naturally, one should be cautious here: the texts were given to the students and then followed by “conventional exercises, problems and applications with modern methods” (p. 5); there may be other ways to pursue a purely genetic approach.

But Glaubitz also examined another approach, that developed by Niels Jahnke, the “hermeneutic approach.” Students in this approach were taught the quadratic equation and formula in a modern conventional way, and, when they were brought face to face with the original texts, they were asked to engage with them in active, often creative, ways, such as writing fictitious interviews with Al Khwarizmi: the original texts were still present, but the students’ own perspective in reading them (including some of their difficulties in reading them) were taken into account. The results here were much more encouraging and contrasted starkly with the approach based on the genetic principle.

---

[30] It is this looking at mathematics as a discipline, from the side as it were, that gives the term “meta-issue,” used by Jankvist and Kjeldsen its aptness. Jankvist and Kjeldsen’s complementary term, I might add, is “in-issue,” by which they mean an internal matter of mathematical content – concepts, methods, algorithms, mathematical proof, etc.

By having students learn, say, the quadratic formula, in a modern way, one might think that the hermeneutic approach is actually introducing anachronism into its historical approach. But, as we discussed at the very start of this part, while a historical understanding of the past demands seeing the past unconditionally, it does not require one to forget the present. We were at pains to show that a historical understanding is marked by a tension between past and present.[31] The problem with, for example, Whiggism is that it sees the present as completely consistent with the past – hence, no tension. When one sees, from the start, that one's position with respect to the past is problematic, one is thrown into the role of being an interpreter. As Jahnke (2000) puts it[32]:

> In traditional theories of hermeneutics the relation between the historical meaning of a text(the intention of its author) and its meaning for a modern reader is amply reflected and identified as the essential problem of interpretation. In fact, seen under the aspect of method, history of mathematics, like any history, is essentially an hermeneutic effort. If history of mathematics is not to deteriorate into a dead dogma, teachers should have some ideas about the hermeneutic process and the fruitful tension between the meaning of a text in the eyes of its author and the meaning for a modern reader. (p. 298)

To use the terminology mentioned in part 2 of this paper, in the hermeneutic approach, one's position with respect to the past is distinguished by being in the present and having present mathematical knowledge, but it is not "privileged." On the contrary, recognizing our position in the present *as present* comes with the recognition that the past is obscure, and, thus, needs to be interpreted. And the phenomenon that is familiar to anyone who has done serious historical work is that more one engages in that interpretive activity the more obscure the past becomes. But this only brings the distinctness of one's modern knowledge into relief. One truly begins to see here how one can bring a historical awareness into mathematics education that will allow not only for genuine insight into the past but also into the present.

21.5 Conclusion

With the discussion of tradition and of interpretation, we come full circle in this chapter and, in certain respect, historically as well. For recall, the word "tradition" was also one translation of the Greek word *paideia*. Its other translations, as we noted earlier, included "education," "civilization," "culture," and, in Latin, *humanitas*. These are all themes that have been central in this chapter. But more than that the tacit message here has been that by taking history of mathematics as a goal, we might be able to restore a sense of mathematical knowledge as the self-knowledge

---

[31] This awareness of the tension between the students' own perspective and that of the original texts also played a part in Radford and Guérette's (2000) successful teaching sequence concerning the quadratic equation and the Babylonian's "naive geometry."

[32] Another account of the details and presuppositions of the approach can be found in Jahnke (1994).

of our human mathematical mind, to paraphrase Collingwood (see Fried 2007): the mathematical mind is indeed a human mind, and doing mathematics is a high human activity. *Paideia* carried that sense of a distinct human possession relating to humanness in its highest and broadest expression.

Now we first mentioned *paideia* in connection to the history of mathematics in ancient education and, specifically, to Proclus. Tradition as historical character in that context had to be taken in a qualified way: mathematical tradition for Proclus was much more of a continuous tradition than it is for us. Thus Proclus' references to mathematicians of the past could genuinely be seen as they were references to "colleagues" no longer alive. For us, there have been breaks in the tradition even though it is still in some sense ours: the past for us is a past that has often been lost or obscured and that requires recovery and interpretation. Our own sense of who we are with respect to our mathematical past requires cognizance of these breaks and the fundamental differences between us and our predecessors. History in the modern sense of Elton, Butterfield, and Oakeshott, while it recognizes commonality, endeavors to refine our understanding of such differences. For this reason, in the development above, it was crucial to confront the historical character of attempts to incorporate history of mathematics in mathematics education, to point out the teleological assumptions of the genetic principle and the inadequacies of the motivational and curricular themes, for example.

The answers to such criticisms, I have suggested, require more than patches. They require perhaps a reorientation vis-à-vis the question of history of mathematics in mathematics education. Instead of asking how we can produce a presentation or program here, a chapter or unit there in the history of mathematics fitting the needs of a set curriculum or addressing the lack of motivation of our students, we may need to ask how we can adjust the meaning of mathematics education itself so that it will accommodate history of mathematics pursued honestly and deeply. No attempt was made to floor an exact proposal because that cannot be done. However, an essential component of any such proposal, we argued, is a view of mathematics as a collection of texts that need to be studied, a collection of authors that need to be engaged. This too, we made clear, cannot be taken a simple proposal. There is more than one way to introduce original texts. A promising suggestion, both theoretically and practically, is Jahnke's hermeneutic approach, which involves both a modern, but not Whiggishly oriented, mathematical knowledge and also an awareness of oneself as an interpreter. The possibility of an approach like the hermeneutic approach makes the possibility of a mathematics education that is truly historically sensitive within reach. Perhaps, we will discover the way to a new *paideia*.

Michael N. Fried is associate professor in the Program for Science and Technology Education at Ben Gurion University of the Negev. His undergraduate degree in the liberal arts is from St. John's College in Annapolis, Maryland (the "great books" school). He received his M.Sc. in applied mathematics from SUNY at Stony Brook and his Ph.D. in the history of mathematics from the Cohn Institute at Tel Aviv University. His research interests are eclectic and include mathematics pedagogy, mathematics teacher education, sociocultural issues, semiotics, history of mathematics, and history and philosophy of education. Besides his papers in mathematics education, he is author of three books connected to the history of mathematics: *Apollonius of Perga's Conica: Text, Context, Subtext* (with Sabetai Unguru) (Brill, 2001); *Apollonius of Perga, Conics IV: Translation, Introduction, and Diagrams* (Green Lion Press, 2002); *Edmond Halley's Reconstruction of the Lost Book of Apollonius's Conics* (Springer, 2011).

Chapter 22
Philosophy and the Secondary School Mathematics Classroom

Stuart Rowlands

22.1 Introduction

Can philosophy have a role in the teaching and learning of mathematics in school? If it can have a role, what is it? There may be several answers according to several perceived roles, such as it enables pupils to think in the abstract, it contextualises an otherwise very formal subject, it situates mathematics in the realm of philosophy; but perhaps the most central answer to which most others are subordinate is that it can aid the understanding of mathematics. A class reflecting philosophically on the concepts of mathematics will most likely attain a deeper understanding of those concepts.

For example, a class reflecting on the difference in abstraction between one sheep and one sheep equals two sheep with $1 + 1 = 2$ (the latter concerns the concept of number; the former is a statement of physics similar to 'one lump of plasticine add one lump of plasticine equals one lump of plasticine'), reflecting on the nature of a geometrical straight-line (e.g. What is it? Can we see one? Does it exist? 'Could industrial artefacts such as aeroplanes and the associated machinery for production ever exist without it?' 'When did it first appear?') or discussing limiting cases to infinity, etc. will most likely develop a *relational understanding* (in the sense of Skemp (1976)) of how these concepts are embedded, connected and embellished in the relevant mathematics, as well as just knowing how to manipulate them according to the rules (Skemp's (1976) *instrumental understanding*). A qualitative understanding of infinity as a limit, with such examples as the proof for the area of a circle, deepens our understanding of why this area is πr^2, despite the unlikelihood of the class arriving

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_22,

at a formal definition of Cantor's infinities. An 'informal' treatment of infinity provides a means to understand why the area of a circle is as it is. This chapter discusses the ways in which philosophy can aid the teaching and learning of the content of secondary school mathematics and how it can also situate mathematics culturally and historically.

One possible objection is that it takes longer to develop a relational understanding than it does an instrumental one (e.g. it takes longer to show *why* the area of a circle is πr^2 than simply giving the formula), but it is shorter in the long run compared with committing to memory all the various ways to tackle a variety of questions with formulae and rule-of-thumb procedures that are given without reason. As Skemp (1971) states, many students pass a public examination in mathematics at one level, but inevitably fail the next level because there is no basis to understand the abstraction necessary for the next level. The student must first master the previous level, not only in terms of passing examinations but also in terms of a conceptual understanding of the relevant domain of knowledge – despite any public recognition of passing that level.

Although it will be argued that philosophical questions do presuppose answers that are right, the classroom discourse need not arrive at completeness for the value of the discourse to take effect. What is being suggested is that philosophy can enrich the subject, not only in terms of the subject coming alive but also in terms of understanding the subject, even if the class does not arrive at any formal definition normally expected at degree level. Another objection is that if the formalism is too difficult then the problem should not be introduced at the secondary school level. For example, if the vast majority of schoolchildren will fail to understand the theory of real numbers with proof, such as the density of the rational numbers and the existence of the irrationals, then the theory should not be introduced at this level. Hopefully, however, all secondary school pupils will have been introduced to the real numbers including the rational and irrational numbers; so why can't the theory of the reals begin here, even though the required formalism may not be reached at this level?

This chapter proposes philosophical discourse in the teaching of school mathematics,[1] with the teacher as a 'sage on the stage' orchestrating the class towards a target concept or a series of target concepts. Unfortunately this chapter seems alone in what it proposes. The literature mainly consists of the Philosophy for Children (P4C) programmes which advocate the teacher as a 'guide on the side' who allows the discourse to go much its own way without intervention. There is very little, however, on philosophy and the mathematics classroom, and the little there is has tended to be an extension of the P4C programmes, with the emphasis on whole-class discussion which Kennedy (2007) termed the 'constructivist classroom' with its egalitarian emphasis on shared meanings.

---

[1] Unfortunately this chapter does not discuss philosophy and undergraduate mathematics as this deserves a chapter in its own right. At this level there is not only a change in content (with an emphasis on formalism and rigour) but also a variety of teaching/learning methods that may not be so appropriate at the secondary school level. Nevertheless Pincock's (2012) *Mathematics and Scientific Representation* would be most appropriate as a text for this level.

P4C advocates a circle or horseshoe of children discussing philosophy with the teacher acting as chair who helps steer the conversation without preconceived ideas as to what the children ought to learn from such a discourse – there is no imposition with what the teacher considers to be right or wrong. By contrast what this chapter proposes is indoctrination, but only in the sense that teaching mathematics is in itself a form of indoctrination: a social-cultural activity that inducts students into the best that has developed out of what is essentially a two and a half thousand year history.[2] It is not indoctrination in the sense of accepting something without reason.

This chapter begins with a literature review, and given the small number of articles on philosophy in relation to the secondary or primary school mathematics classroom, the review will focus on the P4C programme in general but with mathematics in mind, especially since the majority of the small number of articles on philosophy and the mathematics classroom are influenced by this literature.

P4C is not just a strand within education research but has now become part of the practice of teaching and has truly entered the public domain, in the UK at least. For this reason alone, the literature review is relevant given the present-day popularity of the programme, especially in England and Wales where the constraints of the National Curriculum and the excessive bureaucracy of accountability have made this programme very attractive to teachers, educators, curriculum developers and indeed the children themselves; but there is also a more overarching reason for the review – *it has made possible the arguments and proposals of this chapter*. Although this chapter's historical-cultural emphasis in the teaching of mathematics has already been formulated in previous articles,[3] this chapter's consideration of the role of philosophy in mathematics education has been influenced by its own review of the P4C programme. Although critical, this chapter owes a debt of gratitude to the programme in the sense that if the programme never existed, then many of the ideas of this chapter would not have existed either, certainly as far as the ideas of the author are concerned.

---

[2] Although there were great mathematical advances prior to the Greeks, the Greeks created deductive proof and the necessary theoretical objects to accomplish it, culminating in the axiomatic framework of the *Elements*. There was nothing like it beforehand and nothing like it until the nineteenth century when much of mathematics was rewritten in axiomatic form. Prior human achievements in mathematics notwithstanding, Greek deductive geometry was the most stunning advance, and there is a sense in which 'history' begins two and a half thousand years ago – especially since over that period to learn mathematics was to learn the *Elements* (to the delight or chagrin of many pupils).

This is not by any means to undervalue the educational potential in introducing the mathematics of, for example, the Babylonians (is the 360° in the angle measure of a circle now a matter of convention or was there an objective reason for adopting it? Is there a need for base-ten compared with base-60? What prompted their recipe for what is today expressed as the quadratic formula?). However, this article is primarily about engaging pupils consciously with justification and proof, the abstract theoretical objects that were created for the purpose and the impact both culturally and cognitively.

[3] For a theoretical overview of this perspective see Carson and Rowlands (2007); for validation see Rowlands (2010).

Initially the review focuses on the controversies surrounding the programme in the UK, but there are no apologies for this. What is happening to education in the UK at the moment (which essentially began with state control) could happen elsewhere, but perhaps the most important aspect of these controversies is that we have the distinct advantage of observing a development in education research, one that is relevant to this chapter, put into practice with all the controversies from the public surrounding it. The fact that this is happening in the UK is in a sense irrelevant (although some of the issues surrounding its implementation are particular to the UK), and some light on the controversy not only shows what's at stake but also provides the context (or 'backdrop') for what this chapter proposes.

Section 22.2 discusses the present-day impact of P4C and the controversies surrounding its programme in the public domain. It also critiques a fundamental premise of the programme that children as young as five are natural philosophers, although this section does not deny that children do ask questions that can be considered philosophical. This section argues that children are not natural philosophers but they can be trained to think and discuss philosophically.

Although there is much written on the programme in the literature, there is very little on philosophy in the mathematics classroom. What little there is tends to frame philosophy and mathematics in the context of the programme, and this small sample will be critiqued in Sect. 22.3. Section 22.4 may be considered the heart of this chapter, because it puts forward the proposal that philosophy and mathematics can be introduced in a traditional classroom setting with the teacher taking the dominant role. It will be argued that under such a regime the teacher is not imposing her ideas on the class but is able to steer the class into thinking about what is being proposed in terms of philosophy and mathematics – the aim being a deeper understanding of mathematical concepts. Unlike most of the mathematics taught in many (perhaps most) UK classrooms, there will be very little room for faith. In such a programme, children will not be expected to accept the angle property of the triangle (that the three angles of a plane triangle add up to two right angles) because the teacher says so (or because a few triangles have been measured); instead, the class will be directed to consider the nature of deductive proof and to adopt a critical stance that demands justification. The class should then find it easier to construct the proof with just a few hints.

Perhaps the essence of this chapter is that philosophical discussion need never be far away from the many mathematical concepts that we teach. For example, the teacher could raise the question as to how it is possible for the area under a curve to be expressed as an exact number of square units. Exercises for 11-year-olds (or thereabouts) involving the approximation of area using finer and finer grids can provide the springboard for discussing limiting cases and hence the concept of a limit (qualitatively at least; any formalism should perhaps be left to a much later level of development).

The proposed philosophy may be loosely described as the philosophy of mathematics. Issues concerning Platonism and proof may certainly come under that category, but there are also other related issues which although applicable to the philosophy of mathematics are more to do with philosophy in general, such as

Plato's distinction between belief and knowledge. This chapter is more a proposal for philosophy in the broader sense than the specific philosophy of mathematics, but then elementary philosophy of mathematics cannot be separated from broader philosophical considerations.

Especially in a classroom environment, philosophical considerations of mathematical concepts can be a valuable aid in understanding those concepts. The first half of Sect. 22.4 is therefore given over to the added value of philosophy in the mathematics classroom prior to the main proposal presented in the second half, which is that this philosophy would be better framed within a historical-cultural context.

22.2 A Critique of the Philosophy for Children Programme

From small beginnings over three decades ago, P4C is now in the public domain. In the UK, hundreds of primary schools have timetabled philosophy discussions, and some private schools have their own resident philosopher. There are glossy journal front covers emblazoned with P4C and an ideological battle as to whether P4C is suitable for children, fought in the pages of the press with educational commentators and religious leaders on the offensive.

The front cover of the first edition of the Primary Teacher Update, a glossy journal presented upfront next to the candy at the tills of a particular W. H. Smiths, a very large retail corporation that mainly sells magazines and books, stated 'Philosophy for children. Encourage them to think' and shows two young children and their teacher engaged in conversation. The article is written by Lenton and Videon (2011), the founders of P4C, and iterates the misconceptions surrounding the implementation of philosophy for children. On what seems to be based on the P4C literature since the early 1980s, the article mainly provides (very brief but succinct) answers to the following: 'philosophy is too hard for children', 'you have to be academic to understand complex ideas', 'philosophy cannot be fitted into the curriculum', 'you have to be a specialist to teach it', and 'it doesn't have a purpose – what is the point?' Bearing in mind that this is for public consumption, the answers given by the article are too obvious and 'commonsensical'. For example, on the point that philosophy may be too hard for children, the article simply responds that children are naturally inquisitive and want to question. However, the inclination for young children to ask 'why?' may not be sufficient to overcome the difficulties of philosophical discourse. Taken in context, the article was not written for rigorous scholarly discussion, although the P4C academic literature *is* and for that reason is open to critique.

The Primary Teachers Update article is a push for P4C with an editorial giving this push a sense of urgency: we need to equip children with the tools to think independently if we are to avoid the mindless mob violence that has recently occurred across UK cities. P4C is more than trying to improve education in terms of children understanding what is taught across the curriculum (it is stressed that a little philosophical discourse in general can help to question and hence understand the concepts taught across the curriculum); it is also about improving society. P4C seems to have a far-reaching social agenda which some may find unjustified (e.g. can fundamental changes be made through philosophy?). The point is that P4C is now under public scrutiny and the stakes are high.

The article ‘Time to take the won’t out of Kant’ (Lightfoot 2011), emblazoned on the front cover of a magazine (*Tespro*) that comes with the *Times* Educational Supplement (a highly subscribed professional newspaper), outlines the P4C’s current influence and popularity and, with reference to a sympathetic psychologist who actually worked with Piaget, stated that Piaget seriously underestimated the capabilities of the young. It provides much information on relevant materials, where certain P4C programmes can be downloaded and in-service training venues, with the price tag. From relative obscurity P4C is now in the limelight, at least in the UK. It is seen as a panacea for social change and not surprisingly can generate a lot of revenue.

Philosophy for children may have become popular, but it is not without passionate criticism. For example, the UK’s Institute for Public Research proposed that all children should be taught to think critically about religious belief; but this has created the charge of relativism and indoctrination by educational and religious commentators and the press (Law 2008). It is difficult to understand this charge, but as Law argues, a proposition considered true in one religion (such as Christ is God) may be considered false in another (such as Islam); so if religious education regards all religious views as equally valid then we have an exemplar of what it means to be relativist. Philosophy for children, Law argues, can enable a criticism of relativism and need not undermine religious belief. Whereas religious dogma can brainwash the child, philosophy can provide reasons for justification in religious belief (Law 2008).

Both the UK’s Chief Rabbi Jonathan Sacks and the tabloid educational commentator Melanie Phillips blame the Enlightenment for this ‘relativism’, especially Kant, whose watchword in his short article *On Enlightenment* is *Sapere aude* (have the courage to use your own reason) and indeed there are two P4C programmes that are called Sapere and Aude (Law 2008). For Phillips and Sacks, getting children to think for themselves undermines tradition and external authority; but as Law argues, philosophy as a statutory part of the curriculum without exceptions combats the brainwashing aspects of that authority.

It is interesting to note that Kant’s battle cry of the Enlightenment was a battle cry of reason and science against the stultifying dogmas of the preceding age of feudalism. Perhaps Phillips and Sacks would like us to return to the period when scholarship became scholasticism and everyone had to accept certain dogmas on faith for fear of retribution. As Law (2008) recounted, in the late 1960s a friend was punished by a catholic school for asking why the church forbade contraception. Is this consistent with what Phillips and Sacks advocate in terms of ‘external authority’?[4]

---

[4] Perhaps this whole debate concerning schoolchildren, philosophy and religious belief can be resolved if religious education and worship are thrown out of schools. Perhaps the UK should adopt the US model whereby state education excludes any form of worship and religious instruction. The school should be seen as an induction into rationality and reason to which faith and indoctrination have no place.

The book, *Philosophy in the Classroom* (Lipman et al. 1980), has become influential and well referenced. It advocated philosophical discourse for children as young as 5 years of age and stated 'if the educational process had relevance, interest, and meaning for the children, then there would be no need to *make* them learn' (Lipman et al. 1980, p. 5, emphasis given). This seems obvious, yet in England and Wales the National Curriculum and a battery of tests have left no choice but to teach to the test piecemeal bits of knowledge. It is difficult for the science teacher to develop a deep understanding if forces have to be taught one lesson and worms the next. Under the NC, mathematics has gone from mainly algebra and geometry to mainly 'data handling' and 'shape and space', as if relevance can motivate.[5] In practice the angle property of the triangle, Pythagoras' theorem or $x^\circ = 1$, for example, is given without proof as if mathematics is a question of faith – without any epistemology to show why these things are true. As Siegal (2008) argues, education without epistemology reflects a lack of respect towards children. The teachers themselves cannot be blamed because they have already been accounted by endless state inspections that specify the standard and what is expected in terms of teaching and learning outcomes.

Under such a regime P4C must seem like an oasis, its growing popularity is not surprising; but there seems to be an uncritical acceptance of its basic assumption that children are natural philosophers, but are they?

This assumption goes beyond the advocates of P4C. For example, in the novel *Sophie's World*, Sophie encounters her future mentor who points out that all young children have a sense of wonder that is lost as they get older. In P4C, Matthews (1980) argues that children are natural philosophers because they ask philosophical questions but their ability and interest in philosophy, like art, diminishes as they get older. Now while this is (seemingly) true for art, is it true for philosophy? Could every child's fascination for art simply be the motivation to develop sensory-motor skills necessary in performing such art? It seems reasonable to think of this fascination as a part of normal development, sometimes disappearing as the child matures, but philosophy may be a different matter entirely.

For the child to progress in art and for her fascination to be sustained, then she must engage with the various cultural schemata and codes that enable the art to take form (Gombrich 1960). Arguably this would apply to philosophy, but what's in doubt is the initial motivation to do philosophy. Children may have a sense of wonder which is lost through schooling, but is there any intention to be philosophical and do they expect certain criteria to be satisfied in answering their questions? Hand (2008) answers in the negative but maintains that such intention and criteria can be learnt and developed. Like art, children must engage with the various schemata of philosophy (e.g. the kind of questions to ask, such as epistemological or metaphysical, and the sort of answers to be expected) if progress is to be made and interests are to be developed in philosophy.

---

[5] Although most of the mathematics of the NC supposedly reflects mathematical practice in the real world, as Noss (1997) and Dowling and Noss (1990) point out, it does not even do that.

Hand (2008) argues that there is more to being a philosopher than the asking of philosophical questions and that what is missing is the intention of pursuing a line of inquiry in accordance with the question – children lack the appropriate methods of investigation – although with the asking of such questions they can be appropriately taught how to use these methods. Matthews (1980, 2008) has criticised Piaget's deficit model which proclaims young children to be unable to think abstractly, but has Matthews overestimated the child in terms of being a natural philosopher? For Hand (2008) the various methods of philosophical investigation have to be developed.

There is much reference in the literature to Matthews' deficit model of cognitive development in Piaget. For example, according to McCall, 'If you go out in the snow without your mittens, your fingers will freeze!' (McCall 2009, p. 21) involves hypothetical reasoning and yet 3-year-olds will understand this statement. McCall states that 5-year-olds are capable of 'formal operations' in that they can reason about abstract philosophical concepts and can reconstruct the reasoning of other children. Now, without denying the child's sense of awe and wonder of the world and her interactions with it, have we gone completely the opposite way as if her cognitive abilities are adult-like? Consider the following by Lipman and colleagues:

> The rules of logic, like the rules of grammar, are acquired when children learn to speak. If a very young child understands, 'if you do that, you will get punished,' it is assumed that the child understands, 'if you don't want to get punished, I shouldn't do it.' That assumption is usually correct. Very small children, in other words, recognize that the denial of the consequent requires the denial of the antecedent. Although this is a very sophisticated piece of reasoning, children are capable of it in very early stages of their lives. (Lipman et al. 1980, p. 15)

Does the child recognise that the denial of the consequent requires the denial of the antecedent and are they capable of this very sophisticated piece of reasoning? Rather than understand 'if I don't want to get punished, I shouldn't do it', the child might instead understand 'if I don't do that, I won't get punished', meaning not to do it, especially since punishment is not desirable. *How* the child understands might be to do with the discourse and her relationship between the participants.[6] From the hundreds of papers and articles on conceptual change in science education, we find that a wide range of schoolchildren and adults tend to use fallacious reasoning when defending their intuitive ideas of scientific concepts.

In the process of learning, children perform acts of reflective thought, such as whether something has meaning, its relation to the scheme of things or the difficulties they have with the problem. Although reflective, these thoughts seem more to do with metacognition than philosophy; but it does seem likely that metacognitive thinking can be transformed into philosophical thinking if the learner is encouraged to think in the abstract. According to Vygotsky (1994) children are capable of abstract reasoning which depends on the help (or rather, the *scaffolding*) by significant others.

---

[6] From a sample of adults performing a classification task, Wason (1977) shows how even adults deny the relevance of facts or contradict themselves, and how conceptual conflict can arise when the force of a contradictory assertion is denied. This implies that even adults do not acquire the rules of logic just because they speak. The Lipman and colleagues assertion is therefore unwarranted.

The point is that claims about the ability of the young (especially 5-year olds) may be overstated and exaggerated; but they do throw some light on the child's potential. That potential, as we shall see, can only be realised and developed by intervention.

In a P4C discourse children may construct a logical argument and arrive at valid conclusions, but do they become aware of the logical form of an argument or the metaphysical import of a question? Consider the following by Lipman and colleagues:

> The mathematician may insist that children begin by learning simple arithmetical operations, but the children may stagger the teacher by asking, 'what is number?' – an immensely profound metaphysical question. (Lipman et al. 1980, p. 28)

But do they mean this in a profound metaphysical way, or are they at the age when they question everything as a kind of game? Do they even have a *sense* of the metaphysical?

We must shift from the habit of regarding children's metacognitive utterances for philosophical insight.[7] Consider the following:

> This manner of upstaging the normal level of dialogue by leaping to a more general level [for example the child asking 'what is time?' or 'what is distance?'] is typical of metaphysics. Instances of other metaphysical questions your children may already have posed you (or are quietly preparing for you) are these: What's space? What's number? What's matter? What's mind? What are possibilities? What's reality? What are things? What's my identity? What are relationships? Did everything have a beginning? What's death? What's life? What's meaning? What's value? What makes questions like these particularly difficult to answer is that they involve concepts so broad that we cannot find classifications to put them in - we just cannot get a handle on them. (Lipman et al. 1980, p. 37)

It seems almost a conspiracy, children waiting to pounce with metaphysical questions, but isn't this simply a challenge to the terms that are used (especially if they come across such terms as 'matter' and 'identity')? As soon as the adult fails to provide a sensible answer (usually the first time the child asks), the child may decide to persist as a kind of game, knowing intuitively that it causes a mild form of embarrassment. The point is that we may have looked at child development through the lens of our own present development. Piaget may well have underestimated the child, but his stage theory, flawed though it is, rests upon the premise that children are not little adults. The child is not a prototype of an adult whose thoughts are merely refined as she grows up – she has her own way of thinking and looking at the world. Rather than springing forth from some kind of philosophical awareness, a child's philosophical questions may be no more than the metacognitive awareness

---

[7] According to Vygotsky (1987), concepts are not absorbed ready-made by the child but undergo a process of development. Initially, the concept may begin as a complex; for example, the child might use 'dog' not as a member of 'animal' but as an 'associative complex' extended to inanimate objects with fur. A complex often relies on perceptual features. For example, children who think in complexes may successfully complete a classification problem involving geometrical shapes, so the child might appear to think in concepts – until the child attempts a borderline example, such as a trapezium looking very much like a parallelogram, in which the child classifies as a parallelogram without thinking of how a parallelogram is defined (see Vygotsky 1987). The point being the child might not even think in concepts, let alone concepts that may be deemed philosophical.

that adults have great difficulty in answering such questions. With adult supervision, however, it is possible for metacognitive awareness to be transformed into philosophy.

The question is not how we can stimulate their challenge, apparently that challenge is ever present, but how we can challenge them. That challenge is necessary if we are to be certain what the child is driving at. What children mean should not be taken at face value, but as soon as a discourse opens up as to what they mean, we then have an educational situation in which understanding and meanings emerge and change. Intervention is necessary if what the child says is not to be overestimated, bearing in mind that what the child says during the intervention does not necessarily reflect any initial cognitive state or disposition.

What seems promising is the realist philosophy of McCall's CoPI (the Community of Philosophical Inquiry), which asserts that someone can be wrong and contrasts with the P4C Deweyan pragmatic philosophy that truth is constructed and negotiated (McCall 2009, see p. 81). What makes CoPI *essentially* different to all the other approaches such as the Nelson Socratic Method or the various P4C programmes such as Sapere and Aude is its realism:

> The external realist philosophy which underlies CoPI holds that immaterial creations of human beings such as language, concepts, theories, symbols and social institutions, while owing their origins to humans, once made, then exist independently. We can be wrong about them too. (McCall 2009, p. 83)

Perhaps the essential ingredient in any philosophical discourse concerning science and mathematics with children is the view that scientific concepts and laws may be considered to exist in what Popper calls the World Three of the objective content of thought, with discussion as to what existence means here. Are scientific concepts and laws idiosyncratic, are they true because scientists believe in them, are they indubitable facts derived from observation? Any such opinion may be expressed by children who are used to this kind of discourse, and the teacher can always put into perspective that opinion with respect to World Three, bearing in mind that any such opinion opens up a whole world of discourse concerning such issues as Platonism, fallibilism, method, methodology, ontology, epistemology, abstraction and validity.

McCall gives a list of what the CoPI Chair needs to know in order to recognise the various philosophical theories and assumptions that underlie everyday discourse (which contrasts with the view that the teacher does not need to know any philosophy, only the way children learn, e.g. the Primary Teacher Update article by Lenton and Videon (2011)). For the philosophy of science, the list recommends the teacher becoming aware of such things as induction, deduction, falsification and paradigms. Hopefully such a teacher will enable the class to also become aware of such categories in their discourse. Unfortunately, though, there is nothing by McCall on philosophy connected with mathematics.

The section after next is a presentation of how the mathematics teacher can introduce philosophy explicitly in her teaching of mathematics. This is perhaps unique in that many articles on school mathematics with philosophical discourse tend to separate the very learning of mathematics with the discourse, and this is reviewed next.

22.3 A Review of Philosophy in the Mathematics Classroom

There is very little on philosophy in the mathematics classroom, it tends to be implicit in the overall view of the P4C programme. In *Teaching Children to Think* by Robert Fisher (2005), there is reference to Skemp's relational and instrumental understanding in mathematics education but nothing in terms of philosophical discourse and mathematics, despite a chapter on philosophy for children and chapters on creative and critical thinking, With reference to such things as 'shape and space' and 'data handling' of the National Curriculum, however, the book tries to encourage thinking skills and the understanding of how the various mathematical concepts relate to each other, but it has missed the opportunity to use philosophy explicitly as an aid in understanding those concepts. Fisher might reply that he is hamstrung by the NC.

Kennedy (2007), however, connects philosophy with understanding mathematical concepts while also referring to metacognition and creativity. She discusses how a classroom community of mathematical inquiry can become a community of philosophical inquiry by discussing various mathematical problems. She contrasts the transmission model of teaching with the constructivist classroom through which sense-making occurs as a collaborative endeavour. The method is the P4C programme with its participative, dialogical and egalitarian emphasis and states that similar to this have been the works of such metacognitive greats as Schoenfeld (1989) and Goos (2004). The problem here is that there has been a tendency to encourage either metacognitive or philosophical thinking after the content of the mathematics has been learnt, such as solving an integral in a metacognitive way (Schoenfeld 1989) or solving a projectile problem in an investigational way (Goos 2004). How was the content, such as integration or projectiles, learnt in the first place (see Rowlands 2009)?

Nevertheless the article shows a way in which meanings can be constructed in discussing the concepts of ordinary school mathematics philosophically, such as asking 'When can we say that we 'understand' a mathematical concept?'… 'How can we trust in math that is not experienced?' (Kennedy 2007, p. 6). Kennedy sees this as complementing concrete mathematical investigations. Perhaps for the first time, we are seeing a greater integration between philosophy and mathematics in the classroom, but the integration is not complete. Although one complements the other, they are still separate. The question arises: How can we teach mathematics in a philosophical way that doesn't entail teaching the mathematics first prior to any philosophical considerations?

The rest of the article is taken up with examples of discourse in action by showing parts of the transcript concerning two problems. The first is the problem of a frog at the bottom of a 30 ft well. Each hour it climbs 3 ft but slips back 2 ft. How long will it take to get out? The second problem is: given the two infinite sets $\{1, 2, 3, 4, 5,\ldots\}$ and $\{2, 4, 6, 8, 10,\ldots\}$, do both sets have an equal or a different number of elements? The discourse is of a very high standard and like all the examples of this kind (such as in Lipman and colleagues), it is surprising to know these are the conversations of upper primary/elementary children. We are told in each case that the children have already engaged in a community of philosophy for many hours beforehand,

and we get the sense that all this is possible, although we are not told whether the children involved were high developers. We also have to bear in mind that what we see is presumably only part of the many hours of transcript recorded. Nevertheless the conversations seem very mature for primary (elementary) schoolchildren and appear encouraging.

If the class can arrive at the conclusions as presented in the scripts, then this remarkable accomplishment ought to be encouraged, but what if the conversation comes to an impasse, or is a non-starter or the class arrives at a conclusion that is wrong? Must everything be constructed by the class or can/should the teacher give a clue, a hint, or indeed a correct answer? With the first example the class arrived at just how ambiguous the question is (a child says, quite late on in the discussion 'Well that's the way we understood it, but it's not quite clear'. p. 10) – they did the task – but couldn't the teacher point out the ambiguity? In the second example the discussion repeated itself until someone asked the question 'is infinity a number?' which created a new lead. What if no one asked that question? Of course the teacher could always ask such a question to keep the discourse going, but we have to bear in mind that the teacher, under such a programme, must not direct the discourse to arrive at preconceived ideas. There is a sense in which the discourse is directed by the children, and this is perhaps the greatest weakness of the programme.

Despite its criticisms of Piagetian stage theory, the programme itself is quite Piagetian in the sense that the children must find out for themselves rather than being told, although surely a hint here and there is more appropriate than spending a whole lesson trying to fathom the ambiguity of a question. In real life perhaps the problem would be rejected out of hand because of its ambiguity.

The many examples of classroom philosophical discussion in the literature are outstanding in their complexity, abstraction and logic; but we are not given the background of the chosen samples or details of the methodology, and we are not sure of the amount of transcript that is not included. The major problem seems to be the notion that it is OK for children to pursue a path of discussion that leads to nowhere or that they are neither right nor wrong. Of course, some paths do achieve an undecided position, such as the concept of infinity in De la Garza et al. (2000) classroom discussion,[8] but that is because of the nature of the concept under discussion. In general, the teacher should direct the class to the target concept. Hand (2008) criticises the widespread view that philosophy has no right answers by showing that all philosophical questions presuppose answers that are right, despite some questions as yet having no right answers. It is up to the teacher to convince why a particular answer is right (or wrong).

Although a philosophical question presupposes a right answer, the answer may be so formal that it may be inappropriate for secondary school pupils to entertain the

---

[8] 'Many [children] found convincing a view which could well be labelled constructivist – that infinity is not something we imagined as complete, but was a result of the fact that there was no stopping point, that infinity just kept going on. We then turned to measuring infinity and, having detoured through Cantor's proof that the number of integers was equivalent to the number of even integers, ended on a note of indecision' (De la Garza et al. 2000).

question. Nevertheless certain questions that have rigorous formal answers appropriate for undergraduates may have educational value for secondary school pupils. Certain answers lacking in rigour may be appropriate to schoolchildren because they expose or contextualise relevant concepts to be taught or provide a satisfactory ‘completeness’ to the question. Certain paradoxes may not have an answer, but for years may stimulate members of the class to think of one. Although questions presuppose answers, there may be more than one answer. The teacher must consider the educational value of her questions and the kind of answers to arrive at.

Daniel and colleagues (2000) present a research report of an ongoing project to implement a community of enquiry in the mathematics classroom. The article is essentially an argument for why a community of discourse is necessary for the mathematics classroom as opposed to the lack of meaningfulness of the mathematics taught in a traditional classroom. It discusses the myths and prejudices surrounding mathematics and philosophy (that there is only one way of getting the right answer or that philosophy isn’t for children, etc. similar to the Primary Teachers Update article by Lenton and Videon (2011)) but seems to propose that the meaningfulness of a community of enquiry can only be accomplished if the mathematics is related to the everyday experiences of the child. For example:

> Dewey states that as soon as studies in mathematics are dissociated from personal interest and their social utility, that is, when mathematics are presented as a mass of technical relationships and formulas, they become abstract and vain for students. It is only when children become intrinsically interested and conscious of mathematics as a means of solving daily problems (as opposed to end in themselves), that they enjoy playing with numbers, symbols and formulas. (Daniel et al. 2000, p. 5)

Why does developing an intrinsic interest involve the solving of daily problems? Presumably Euclidean geometry, which is an end in itself and can be unrelated to practical problems, will not do here. Like most communities of enquiry, an ‘everyday’ story is presented and a list of mathematical/philosophical questions (involving such concepts as truth, proof and infinity) are asked and pursued. The story seems to be the ‘everyday’ from which abstract problems arise – but this is not ‘mathematics as a means of solving daily problems’ as stated by Daniel and colleagues (2000). As this is an ongoing project, no results are discussed, although a summary of the results of a teacher questionnaire is stated. According to the teachers, some of the students reported that relating the discussion to mathematics wasn’t much fun and that sometimes they don’t want to hear about mathematics. Nevertheless they took well to the discourse. What is interesting is that they are not used to this kind of discussion involving mathematics.

Outside of the P4C programme, Prediger (2007) argues that philosophical reflections must play a prominent role in the learning process if an adequate understanding of mathematics is to be achieved by the class. By philosophical reflections she does not mean reflecting on classical philosophical theories, but reflecting on the mathematical activity itself, expressed by the verb *philosophize.*

What will be presented in the next section is an argument for philosophy to be integrated with a cultural-historical approach to teaching mathematics in order to engage children, for children to understand the nature of the concepts that they are expected to learn and to situate these concepts in the society that they belong. However, philosophy without the history (or perhaps with a little history) of mathematics can still be value-added, and this is discussed next.

22.4 A New Emphasis on Philosophy in the Mathematics Classroom

Philosophy without (or with little) history may seem a little empty, but it can have an add-on effect. The philosophy may only be related to the mathematical issue at hand (e.g. the concept of limit by dividing a circle into equal sectors and rearranging them to form a parallelogram of sorts – the notion of infinity explored by considering an ever-increasing number of sectors in the proof of $A = \pi r^2$), but much of what is taught can be done in a philosophical manner, such as the Socratic method of asking conceptual questions, parallel questions, contradictions, conjectures and counterexamples. The teacher orchestrates the class towards the target concept (or each target concept in succession), and philosophy provides the opportunity for exploration into the concepts to be learnt.

This is what Jankvist (2012) characterises as the *illumination approach* whereby the philosophy supplements the mathematics, although Jankvist's *philosophical discussion approach* (whereby groups of students enter debate concerning philosophical issues such as whether mathematics is discovered or invented) can also be included.[9] Using Jankvist's taxonomy, this is philosophy as a *means* rather than as an *end*. Similar to Jankvist, however, it will be argued that it would be more advantageous educationally if that philosophy was concerned with the history of mathematics. Meanwhile we shall look at various examples of philosophy and mathematics that can be introduced to the classroom but without, or with a minimal, history.

As an example of value-added philosophy, consider the paradox of Gabriel's horn (or the wizard's hat) that is asymptotic. A surface is generated by the 360° rotation about the x-axis of the curve of the function $f(x) = 1/x$ for $x \quad 1$ (Fig. 22.1).

This has a fixed volume (π cubic units) but an infinite area (see Clegg 2003). How is it possible for a finite volume to be enclosed by an infinite surface area (Clegg states that he has yet to see a satisfactory explanation)? After the calculus of basic volumes and surface areas have been learnt, such a question posed can raise discussion as to what volume, surface area and limiting case actually mean (it may be worth considering a cross-section perpendicular to the x-axis: a circle of radius r in which $r = f(x)$, followed by the rate in which the circumference decreases compared to the rate in which the area decreases, with respect to r. Similarly, by considering x the rate in which the surface area decreases can be compared to the rate in which the volume decreases, with respect to r). This can be a good prerequisite for fractals

---

[9] This is not, however, an instructional unit on philosophy and mathematics (Jankvist's *modules approach*) nor is it a course that pursues a particular philosophy of mathematics (Jankvist's *philosophy approach*).

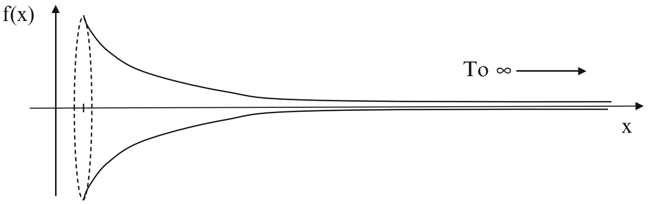

Fig. 22.1 Gabriel's horn (or the wizard's hat) – finite volume, infinite surface area

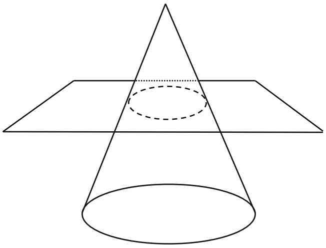
Fig. 22.2 A right-cone cut by a plane parallel to its base – are the two *dotted circles* (shown as one *dotted circle*) equal or unequal?



such as the Koch snowflake that has finite area but infinite perimeter, or the Sierpinski carpet which has zero area but has a non-empty interior – all of which can be discussed meaningfully prior to or without the formalism.

If a cone is cut by a plane parallel to its base, are the two circles formed out of the cut the same or different (although this can be introduced without reference to history, in fact it came from the Ancient Greeks) (Fig. 22.2)?

If the same, then we have a cylinder; if different, then the surface would not be as smooth as it is. This example, like many others, lends itself to the many ways in which the teacher can direct the discussion (e.g. 'my friend has an electron microscope and she didn't find any cone to be made of cylinders. What do you make of that?'). This paradox may not only create cognitive conflict, which some regard as essential in cognitive development, but lends itself to the ideas of a limit (the thickness of a cylinder having zero limiting length).[10]

Another example is Galileo's wheel paradox: the wheel fixed within a wheel (see Clegg 2003) (Fig. 22.3).

In one revolution the smaller wheel has travelled the same distance as the larger wheel, so it must have rolled more than one revolution, which is absurd. Although this paradox can be presented ahistorically, nevertheless historical considerations can always serve to illuminate. For example, consider, as Galileo does in his *Dialogue on the Two Principal World Systems,* two concentric octagons as shown (Fig. 22.4).

---

[10] Of course a little historical excursion can reveal how the Sophists used indivisibles and how the school allied to Plato used Eudoxus' method of exhaustion. The two can be compared in Archimedes's various proofs for the quadrature of the parabola (and the *Palimpsest*, the book where Archimedes uses indivisibles, has itself a wonderful history).

Fig. 22.3 A wheel fixed within a wheel and concentric

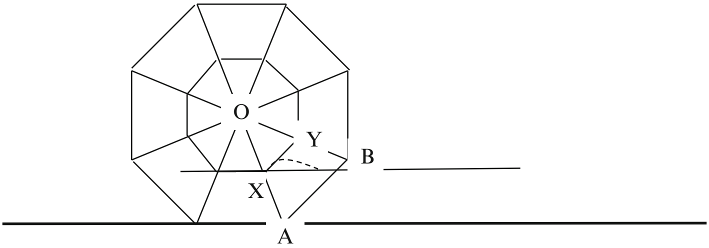


Fig. 22.4 Representing the circular wheels as octagons

In a one-eighth turn of the larger octagon, triangle OAB has been rotated 45° clockwise about a stationary point A. However, line XY has not only rotated 45° clockwise as well, but the point X about which XY has rotated has itself moved along the arc of a circle as shown. As Clegg states, side XY is lifted off the track.

The paradox is that with two concentric circles, there is sense in which no point on the smaller circle has left the track, yet in one revolution, a point on the smaller circle has traversed pi times the diameter of the larger circle, not the smaller. Of course, no point on the smaller circle will stay on the track, the loci being a cycloid that is smaller in height compared with the cycloid of a point on the larger circle; but we have to account for the horizontal displacement. Galileo (as Salviati) considers two concentric regular polygons of 100,000 sides in which after one turn the smaller polygon has traversed 100,000 smaller sides plus 100,000 tiny gaps between each side (we still have the isosceles triangle OAB, but with a much smaller AB, in which the 'tiny gap' is XY lifted off the track). One educational value of this example (and one that is stated by Clegg 2003) is that we can see Galileo tackle the complexity of the number of sides increasing towards infinity with the number of 'tiny gaps' also increasing to infinity but with the 'gaps' decreasing to zero.

Unfortunately Galileo does not solve the paradox, which was transformed into the definition of infinity by Dedekind and became solvable when presented in the new context of sets around 1870. Set theory is very abstract, so presenting the paradox to schoolchildren does not mean that they will eventually see the solution, but they can see the problem and the way Galileo tackled it.

Do complex numbers really exist? It is perhaps surprising that many websites state categorically that they do *really* exist (rather than just *assume* they exist). Some websites justify the assertion by referring to the very successful applications of complex numbers; but does success necessarily imply existence (certainly not for the relativist)? Complex numbers are counterintuitive, yet they are usually introduced in a matter of minutes, justified with reference to the complex roots of a quadratic and followed by its algebra in the hope that students will subsequently appreciate what they are through their applications. Philosophical discourse could make intelligible something that is counterintuitive, such as whether it is a question of existence or formalism (e.g. is the formalism reduced to $a+ib=c+id$, with $i^2=-1$, implies $a=c$ and $b=d$?). Of course, a little history (such as the reluctance of many mathematicians, from the Renaissance to the nineteenth century, to accept complex numbers) can put into context for the students their difficulties with complex numbers, especially since these difficulties plagued the best minds.

Is there a smallest number after 0? This question can be asked across the range from schoolchildren to undergraduates with the discourse appropriate to the level of development already attained. For example, schoolchildren could be introduced to the paradox of a 'next' number having an infinite number of decimal places.

Certain topics can be discussed in a philosophical manner even though the discussion may not be philosophical. For example, if $a^n=b^m$, when can we say $a=b$? What values of x and n satisfy $x^n=1$?

Philosophical discourse can also highlight the aesthetics and 'divinity' of mathematics; for example: Is Euler's equation ($e^{i\pi}+1=0$) evidence for the existence of God? Surely the coming together of the five most important numbers reveals divinity? How is it possible for a particular irrational number, raised to the power of a particular irrational number times i, to equal -1?

If $y=f(x)$ enables us to map x onto y, what can we make of dy/dx? A function is defined in terms of the way it maps the elements in the domain to the elements in the range – it can be said that a function is a *process* – so how come it is an object that can be differentiated? It would be worthwhile looking up David Tall's notion of *procept* (e.g. Tall and Gray 1994), even though this is for educators rather than for children.

How does the circumference of a circle relate to the area changing with respect to the radius? How does the surface area of a sphere relate to the volume changing with respect to the radius?

Many of these discussions are about mathematical paradoxes and can always make the subject more interesting than it already is (and pupils will always encourage it, even if to delay pencil and paper exercises). Skilful use will encourage a deep understanding of the concepts involved, something that Fisher (2005) refers to in terms of Skemp's relational and instrumental understanding; and the formalism can wait until the appropriate level of development. Such philosophy can either be an add-on ('bolt-on'), such as the wizard's hat, or it can be integrated into the introduction of a mathematical concept, such as complex numbers. Either way, it is value-added.

Of course, certain ground rules have to be maintained, such as not to ridicule anyone's contribution, not to hog the limelight (and try not to avoid it either). Initially more rules and a stricter regime may have to be enforced (e.g. 'hands up rather than call out'), but most likely it will become more relaxed and informal, everyone behaving in a respectful manner towards everyone else and the discourse. Most of the time the teacher should be at the front, rather in the traditional manner (and, incidentally, the pupils should perhaps sit in rows facing the front). The teacher *is* the sage on the stage, consciously directing the discourse towards fixed aims (although the discourse may be such that she allows it to go its own course without intervention) with preconceived ideas as to what she wants her class to arrive at. There has to be a target concept. This is not brainwashing, nor is it getting pupils to believe what she believes without realising it. It is teaching mathematics but with a little philosophy directed by the teacher – in the discourse she gives reasons for why something is the case and this can always and hopefully will be challenged. This is philosophy in the mathematics classroom with the teacher facing the class (sage on stage) most of the time (allowing for debate and the conversation going its own way), included in normal mathematics classes 5 h a week, versus philosophical discourse around a circle or horseshoe (a metaphor of the guide on the side) usually timetabled for 1 h a week.

The main proposal of this chapter is more than philosophy as a bolt-on; it is the teaching of mathematics with philosophical considerations but also within a cultural-historical perspective. Such a perspective will enable pupils to see and learn the great transformative events in the history of mathematics that transformed culture as well as cognition.

The main proposal is consistent with Jankvist's (2012) integration of history and philosophy in the teaching and learning of mathematics. The history is akin to Jankvist's *illumination approaches* that 'spice up' the mathematics within the historical context; and although not incompatible, this has less to do with the *modular approach* that is devoted to history or the *history-based approaches* that investigate a development of mathematics. The main proposal has more to do with history as a means rather than as an end, and although the use of original sources can serve a purpose, the history is primarily concerned with the transformative events that transformed cognition and culture as well as the mathematics. This is history to serve the understanding of the mathematics and to place the mathematics in context. Perhaps with certain exceptions such as Greek geometry, the history is not *necessarily* to understand the mathematics as constructed and perceived at the time. The history can have a place in understanding past developments from the standpoint of today – provided any historical specificity is not lost through a whiggish interpretation.

Although these transformative events may be considered 'epistemological obstacles' for both pupils and the mathematicians of the time, the proposal is not based on the recapitulation theory that historical obstacles parallel the difficulties that pupils have. This is simply because the obstacles to be raised will most likely be qualitatively different to the obstacles of the time, represented by the difference in notation. Nevertheless certain historical obstacles may be chosen to engage the class with the difficulties pertinent to understanding the relevant mathematics and, just as important, to see how this mathematics transformed cognition as well as culture. It also shows how the relevant concepts were hard-won, something that pupils can identify with in terms of their own difficulties.

Consider abstraction and proof, the two transformative events that occurred simultaneously, which transformed mathematics from an empirical affair to a science of reason that not only transformed Greek society at the time (see Kline 1972) but eventually led to the scientific revolution and the technological society we know today. For over two millennia, classical geometry served as a major rite of passage into scientific culture, as a world view, as a conceptual lens and as the introduction to rationality. From Thales to Euclid, classical geometry expanded into a world of abstract, formalized, theoretical objects and purely intellectual processes. Initially children are given a story of how Thales learnt the practical geometry of the Egyptians, a geometry borne out of the annual flooding of the Nile, and how he abstracted the notion of the geometric straight-line from observing stretched rope. They can then go outside with clipboard and paper and draw two intersecting ropes in six stages of abstraction leading to the platonic form of two intersecting lines (see Carson and Rowlands 2007; Rowlands 2010). The class is made aware that what we know about Thales is second-hand, written by Greek historians and commentators (Eudemus, Aristotle, Proclus) centuries after the event, so we don't actually know how Thales performed the abstraction necessary to have created the theoretical objects of geometry. He is credited for the very first five proofs which may not have been possible without the construction of added lines, which suggests that he did undergo some form of abstraction.

The point is the emphasis on this remarkable 'event' itself (if it was an event) that changed the course of the history of mathematics and indeed culture itself. This is not history as an examination of what actually happened because we only know what happened second-hand centuries after the event. Thales becomes a narrative device in contextualising what would otherwise be purely formal and symbolic, and although historical detail whenever possible is extremely important, it is more Thales the myth than the actual historical figure itself.[11]

During each stage of abstraction, the teacher asks what abstraction means, what has been left behind and what has been taken forward during each stage and introduces Thales' attempt to demonstrate that opposite angles of two intersecting lines are equal, despite the fact that it is obvious that they are equal. The class is not given a proof, but constructs a proof under the guidance of the teacher who is careful not to give information explicitly (see Rowlands 2010), although information is conveyed implicitly through the asking of questions. During the fourth level of abstraction (*personal concept*), the class is invited to close their eyes and think of two intersecting lines, to think of what has been taken forward and what has been left behind and how this differs to their previous drawings of two intersecting lines (the *literal representation* and the *abstract representation*). At the fifth level, the class considers the concept of two intersecting lines as it appears in textbooks (the *authorised concept*). At the sixth level (*platonic form),* the class is introduced to the platonic form of two lines intersecting and asked where the truth of opposite angles being

---

[11] At the secondary level the aim has more to do with developing an understanding of mathematics itself (and its place in terms of impact) than it has with understanding its history. The same with philosophy; for example, a secondary school mathematics teacher doesn't raise Plato's distinction between knowledge and belief because it happens to be a good thing to know, but because it illuminates the concept of proof.

equal resides. As part of the course, the pupils can be introduced to other Forms, such as Virtue or Shape, and to see how Socrates rejects given examples of a Form in favour of it being well defined.

Care should be taken, however, not to present these ideas as true. Arguably (and similar to the sophists), there is no Form of Justice or Virtue, and these concepts do not transcend cultural boundaries; but the Forms can be contextualised by emphasising the Forms as representing abstract objects that could have easily disappeared, leaving the world to concrete exemplars. Subsequently the class can then learn the basics of Greek deductive geometry with the opportunity to discuss wider philosophical issues such as whether mathematics is invented or discovered and the immortality of the soul (similar to Plato's *Meno,* the class who has constructed a proof but without the teacher giving information can question where their knowledge and understanding comes from). During this process the class can become aware of the theoretical objects of geometry (the point as a dimensionless object, the straight-line as having only one dimension, the circle both as an object and as the locus of a moving point, a fixed distance from a fixed point, the plane having no thickness, etc.) that they are normally expected to use in a traditional lesson but ordinarily have no idea as to what these objects are. The cultural aspect includes how the geometry transformed Greek society (art and architecture, philosophy, law, etc.; see Kline 1972) and how our modern technological society evolved from this (the scientific revolution of the 1600s would not have been possible without the abstraction and idealisation of Greek geometry).

Thales is not only credited as the first Greek geometer but also the first Western natural philosopher, who tried to explain the world without reference to divine will or intervention. According to Aristotle's *Metaphysics*, Thales maintained that water is the 'material principle' of the world from which everything is made (see Barnes 1987). Geometry and philosophy grew up together, culminating in Plato's famous statement at the entrance to his Academy ('He who is ignorant of geometry should not enter here'). This is not surprising if you regard geometry and philosophy as somehow having similar levels of abstraction – something that can be discussed with the class.

It is hard to imagine a discourse on proof with very little reference to philosophy, yet if proof is taught, then it is seemingly done so with little regard as to its nature. Proof is often a means to an end, an accomplishment of a task, yet there is little reference to what it is or just how important it is.[12] According to Kunimune et al. (2009), there are many Japanese children who are capable of Euclidean proof who do not see the importance of deductive proof over inductive procedures. This is perhaps common wherever deductive proof is taught, but it is odd that children can perform proof without acknowledging its importance and relevance.

Get a class who can use the protractor to each draw their own triangle and then to measure the angles. Record their answers. Here we have a whole new universe of

---

[12] And as far as the majority of English and Welsh classrooms are concerned, proof no longer exists and perhaps because many teachers and curriculum designers can remember the negative experience of having to regurgitate proof in examinations. For some educationalists, proof means rote learning.

discourse opening up – from the student unwilling to believe that the angles add up to 180° because hers add up to 181° (a problem for the radical constructivist) to whether the measurements of a million students would be enough to justify the angle property – leading hopefully towards a formal proof. If appropriate, the teacher could introduce Bertrand Russell's good inductivist turkey (ever since it could remember, it was fed breakfast at 9.00 a.m., but decided not to be certain that it would be fed at 9.00 a.m. the next day until it amassed enough evidence. After the days, weeks and months went by, it decided that it could be certain; but the next day was Christmas, and rather than having breakfast at 9.00 a.m. had its throat slit (Chalmers 1982)) and compare inductive procedures with deductive proof with specific reference to the triangle. Given their sense of wonder and their abilities, it is possible to engage children with the concept of proof, especially from a philosophical approach that encourages them to express what they think on the subject, freely and without any fear of giving a wrong answer. Eventually, they will expect epistemological reasons for why something is the case or why they have to learn it, giving them a critical edge to their learning.

Iversen (2009) suggests the comparison of proofs in both mathematics and philosophy as well as the comparison of other similar concepts in both domains as a way of developing a cross-curricular competence of mathematics. Now if this was done in a historical-cultural way so as to show the impact of the *Elements* and proof in particular on society (e.g. Spinoza's *Ethics* and Newton's *Principia* in the Euclidean deductive style, the ideas of proof and deduction in law to even the self-evident truths of the American Declaration as axioms), then it can be shown how proof impacted philosophy, especially since they grew up together for 300 years. Unfortunately the suggested St. Anselm's ontological proof for the existence of God (essentially: perfection must involve existence) is a very poor example.

Unlike perfection, existence cannot be predicated and so this seeming 'proof' compares badly with, say, the proof of the angle property of the plane triangle.

Philosophy has so much more to offer. Why not engage students with the notion of proof in conjunction with Plato's distinction between knowledge and belief as a backdrop? For belief to become knowledge, it has to be shown why the belief is true. Showing why becomes the anchor for certainty and proof can be seen as the highest warrant for certainty, with the notion of fallibility brought in to discuss the context in which we can say a mathematical proposition is true. Proof is perhaps the highest form of human achievement concerning justification[13] – so philosophy ought to be used to bring out the role of proof as a stunning advance in human ingenuity – it would be a pity if philosophy was merely 'compared' with mathematics in the sense of both having similar ('cross-curricular') notions, such as proof, only to find that some of those notions aren't so similar after all (such as St. Anselm versus Euclid).

---

[13] Even social constructivists such as Paul Ernest love and rely on Godel's proof, even though they don't like proofs in general (Ernest goes so far as to regard proof as Eurocentric and its glorification racist). This and other social constructivist contradictions can be found in Rowlands et al. (2010).

Just as history and philosophy have a very important role in science education (an exemplar being Michael R. Matthews' International Pendulum Project), so history plays a very important role in discussing philosophy in the mathematics classroom. The transformative leaps in the history of mathematics, such as Thales' abstraction from concrete exemplars to theoretical objects and his beginnings of what was to become deductive proof, provide the basis for understanding the terms of discourse and how these theoretical objects relate conceptually. This can be achieved with almost any level of development, and there is evidence to show the possibility (see Rowlands 2010), not only with high achievers but more importantly with low developers as well.

With no doubt the exclusion of rigorous foundationalist issues such as logicism, formalism and intuitionism, the nature of mathematics can be discussed in terms, for example, of platonic ideals and whether or not mathematics is invented or discovered (see Rowlands and Davies 2006). This is not teaching philosophy per se, but using philosophy to enhance a deeper understanding of the mathematical concepts involved, for example, the concept of infinity regarding the proof for the area of a circle, the finite sum of a converging infinite series (which can be related to an adaptation of one of Zeno's paradoxes) or the derivative. Berkeley's criticism of the derivative as the 'ghost of departing quantities' can be useful here.

The most important emphasis, however, has to be the philosophical consideration of the transformative leaps that have occurred in the history of mathematics, such as the advent of symbols, lines-rays-segments-angles-triangles; constructions; the circle as a mathematical concept; the advent of formal proof; infinity and the relationship between algebra and geometry (see Carson and Rowlands 2007). There were three major overarching transformations in the history of mathematics: Greek geometry leading to the axiomatic form of the *Elements*; the ideas of the seventeenth century that culminated in the works on calculus by Newton and Leibniz (perhaps this would not have happened if Hindu and Moslem developments had not reached Europe) and the rewriting of mathematics in axiomatic form in the nineteenth century followed by the 'rebirth' of mathematics under Riemann, Dedekind, Cantor and Hilbert. Perhaps the second ought to be left until the pupils reach at least 16/17 years of age and perhaps the third ought to be left until university, but the first gives ample scope for philosophical discourse at the secondary level without the demands for rigour. The concept of irrational number, for example, can be introduced in terms of the Pythagoreans describing the world in terms of number and their discovery that the diagonal of a square cannot be measured exactly (with auxiliary issues such as killing for love, out of vengeance, for country, on the one hand, and killing for squealing that $\sqrt{2}$ is irrational, on the other). A formal theory of the real numbers is not necessary at this level.

Whatever the emphasis on philosophy, however, the overall emphasis has to be on the metatheory of the mathematical concepts to be taught, such as the nature of the concept and its place within a system of concepts, its impact in terms of that system and its impact cognitively and socioculturally.

Philosophy presupposes answers that are either right and wrong, that answerability is a necessary feature of questions and philosophical inquiry is not a futile quest into questions that have no right or wrong answers (Hand 2008); and this is particularly the case when the philosophy discusses mathematical concepts, but children ought to engage in mathematics with philosophy but without the fear that their answers may be wrong. Here metacognitive skills may be enhanced as pupils try to relate their understanding to the cognitive demands of the course (and making public without fear of ridicule).

Perhaps more importantly, however, is that philosophy and mathematics can encourage creativity in Boden's (1994) transformative sense, for example, by giving the freedom to explore the dropping of some of the constraints of the subject, such as dropping Euclid's fifth axiom (the parallel postulate) to see whether the angle property of the triangle still holds prior to triangles drawn on spheres. Mathematics and philosophy within a cultural-historical context provides the opportunity to explore the creativity involved in such transformative leaps that changed cognition and culture. Students will begin to see creativity as a human endeavour to which they belong, especially if they appreciate the cultural-historical significance of fundamental concepts, their cognitive impact and just how hard-won they were. Creativity in Boden's transformative sense requires both learning the subject to exhaustion and having the freedom to play at a meta-level (see Rowlands 2011). That meta-level can be attained with the use of philosophy, especially from an historical-cultural perspective.

22.5 Conclusion

Hopefully it has become evident that what is being proposed is far removed from the philosophy for children programme: the teacher will always have preconceived ideas as to what she wants her class to know and understand. But this is not the imposition of the teacher's views upon the class. The imposition is the mathematics, but the teacher will hopefully develop the critical state of mind that challenges what is considered true in mathematics and hopefully develop the ability to become creative within mathematics.

The aim of this chapter is not to disparage the philosophy for children programme, although what is being proposed is quite a radical departure from that programme. Nor does it mean a radical overhaul of the traditional classroom. Mathematics is still taught but with the encouragement of becoming critical, that nothing is given on faith and that what is taught becomes part of the heritage that children belong and have the right to become enculturated. It is about the learning of mathematics that has become the fabric of today's technological society but with a comprehension and a critical stance that can encourage the child to become a discerning citizen of that society. Such an approach outlined above not only has the potential to enhance metacognition but creativity as well, not in the sense of novelty but in the sense of transforming the subject. Only then will mathematics be truly owned by all children.

When truly owned, then perhaps more students will be taking a mathematics degree at university, and perhaps the lectures will be similar to the ideal Socratic discourse of Lakatos' *Proofs and Refutations*. In Proof and Refutations the teacher leads the discussion with (admittedly) very bright students; but this may be possible with all students of varying levels of development if the mathematics has already been introduced philosophically, as a Socratic discourse, at the secondary school level. Lakatos' Socratic discourse is the ideal to which we can aspire – in our own classrooms and hopefully, 1 day, to the next level of learning/teaching mathematics that encompasses this ideal.

What has been proposed is only possible if student teachers are trained in introducing philosophy to the mathematics classroom, trained not only in raising philosophical questions concerning the mathematics taught but also in terms of establishing the classroom norms for the discourse to take place. Philosophy as well as history should be mandatory in mathematics teacher training. Not necessarily philosophy and history per se, but as aids in the teaching of mathematics.

Chapter 23
A Role for Quasi-Empiricism in Mathematics Education

Eduard Glas

23.1 Introduction

In modern philosophy of science, there is virtually no disagreement about the fallibility of empirical scientific knowledge. We just cannot be absolutely sure that a scientific theory will stand up to all future tests. Mathematical propositions, on the other hand, do not refer directly to matters of empirical fact and therefore look like products of pure thought, immune to empirical refutation. They seemingly possess the absolute certainty of analytic statements or logical truths.

This view of the matter has had a strong impact on the public image of mathematics and, in particular, on the way in which teachers and their pupils regard the mathematics taught in school. They still often look upon mathematics as the one teaching subject where practical experiences are irrelevant and where there are single right answers to all questions, whose correctness is beyond all doubt. Is a different view at all possible?

Although it is true that mathematical propositions are not straightforwardly empirically falsifiable, they are not immune to all (other) forms of criticism. They may, for example, be criticised for failing to solve the problem which they were designed to solve. In science, too, deficiencies in problem solving or explanatory potential are normally counted as negative evidence. So in this respect, mathematics is not unique and not as radically different from science as those who entertain the above view suppose.

Throughout this chapter, extensive use has been made of previous articles mentioned in the references.

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_23,

Especially the most advanced sciences are very much like mathematics in that their conceptual apparatus and organisation are to a large extent non-observational and self-supporting. Only think of the theory of relativity, which depended on the nonempirical principle of relativity and the non-Euclidean geometries developed in the second half of the nineteenth century. Einstein's achievements relied on thought-experiments and mathematics; empirical methods became relevant only when confirmation or corroboration was called for. More recently, the fruitful interaction between string theory and differential geometry has even led to a reversal of the direction of influence: mathematical physicists constantly reveal new mathematical structures undreamt of before.

The derivation from scientific theories of empirically testable consequences may require considerable theoretical effort, and their confrontation with observational material is itself dependent on theoretical assumptions about the meaning of terms, the interpretation of observations, theories of experimental design and procedure, ceteris paribus clauses, etc., briefly: on more basic theories. Testing a scientific theory therefore ultimately boils down to checking its consistency with respect to lower-level theories (much like mathematics), and it is often possible (though not always rational) to resolve empirical difficulties without giving up the theory under examination. It appears therefore that while mathematics is to a certain degree 'science-like', modern science is also much more 'mathematics-like' than has traditionally been supposed, and any difference between the two is at most only a matter of degree.

Although once couched in formal language physical theories are no more directly refutable than mathematical theories, nobody would for that reason deny them their empirical character. Neither should the impossibility of a direct empirical refutation of a mathematical theory count as sufficient reason for denying mathematics all claims to empirical significance. Formalised mathematics can effectively be immunised to all informal counterevidence: a formal mathematical theorem may be upheld 'come what may'. But the same applies to a considerable extent also to modern, mathematically impregnated science. And in either case, our actually choosing to do so would imply resigning ourselves to stagnation of the growth of knowledge. Informal counterexamples to formal theorems can be ignored; but by ignoring them, we also ignore the best opportunities for achieving progress. This is precisely the important lesson contained in Imre Lakatos' work on *Proofs and Refutations* (Lakatos 1963–64, 1976), which may be regarded as the seminal text for the quasi-empirical approach to mathematics.

In the acknowledgement preceding the said articles, Lakatos tells us that 'the paper should be seen against the background of Pólya's revival of mathematical heuristic, and of Popper's critical philosophy' (Lakatos 1976, p. xii). It will be opportune, therefore, to sketch these backgrounds first and next to proceed with an analysis of Lakatos' quasi-empirical heuristic against these backgrounds. Although there are other approaches to the philosophy of mathematics that go under the head of quasi-empiricism, the present discussion will be restricted to the said criticist-objectivist strand, construed as a self-contained whole. A short assessment of the educational implications of the quasi-empirical view of mathematics will be given in the concluding section. These implications have no direct bearing on the actual practice of teaching mathematics in the classroom, but mainly – not less importantly – on the *image* of mathematics that is conveyed in education.

23.2 Pólya's Problem-Solving Heuristic

Lakatos' fellow Hungarian and friend György Pólya (1887–1985) was an important reformer of mathematics education and a champion of informal styles of reasoning in mathematical problem solving (Pólya 1954, 1957, 1962, 1968, 1973). He extensively discussed several ways of fruitful thinking in mathematical problem situations. By its enormous wealth of examples, this extensive body of work had a profound impact on mathematics education.

Underlying Pólya's approach was the crucial distinction between demonstrative and plausible reasoning. Presented in the standard Euclidean manner, mathematics appears as a systematic deductive enterprise. Demonstrative reasoning refers to this well-known deductive or Euclidean mode of presentation. It has rigid standards which are codified and clarified by logic. This style of reasoning is safe, beyond controversy, and final. It is the mode of argumentation needed for the ultimate proof of mathematical propositions.

Plausible reasoning, by contrast, refers to argumentation in the inductive or even experimental style. Mathematics in the making is said to exhibit the character of an experimental inductive science based on plausible rather than demonstrative reasoning. Especially inductive generalisation and reasoning by similarity and analogy are essential for the discovery or invention of conjectures. As problem-solving strategies, they are domain specific and situational; their standards are fluid, not rigid; and they are directed towards both the generation and the support (though not the proof) of mathematical hypotheses.

> Mathematics in the making resembles any other human knowledge in the making. You have to guess a mathematical theorem before you prove it; you have to guess the idea of the proof before you carry out the details. You have to combine observations and follow analogies; you have to try and try again. (Pólya 1973, p. vi)

Pólya thus entertains an 'empiricist' position with respect to the generation of mathematical knowledge and even the generation of proof ideas, though not in regard of proof itself. But in the birth phases of a mathematical theory, in particular, there is ample space for inductive reasoning, generalisation, specialisation and analogy, and these informal modes of reasoning are reproducible in the classroom. The didactic relevance is obvious from the wealth of examples which are offered for imitation and practice, enabling learners to grasp the relevant concepts and to re-create as it were the theory in question. Pólya suggests that the traditional deductive view of mathematics seriously obscures the inductive nature of the reasoning that mathematicians use when deriving their conjectures and dreaming up their attempts at deductive proofs:

> The result of the mathematician's creative work is demonstrative reasoning, a proof, but the proof is discovered by plausible reasoning, by guessing. (Pólya 1954, p. 158)

Pólya was exceptional through his interest in heuristic, the till-then largely neglected problem of the reasoning processes underlying discovery. Especially since Reichenbach's canonisation of the distinction between the context of discovery and the context of justification, methodological analysis had more and more become restricted to the explication of concepts and the verification of already articulated theories. Discovery was considered a process devoid of logic and therefore of interest only to psychologists. For Pólya, however, discovery in mathematics follows certain rules that together represent a 'heuristic', an *ars inveniendi* (art of invention). It concerns the discovery of mathematical 'facts', which subsequently still are to be proved in a strictly deductive way. But heuristic, the logic of mathematics in the making, is largely inductive or, in other words, 'quasi'-empirical.

Pólya's achievements clearly are above all of great pedagogical and didactic relevance. As he himself testified, it had never been his intention to write philosophical treatises. Still, his work contains many philosophically important issues which, however, showed to full advantage only in the hands of Imre Lakatos. Testing mathematical conjectures by 'quasi-experiments' represents just one of the more important examples of what Lakatos owed to Pólya.

23.3 Between Pólya and Popper: Lakatos' Heuristics

Imre Lakatos (1922–1974) went on where Pólya had stopped. He transformed the idea of heuristic into a critical methodological concept, the method of proofs and refutations. In some ways, it surpassed Popper's logic of scientific discovery, but it surpassed even more Pólya's idea of heuristic as an 'art of invention', and especially the latter's inductivist conception. Lakatos' heuristic was based on the use of counterexamples – suggesting falsification – as critical tools for the achievement of *growth* of knowledge.

Heuristic for Lakatos was a truly methodological notion, *viz*., a set of criteria indicating which paths should be followed and which should be avoided in order that our knowledge may grow. It is neither a logical nor a psychological subject, but an autonomous methodological discipline, the 'logic of discovery':

> there is no *infallibilist* logic of scientific discovery, one which would infallibly lead to results; there is a fallibilist logic of discovery, which is the logic of scientific progress. Popper, who has laid down the basis of *this* logic of discovery, was not interested in the metaquestion of what was the nature of his inquiry and he did not realise that this is neither psychology nor logic; it is an independent discipline, 'heuristic'. (Lakatos 1976, pp. 143–144, footnote)

Lakatos not only applied Popper's 'logic of discovery' to mathematics but brought a much larger part of the Popperian corpus to bear on mathematics, *viz*., the centrality of problems and their dynamics rather than static definitions, methodological rules to prevent loss of content, the use of models to test lemmas separately and the associated distinction between global and local counterexamples (cf. Glas 2001), and more especially a group of ideas clustering around Popper's doctrine of the relative autonomy of objective knowledge, which was fully endorsed by Lakatos:

> Mathematical activity is human activity. Certain aspects of this activity … can be studied by psychology, others by history. Heuristic is not primarily interested in these aspects. But mathematical activity produces mathematics. Mathematics, this product of human activity, 'alienates itself' from the human activity which has been producing it. It becomes a living, growing organism that *acquires a certain autonomy* from the activity which has produced it; it develops its own autonomous laws of growth, its own dialectic. (Lakatos 1976, p. 146)

Proofs and Refutations is written in the form of a classroom dialogue between a teacher and pupils bearing the names of Greek letters and representing various ways of dealing with counterexamples. In the beginning, we have a theorem (about the relation between the numbers of vertices, edges and faces of polyhedra) and a counterexample. What follows is a direct confrontation between two equally dogmatic epistemological positions. Pupil Delta typically tries to save the proposition by 'conventionalist stratagems' – introducing ad hoc redefinitions of terms in order to render counterexamples harmless (appropriately dubbed monster barring, exception barring and monster adjustment by Lakatos). These strategies effectively immunise the theorem from refutation but also rid it of more and more of its informative content, until at last it has become an utterly uninteresting truism. Pupil Gamma, on the other hand, insists on exact definitions of the fixed meanings of terms. He therefore regards any counterexample as conclusive proof of the falsity of the theorem. He typically is a 'naïve falsificationist'. Neither Delta nor Gamma handles a critical methodology in the Popperian sense, that is, a set of rules delimiting the sorts of arguments that are fruitful to the *growth* of knowledge, getting at theorems that say 'more' that is also 'more nearly true'. Neither of the dogmatic positions represented by Delta and Gamma *uses* the counterexample in a constructive fashion to learn from it how a better theorem might be obtained. Both Gamma's and Delta's modes of argumentation are in this sense detrimental to the growth of knowledge; they are not rational because they fail to take adequate account of the problem situation.

Rejecting the use of conventionalist stratagems does not imply that all counterexamples should be uncritically accepted; we may rationally defend a theory, provided that adjustments are not entirely ad hoc and do not lead to unnecessary losses of content. So there is always a methodological *decision* to be made when a theorem is confronted with a counterexample, the rationality of which depends on the particular problem situation, especially on whether it would lead to a content-increasing or a content-reducing problem shift.

The teacher develops the Lakatosian methodology by participating in and drawing the lesson from the discussion that follows after the initial confrontation. He lets the pupils lay down the conclusions in a number of methodological rules which, typically, are all concerned with making a justifiable *decision* about what to do if a counterexample, either global (against the theorem as a whole) or local (against a lemma in the proof), turns up. All the rules begin with 'if you have…'; they are not concerned with the question of 'how to find' (Pólya's *ars inveniendi*) but with the logic of discovery in the (Popperian) sense of making justified decisions – justified by preventing loss of content. The rules say that if you have a global counterexample, analyse your proof, make all hidden lemmas explicit, find the guilty one and improve your conjecture by incorporating this lemma in the form of a condition. If you have a local counterexample, check to see whether it is not also global. If it is, apply the previous rule. If it is not, try to improve your proof analysis by replacing the refuted lemma with an unfalsified one (Lakatos 1976, p. 50).

Much of the methodological discussion thus consists in specifying the appropriate methodological rules to counter conventionalist stratagems by turning global counterexamples into local ones and *using* them to get at improved theorems-*cum*-proofs, without unnecessary losses of informative content. But besides preventing loss of content, we aim at increase of content; the fifth methodological rule indicates how this is to be done: if you have counterexamples of any type, try to find, by deductive guessing, a deeper theorem to which they are counterexamples no longer (*ibid*., p. 76). Increase of content may also be achieved through the formation of new concepts as a by-product of the development of the initial naïve conjectures into more and more sophisticated propositions. The formulation, analysis and reformulation of proofs will often, perhaps unconsciously, lead to a redefinition of the terms used – a development from naïve concepts to 'proof-generated' concepts. We may even 'stretch' concepts deliberately beyond their original domain of application in order to reveal possibly unsuspected new relationships that could not even be articulated in terms of the original, more naïve concepts.

Central to the method of *Proofs and Refutations* is the role of *proofs* in the growth of mathematical knowledge. Proofs are not ends, in the sense of establishing once and for all the truth of a theorem, but means to get at richer, deeper, more interesting theorems. Lakatos introduced a structural epistemological similarity between 'proofs' in mathematics and experimental 'tests' in science (proofs are 'tests' – as in the 'proof' of the pudding). As scientific theories are tested by experiments that anchor them to lower-level statements, so mathematical theorems are tentatively proved by deriving them – by means of a thought experiment – from more basic lemmas. Proofs thus play a role analogous to corroborating experimental tests in science. In the justificationist tradition, proofs are supposed to link theorems to indubitable axioms whose truth immerses the whole propositional system through channels of truth preserving – i.e. deductive – arguments. In Lakatos' quasi-empirical heuristic, it is not truth streaming downward from the axioms but the upward retransmission of falsity (in the form of counterexamples) that is crucial for the growth of knowledge.

23.4 Fallibilism and Quasi-Empiricism

The most important background to Lakatos' quasi-empiricism is, of course, the critical fallibilism of his one-time teacher at the London School of Economics, Karl Popper (1902–1994). Popper did not consider anything, including mathematics and even logic, as absolutely certain (Popper 1984, pp. 70–72). He argued that we should never save a threatened theoretical system by ad hoc adjustments that reduce its testability (Popper 1972, pp. 82–83) – a view to be exploited by Lakatos to such dramatic effect in the dialogues of *Proofs and Refutations* under the heads of monster barring, exception barring and monster adjustment.

Popper's fallibilism implies the non-existence of solid foundations to stop the infinite regress in proofs and definitions; all knowledge is conjectural, consisting of attempts at solving problems. Central to mathematics are problems, and striving after exactness for its own sake is futile:

> Absolute exactness does not exist, not even in logic and mathematics . . . and the demand for "something more exact" cannot in itself constitute a genuine problem (except, of course, when improved exactness may improve the testability of some theory). (Popper 1983, p. 277)

In much the same vein, Lakatos took up a critical analysis of modern attempts to place the whole of mathematics on a perfectly exact basis of ultimate logical intuitions in his paper on 'Infinite Regress and Foundations of Mathematics', which dates back to 1962, before the articles on *Proofs and Refutations* appeared (1963–1964) (Lakatos 1978b, pp. 1–23). From the outset, Lakatos made it clear that his aim was to break ground for a critical programme in mathematics, the programme of Popper's *critical fallibilism* (*ibid*., pp. 9–10).

So far, Popper and also Lakatos himself (in his thesis) had only considered *informal* 'preformal' mathematical theories. But it is one thing to show that informal mathematics is conjectural, it is quite another thing to show that uncertainty is not just a *Kinderkrankheit* of informal mathematics, which has now been cured by founding the discipline on rigorous logic and 'ultimate' (set-theoretic) axioms. Mathematical theories are fallible not only as long as they have not been properly founded: the foundational programmes are themselves just hypotheses. The arithmetisation of mathematics by Cauchy and his followers was a wonderful Euclidean achievement, but like any other theory, it was susceptible to criticism. The most incisive critical arguments came from the doubts of the pursuers of the quest for certainty themselves (notably Frege and Russell):

> Have we *really* reached the primitive terms? Have we *really* reached the axioms? Are our truth-channels *really* safe? (*ibid*., pp.10–11)

Lakatos concentrated specially on Russell,

> showing how he failed in his original Euclidean programme, how he finally fell back on inductivism, how he chose confusion rather than facing the fact that what is interesting in mathematics is conjectural. (*ibid*., p. 11)

Russell never had seriously considered the possibility that mathematics may be conjectural. Instead, he came to hold that some axioms of logic are to be believed, not on their own account, but on account of the indubitability of their logical consequences (*ibid*., p. 17). According to Lakatos, Russell failed to draw the right conclusion

> that the infinite regress in proofs and definitions in mathematics cannot be stopped by a Euclidean logic. Logic may *explain* mathematics but cannot *prove* it. It leads to sophisticated speculation which is anything but trivially true. … The logical theory of mathematics is an

> exciting, sophisticated speculation like any scientific theory. It is an empiricist theory and thus, if not shown to be false, will remain conjectural forever. (*ibid*., p. 19)

Lakatos did not deny, of course, that virtually the whole of mathematics could be derived from axiomatic set theory. The fundamental assumptions of set theory, however, are far from self-evident or trivially true. They might be overthrown, replaced or supplemented by new axioms, especially in view of the 'independent' questions, the remaining problems which are not decidable by the standard axioms. Given that these axioms cannot themselves be proved, any sort of arguments that may be offered for or against them will in the end rest on what one *guesses* to be true (or convenient).

Lakatos drew attention to the danger that those (like Russell) who recognise the science-likeness of mathematics turn for similarities to a noncritical (non-Popperian), justificationist image of science, fall back on inductivism and psychologism and keep searching for the ultimate authoritative basis for justifying certain *beliefs*.

> But why on earth have "ultimate" tests, or "final" authorities? Why foundations, if they are admittedly subjective? Why not honestly admit mathematical fallibility, and try to defend the dignity of *fallible* knowledge from cynical scepticism . . . ? (*ibid*., p. 23)

At the London Colloquium of 1965, Lakatos commented on a lecture of Kalmár in which the latter discussed and defended the position that mathematics is an empirical science (Lakatos 1967, pp. 187–194). It is here that Lakatos introduced his distinction between *quasi*-Euclidean and *quasi*-empirical theories and laid down the claim that mathematics is quasi-empirical.

He explained that a theory may be non-empirical yet quasi-empirical, or empirical yet quasi-Euclidean for that matter, the distinction referring only to the direction of the characteristic truth-value flow (top-down or bottom-up). The claim that mathematical theories are quasi-empirical therefore says in effect that the characteristic logical flow in mathematical theories is the bottom-up retransmission of falsity. Euclidean theories are here considered as limiting cases of quasi-empirical theories: a system is Euclidean if it is the logical closure of the accepted basic statements and quasi-empirical if it is not. Whereas a Euclidean theory may be claimed to be true, a quasi-empirical theory can at best be well corroborated (when it has an impressive record of passed tests), but ultimately has to remain conjectural. In a quasi-empirical theory, the axioms do not *prove* the theorems in a strict sense, but they *explain* them by showing of which more fundamental assumptions they are the logical consequences. The basic rule of quasi-empirical methodology is

> to search for bold, imaginative hypotheses with high explanatory and heuristic power; indeed, it advocates an uninhibitedly speculative proliferation of alternative hypotheses to be pruned by severe criticism. (*ibid*., p. 202)

Lakatos deemed it not superfluous to state expressly in a footnote that *of course* the paradigm of quasi-empirical methodology is Popper's scientific methodology.

The axioms of a formal theory are often regarded as implicitly defining the concepts that they introduce. If this view is accepted, then there could be no potential mathematical falsifiers except logical ones (i.e. statements of inconsistency). But

Lakatos vehemently opposed the utterly *un*historical identification of mathematics with the set of all consistent formal systems and insisted that we should speak of formal systems only if they are formalisations of some informal theory. A formal theory then may be said to be ‘refuted’ if one of its theorems is negated by one of the theorems of the corresponding informal theory. Such informal theorems he called *heuristic falsifiers* of the formal theory (Lakatos 1978b, p. 36).

The axioms of set theory, for example, may be tested for consistency, and the definitions may be tested for the correctness of their translation of branches of mathematics such as arithmetic. If a counterexample from arithmetic can be formalised in the system, the formal theory is thereby shown to be inconsistent (in which case we have a logical falsifier). But if the system is consistent, the counterexample cannot be formalised. Such a heuristic falsifier therefore does not show that a formal theory is inconsistent, but only that it is a false theory *of arithmetic*, while it still may be a true theory of some mathematical structure that is not isomorphic with arithmetic. The axioms then do not properly *explain* the informal theory that they were designed to explain.

So Lakatos found mathematical analogues of Popperian potential falsifiers in theorems of arithmetic or other branches of classical mathematics that are potential counterexamples to corresponding theorems of the formalised theory. It enabled him to give an epistemological underpinning to such notions as the content of a mathematical theory (the arithmetical content of a formal theory in particular), content-increasing and content-decreasing problem shifts and so on, in terms of sets of potential falsifiers – as Popper had done for natural science.

Strictly speaking, a heuristic falsifier is no more than a rival hypothesis that merely *suggests* a falsification, and suggestions may be ignored. This, however, does not separate mathematics as sharply from natural science as one might think. Popperian basic statements, too, are only hypotheses after all. They are accepted tentatively for the purpose of a particular discussion of a particular problem, but may become highly questionable in a different discussion of a different problem. They do not constitute some bedrock of knowledge, but are more like ‘piles driven into a swamp’ (Popper 1972, p. 111). Lakatos was fully in agreement with this view when he claimed that

> the crucial role of heuristic refutations is to shift problems to more important ones, to stimulate the development of theoretical frameworks with more content. (Lakatos 1978b, p. 40)

What remains is the question about the basis on which truth values are first injected into the potential falsifiers of mathematical theories. Since on his view the only interesting and respectable formal theories are formalisations of established informal theories, this question in part reduces to inquiring into the nature of the basis on which initial truth values are injected into the basic statements of the informal predecessors. The answer should be sought by tracing back (through rational reconstruction) the series of *problem shifts* that constitutes the development of the field. Perhaps mathematics might ultimately turn out to be ‘indirectly empirical’; or perhaps the source of the initial truth value injection is to be found in construction, or intuition, or convention.

> The answer will scarcely be a monolithic one. Careful historico-critical case-studies will probably lead to a sophisticated and composite solution. But whatever the solution may be, the naïve school concepts of static rationality like *a priori*/*a posteriori*, *analytic*/*synthetic* will only hinder its emergence. These notions were devised by classical epistemology to classify Euclidean certain knowledge – for the problem shifts in the growth of quasi-empirical knowledge they offer no guidance. (*ibid*., pp. 40–41)

23.5 Mathematical Quasi-Experiments

The pivot on which Lakatos' programme turned was his construal of informal proofs as thought experiments for the appraisal of mathematical knowledge. The standards of appraisal do not come from the study of foundations and formal systems, but from the logic of proofs and refutations, that is, of quasi-experimental tests and improvements. Mathematics is like science, not because it is somehow based on sensual experiences, but because it likewise proceeds through fallible trials and tests, and for this reason, it may be called a quasi-experimental science.

The science-like practice of working 'upwards' from facts to theories (lemmas, axioms, rules) corresponds nicely with the age-old 'method of analysis and synthesis', which pervades the entire history of exact science and of which Lakatos' method of proofs and refutations may be considered a logical extension. In analysis, a mathematical conjecture is tested by searching for concomitants that must be true if the conjecture were true. If in so doing one hits upon an obvious falsity, the conjecture must be false. But if only already established or trivial truths are hit upon, the conjecture may be true. Synthesis then consists of the construction of a compelling argument with the aid of the insights learned from the analysis. Lakatos' method goes on to test in this way the proofs themselves, searching for heuristic counterexamples in order to make hidden lemmas explicit and thus to get at improved theorems-*cum*-proofs, with enhanced generality, scope, profundity, problem-solving and explanatory power, etc.

On Lakatos' view, the Greeks had subjected the unproven mathematical facts inherited from the barbarians to a great many such analyses. They found that some lemmas kept cropping up, whereas their alternatives remained sterile, thus yielding series of corroborated analytical components converging on a small number of indubitable truths, which were to constitute the hard core of axiomatisation programmes such as Euclid's *Elements*.

This account can in fact be substantiated by Euclid's proposition 32, which says that any exterior angle of a triangle equals the sum of the opposite interior angles and that the sum of the interior angles equals two right angles. For the proof, one has to produce the side AC of a triangle ABC beyond C and to draw a line through C parallel to AB. The proposition then can be 'seen' to follow directly from the equality of the angles that the said parallel makes with the sides AC and BC. Thus the statement about parallels is the premise from which the synthetic argument starts, and by reversing it, one gets a glimpse of the analytic procedure through which the premise was originally found. By producing lines and drawing parallels, many properties of figures could be seen to be consequences of the said property of parallels, which thus became a hard-core element in the axiomatisation.

Curiously enough, Euclid's fifth postulate, the so-called parallel postulate, does not speak of parallels, although the relevant properties of parallels are direct consequences of it. It says that two lines will meet, if sufficiently produced, at the side on which the sum of the interior angles with an intersecting line is less than two right angles. This formulation is highly suggestive indeed of the above account of its analytic origins. The equality of angles in the proof of proposition 32 follows immediately in case the sum of the said interior angles happens to be exactly equal to two right angles.

The analytic-synthetic procedure is an 'experiment' in that it involves 'real' actions (drawing and producing lines) in order to 'see' how certain properties of figures obtain. This way of 'seeing' is not based on logical connections between statements, but on intuitively recognisable relations between and within figures, which as such are not readily formalisable. What is laid down in the postulates are not truths but requirements for the construction of geometric demonstrations; it is required, for instance, 'that through any two points a line can be drawn' (post.1), 'that any line can be produced' (post.2), 'that given a (mid) point and a line (radius) the circle can be drawn (post.3) and 'that all right angles are equal' (post.4). The procedure is *quasi*-experimental in that the actions are idealised: although visible lines and points occupy space, a *mathematical* point is defined as 'that which occupies no place' and a *mathematical* line as 'length without breadth'. These definitions make sense only if one assumes every rational person to be already in possession of intuitive notions of what a point (dot) and a line (stripe) are; they merely stipulate which aspects of these intuitions may, and which may not, be used in a mathematical demonstration. The experiment is done by drawing visible lines through visible points, but in the argumentation, abstraction is made of their sensual features.

Analysis became especially important as a method for proving *ex absurdo*, in which case the negation of a proposition is analysed. For when a concomitant of the negated proposition is found to be obviously false, this proves indirectly that the proposition itself must be true. The analysis as such proves the proposition, and the (often laborious) task of constructing a synthetic argument can be avoided. Greek mathematics after Euclid thus came to abound with indirectly proven propositions, without the slightest hint as to the way in which they were discovered, and also without the intuitively compelling demonstrations that synthetic proofs supply. The heuristic dimension being almost completely hidden from view, the classical image of mathematics as a deductively closed Euclidean system became firmly established for a long time to come. If Archimedes' treatise *On Method* (to be discussed in what follows) had not been discovered (in 1906), virtually nothing at all would have been known about Greek heuristics (Lakatos 1978b, p. 100).

In contrast to Lakatos' negative view of premature axiomatisation, Hintikka and Remes have shown convincingly that even in an axiomatised system, the construction of a proof required a veritable method of discovery, and analysis furnished this method. It involved the introduction of tentative auxiliary constructions, which necessitated a subsequent synthesis to warrant the results. What was analysed were configurations, not deductive connections or proofs, and the steps of analysis did not lead from one proposition to another, but from figure to figure (Hintikka and Remes 1974, p. 32). The need of introducing auxiliary constructions constituted the unpredictable and recalcitrant element in the methodological situation. The natural course of an analysis was not linear but took the form of a more complicated network of connections, and this made synthesis non-trivial and necessary for warranting the reversibility of the several steps. This presented no insuperable difficulties, as in a geometrical analysis the steps will be reversible anyhow, being mediated by functional interdependencies between geometrical entities in a given figure (*ibid.*, p. 37). The aim of the analysis was to find the *crucial* auxiliary constructions, but this aim could only be attained if enough hypothetical constructions were already anticipated in the analysis. One had to trust one's intuitive insight in finding the relevant geometrical interdependencies, and this way of proceeding made it imperative to justify the procedure afterwards by a synthesis: together they constituted two inseparable halves of one quasi-experimental method.

The creators of modern science – Descartes, Galileo and Newton – held the ancient method of analysis and synthesis in high esteem and shaped their methodology on it (for a general overview, see Otte and Panza 1996). I will present just a few examples to illustrate my earlier statement that not only is mathematics science-like, science is also mathematics-like, which indeed renders the classical *a priori/a posteriori* and *analytic/synthetic* distinctions merely a matter of degree.

Geometrical analysis was a systematic inquiry into the interdependencies between known and unknown 'objects' in a given configuration, and it was but a relatively small step to regard a real experimental setup likewise as a sort of analytic situation. Galileo's seemingly 'real' experiments, for instance, turn out to have been intended as demonstrations that the effects calculated on the basis of presumed relationships could actually be produced. These relationships as such had however been discovered in a 'quasi-mathematical' way, through thought experiments.

The insight, for instance, that in vacuum all objects fall with the same speed, was obtained in the following way. Suppose a heavy object H falls faster than a lighter object L – as common opinion would have it. Now connect both objects through a thread of negligible weight. As object H now has to pull the slower object L, it will move less fast than when falling alone. On the other hand, the combined object is heavier and therefore would have to fall faster. From this contradiction, it follows that the supposition must have been false. So all objects fall with the same speed.

Galileo's version of inertial movement was based on consideration of the movement of objects on an inclined plane. Movement upwards on this plane will be decelerated, and movement downwards will be accelerated, so movement on a horizontal plane (abstraction made of resistance) will continue uniformly. Note that 'horizontal' here means parallel to the surface of the earth. Galileo's inertial motion is circular.

As he wrote in a letter:

> I argue *ex suppositione* about motion, so that even though the conclusions should not correspond to the events of the natural motion of falling heavy bodies, it would little matter to me, just as it derogates nothing from the demonstrations of Archimedes that no moveable is found in nature that moves along spiral lines. But in this I have been, as I shall say, lucky; for the motion of heavy bodies and its events correspond punctually to the events demonstrated by me from the motion I defined. (letter of 1639, quoted in Drake 1975, p. 156)

In fact Galileo had begun by defining uniformly accelerated motion as 'such motion of which the increment of speed is proportional to the distance traversed' and replaced 'distance traversed' by 'time passed' only after he had noticed that the calculations based on the former definition did *not* conform to the properties of natural accelerated motions such as free fall.

Both Galileo's method and the new science of motion to which it gave rise were indeed moulded on the typical example set by Archimedes in his treatise *On Method*. It concerns the determination of the area of the segment of a parabola by means of an analogy with statics – applying what is now known as Archimedes' law of the lever. His reasoning did not consist of a linear chain of deductive arguments, but involved a complicated network of known relations within and between figures. He 'thought of' line segments parallel to the axis of the parabola and contained within the segment of the parabola as weights and, by invoking the said network of relations, was able to 'balance' them against corresponding line segments within an inscribed triangle (T) with the same base and height as the segment. As 'all' the line segments making up the figures could thus be set in equilibrium, the segment as a whole could be balanced against the total weight (=area) of the said triangle, placed in its centre of gravity. The law of the balance then gave the ratio between the area of the segment of the parabola and that of its inscribed triangle as 4:3 (Dijksterhuis 1987, Chap. X) (for a more detailed account of this and still other examples of mathematical thought experiments, see Glas 1999).

Archimedes regarded his method as a way of exploring, not of proving. However, the reason for this was not that it involved mechanical notions, but only that taking areas to be made up of line segments lacked demonstrative force. In his treatise *Quadrature of the Parabola* (Dijksterhuis op.cit., Chap. XI), he once more demonstrated the same theorem by means of statical considerations, but this time without 'summing' line segments, and here the argument was presented as a geometric proof that satisfied all requirements of exactitude.

Still, the thought experiment was of vital importance not only for the discovery of the mathematical proposition but for its final justification (proof) as well – which makes it a nice example of Lakatos' interpretation of proofs as quasi-experiments. The ratio found by means of the balancing experiment entered in the very reasoning through which the crucial lemma for the final proof was constructed. The procedure can be reconstructed as follows:

The inscribed triangle (T) cuts off two new segments, in which triangles with the same base and height as these segments can be inscribed. Together their areas can be shown to be (1/4)T. The same procedure can be applied to the new segments thus obtained and so forth. After n steps, the total area covered by the triangles will be

$(1+1/4+1/16+\ldots+1/4^n)$T. Now assuming the outcome of the thought experiment to be true, the segments generated in each step will exceed their inscribed triangles by 1/3, so that adding $(1/3)(1/4^n)$ to the last term of the series should yield the hypothesised value (4/3)T. And indeed the last two terms of the series $1+1/4+\ldots+1/4^n+(1/3)(1/4^n)$ add up to $(4/3)(1/4^n)=(1/3)(1/4^{n-1})$, and this added to the previous term in the series yields $(1/3)(1/4^{n-2})$, etc. The series 'eats' itself as it were from tail to head. Therefore, the sum of the whole series equals $1+1/3=4/3$. Accordingly, the area covered by the inscribed triangles after n steps equals $4/3-(1/3)(1/4^n)$ times T (we have to subtract the $(1/3)(1/4^n)$ that was first added to the series). To this lemma, found by using the outcome of the thought experiment as guiding hypothesis, the double argument 'ex absurdo' could be applied which finally delivered the exact proof.

This kind of proof required the adoption of a lemma of Euclid's: 'if from a quantity is subtracted more than half, from the remainder again more than half, and so on, it will at length become smaller than any pre-assigned quantity'. The proof then consisted in showing that the area of the segment cannot possibly be smaller than (4/3)T, for however small one assumes the difference to be, the term $(1/3)(1/4^n)$ can in virtue of the said lemma always be made smaller still by taking n great enough. The assumption that the area of the segment would be greater than (4/3)T is refuted in a similar fashion. Therefore the area of the segment cannot possibly be either greater or smaller than (4/3)T; hence it necessarily must be exactly (4/3)T.

As already said, it was the thought experiment itself that delivered the necessary tools for the construction of a rigorous proof. It was not just a suggestive aid in discovery but also delivered essential structuring and guiding assumptions for the construction of the crucial lemma for the final proof. Heuristic and justificatory procedures are complementary, the former necessitating the latter and the latter depending on the former for their crucial structuring and guiding assumptions.

Mathematics does proceed through 'trying out and testing' but also in a somewhat wider, less theory-centred sense than envisioned by Lakatos. Not all scientific experiments are tests of theories, and the same is true of thought experiments. Not all trials and tests in mathematics are aimed at proving and refuting propositions – as Lakatos would have it – nor are discovery and innovation confined to the preformal or pre-axiomatic phases of a mathematical theory (this point is also argued by Corfield 1997, 1998). Thought experimentation also is a major analytic tool for conceptual development and change by bringing to light unsuspected connections between different scenes of inquiry, which enable progress to more comprehensive, integrated and unified theories.

Although the prefix 'thought' might suggest otherwise, thought experiments need not literally be performed in thought in the sense of involving mental representations or images. Archimedes 'thought of' line segments as possessing weight, but this is not essentially different from normal geometric practice, in which lines, for instance, are 'thought of' as possessing length but not breadth, etc. The way in which Archimedes conducted his statical argument was in all respects similar to the construction of a geometric proof. Archimedes also based his statics proper on postulates – not empirical generalisations – in exactly the way in which Euclid had axiomatised plane geometry and in which Galileo much later founded his new science of motion.

In mathematics and science alike, (thought)experiments are attempts *at once* to prove a theory *and* to *im*prove it. Proofs in informal mathematics do not justify accepting a result unconditionally, but they do justify accepting it provisionally, until it is improved by a new thought experiment. The improvement is a 'refutation' of the previous result only in the sense that it shows it to be lacking in generality and scope, deficient in unifying, explanatory and problem-solving capacity as compared with the new result, which not only implies a better proof but a better theorem as well.

23.6 Popper's Quasi-Empiricist View of Mathematics

Popper had not originally intended his methodology of conjectures and refutations to apply to mathematics, but he was delighted with Lakatos' having it thus applied (see, for instance, Popper 1981, pp. 136–137, 143, 165). One typical statement that shows Popper's endorsement of Lakatos' quasi-empiricist philosophy of mathematics is the following:

> The main point here I owe to Lakatos' philosophy of mathematics. It is that mathematics (and not only the natural sciences) grows through the criticism of guesses, and bold informal proofs. (*ibid.* p.136)

Lakatos not only applied Popper's method in a domain which Popper had not envisaged but also brought a much larger part of the Popperian corpus to bear on mathematics, especially the doctrine of the relative autonomy of objective knowledge, which is part and parcel of the 'dialectic' of *Proofs and Refutations* and hence of quasi-empiricism. It is this objectivism, of course, that made him in the said work to focus on the rationally reconstructed history of problems, theoretical proposals, critical arguments and so on and to relegate the 'real' history of the thoughts and ideas of 'real' mathematicians to the footnotes.

It is in his discussion of Brouwer's intuitionism (Popper 1981, p. 134f) that we get a clear idea of the implications of Popper's objectivist philosophy for mathematics. Brouwer had been right in insisting that mathematics is a human creation or invention, but failed to see that it is also partially autonomous. Popper's 'epistemology without a knowing subject' is an account of how mathematics can be man-made *and* relatively autonomous at the same time, that is, how mathematical objects can be said in a way to exist objectively *although* they are human creations (for a more detailed account of Popper's philosophy of mathematics, see Glas 2001 and 2006).

Brouwer's 'primal intuition of time' cannot be an authoritative source of knowledge, simply because there are no authoritative sources of knowledge. Any proposed rock-bottom principle, whether self-evidence, indubitability, primal intuition or whatever – introduced to stop the infinite regress of proofs – would make critical discussion impossible when there is no agreement on such a principle. But different people at different times happen to have quite different intuitions about what is self-evident and what is indubitable. On Popper's view, intuition is a culture- and time-dependent phenomenon which *changes* with the development of science and the use of argumentative language:

> discursive thought (i.e., sequences of linguistic arguments) has the strongest influence upon our awareness of time, and upon the development of our intuition of sequential order. (*ibid*., p. 138)

The objectivity of mathematics is inseparably linked with its criticisability, and therefore with its linguistic expression:

> Language becomes the indispensable medium of critical discussion. The objectivity, even of intuitionist mathematics, rests, as does that of all science, upon the criticizability of its arguments. (*ibid*., pp. 136–7)

> Though originally constructed by us, the mathematical objects (the objective contents of mathematical thought) carry with them their own unintended and sometimes undreamt-of consequences. For instance, the series of natural numbers – which is *constructed* by us – creates prime numbers – which we *discover* – and these in turn create problems which are certainly not our own invention. *This is how mathematical discovery becomes possible*. Moreover, the most important mathematical objects we discover . . . are *problems* and new kinds of *critical arguments.* (*ibid*., p. 138)

It is in this sense that mathematical objects and problems may be said to have an independent and 'timeless' existence (i.e. irrespective of when, if ever, people become aware of them). Like Plato, Hegel and others, Popper used mathematics as the paradigmatic example of the relative autonomy of the world of intelligibilia (all that which can be an object of thought), which he called the 'third world'. It is not a static but a developing realm which

> has grown far beyond the grasp not only of any man, but even of all men (as shown by the existence of insoluble problems). (Popper 1981, p. 161)

But of course Popper was neither a Platonist nor a Hegelian. In sharp contrast to Hegel and Plato, he tried to bring the (third) world of objective ideas down to earth and to analyse its relationships with the physical (first) and the mental (second) world. Plato's world of ideas was inhabited by perfect and unchanging concepts in themselves; Popper's third world is man-made, imperfect and ever changing, consisting not of immutable concepts but of fallible theories, problems and arguments. Hegel's 'objective mind' was changing, too, but entirely of its own accord, following the dialectic of thesis, antithesis and synthesis, in which physical, mental and logical processes were considered 'identical'. Popper's third world, to the contrary, is the evolutionary product of the rational efforts of humans, who by trying to *eliminate* contradictions in the extant body of knowledge produce new theories, arguments and problems. Far from being 'identical' with the mental world, let alone the physical world, the third world *interacts* with them, but only through one or more subject's being aware (perhaps erroneously) of third-world relationships.

Popper's book *Objective Knowledge* dates from 1972, but essential parts of it had already been published in 1968, whereas the underlying *objectivist* epistemology had of course been paramount in Popper's works from the very beginning (e.g. Popper 1972, pp. 31–32, 44–48). The contents of theories or statements stand in logical relationships with each other – we might, for example, ask whether a statement is compatible with a theory, whether propositions are consistent with each other or contradictory, whether one is the deductive consequence of another or others, whether an inference is valid or invalid and so on. All these are *objective* questions; they are independent of the mental states (belief, conviction, doubt, etc.) that persons can have with respect to the contents involved. Objective contents thus possess various properties and relationships that are independent of anybody's being aware of them, and it is these objective features that are the concern of the objectivist theory of knowledge. It is of course perfectly well possible, and also highly interesting, to study knowledge as a mental phenomenon, in which case we are engaged in empirical scientific (psychological) inquiry (but here also it is advisable to take the objective features of knowledge into account, cf. Popper 1981, p. 149). Philosophical epistemology, on the other hand, is 'epistemology without a knowing subject': it studies objects and relationships in the third world, which consists of the *products* of human mental efforts, products which (by their unforeseeable and incalculable objective entailments) transcend the grasp of their producers and hence come to exist as objective artefacts.

It is of course trivially true that knowledge in the said objective sense can subsist without anybody being aware of it, for instance, in the case of totally forgotten theories that are later recaptured from some written source. It also has significant effects on human consciousness – even observation depends on judgements made against a background of objective knowledge – and through it on the physical world (for instance, in the form of technologies). Human consciousness thus typically acts as a mediator between the abstract and the concrete, or the world of culture and the world of nature. To acknowledge that linguistically expressed knowledge can subsist without humans, that it possesses independent properties and relationships, and that it can produce mental and also – indirectly – physical effects, is tantamount to saying that it in a way exists. Of course, it does not exist in the way in which we say that physical or mental objects or processes exist: its existence is of a 'third' kind.

Popper's insisting upon the crucial distinction between the objective (third-world) and the subjective (second-world) dimension of knowledge enabled him also to overcome the traditional dichotomies between those philosophies of mathematics that hold mathematical objects to be human constructions, intuitions, or inventions, and those that postulate their objective existence. His tripartite epistemology accounts for how mathematics can at once be autonomous *and* man-made, that is, how mathematical objects, relations and problems can be said in a way to exist independently of human consciousness *although* they are products of human (especially linguistic) practices. Mathematics is a human activity, and the product of this activity, mathematical knowledge, is a human creation. Once created, however, this product assumes a partially autonomous and timeless status (it 'alienates' itself from its creators, as Lakatos would have it), that is, it comes to possess its own objective, partly unintended and unexpected properties, irrespective of when, if ever, humans become aware of them.

Popper regarded mathematical objects – the system of natural numbers in particular – as products of human language and human thought: acquiring a language essentially means being able to grasp objective thought *contents*. The development of mathematics shows that with new linguistic means new kinds of facts and in particular new kinds of problems can be described. Unlike what apriorists like Kant and Descartes held, being human constructions does not make mathematical objects completely transparent, *clair et distinct*, to us. For instance, as soon as the natural numbers had been created or invented, the distinctions between odd and even, and between compound and prime numbers, and the associated problem of the Goldbach conjecture came to exist objectively: Is any even number greater than 2 the sum of two primes? Is this problem solvable or unsolvable? And if unsolvable, can its insolvability be proved? (Popper 1984, p. 34). These problems in a sense have existed ever since humankind possesses a number system, although during many centuries nobody had been aware of them. Thus we can make genuine *discoveries* of independent problems and new hard facts about our own creations, and of objective (not merely intersubjective) truths about these matters.

Nothing mystical is involved here. On the contrary, Popper brought the Platonist heaven of ideal mathematical entities down to earth by characterising it as objectivised *human* knowledge. The theory of the third world at once accounts for the working mathematician's strong feeling that she or he is dealing with something real, and it explains how human consciousness can have access to abstract objects. These objects are not causally inert: for instance, by reading texts we become aware of some of their objective contents and the problems, arguments, etc., that are contained in them, so that the Platonist riddle of how we can gain knowledge of objects existing outside space and time does not arise.

Cultural artefacts like mathematics possess their own partially autonomous properties and relationships, which are independent of our awareness of them: they have the character of hard facts that are to be *discovered*. In this respect they are very much like physical objects and relations, which are not unconditionally 'observable' either, but are only apprehended in a language which already incorporates many theories in the very structure of its usages. Like mathematical facts, empirical facts are thoroughly theory-impregnated and speculative, so that a strict separation between what traditionally has been called the analytic and the synthetic elements of scientific theories is illusory. The effectiveness of pure mathematics in natural science is miraculous only to a positivist, who cannot imagine how formulas arrived at entirely independently of empirical data can be adequate for the formulation of theories supposedly inferred from empirical data. But once it is recognised that the basic concepts and operations of arithmetic and geometry have been designed originally for the practical purpose of counting and measuring, it is almost trivial that all mathematics based on them remains applicable exactly to the extent that natural phenomena resemble operations in geometry and arithmetic sufficiently to be conceptualised in (man-made) terms of countable and measurable things and thus to be represented in mathematical language.

It is especially the (dialectic) idea of *interaction* and partial *overlap* between the three worlds that makes Popper's theory to transcend the foundationist programmes. Clearly, objective knowledge – the objective contents of theories – can exist only if those theories have been materially realised in texts (at world-1 level), which cannot be written nor be read without involving human consciousness (at world-2 level).

Put somewhat bluntly, Platonists acknowledge only a third world as the realm to which all mathematical truths pertain, strictly separated from the physical world; intuitionists locate mathematics in a second world of mental constructions and operations, whereas formalists reduce mathematics to rule-governed manipulation with 'signs signifying nothing', that is, mere material (first-world) 'marks'. In all these cases, reality is split up into at most two independent realms (physical and ideal or physical and mental), as if these were the only possible alternatives. Popper's tripartite world view surpasses physicalist or mentalist reductionism as well as physical/mental dualism, emphasising that there are *three* partially autonomous realms, intimately coupled through feedback. The theory of the interaction between all three worlds shows how these seemingly incompatible mathematical ontologies can be reconciled and their mutual oppositions superseded (Popper 1984, pp. 36–37; cf. Niiniluoto 1992).

To stress the objective and partly autonomous dimension of knowledge is not to lose sight of the fact that it is created, discussed, evaluated, tested and modified by human beings, nor does it imply that the role of mathematicians is reduced to passive observation of a pre-given realm of mathematical objects and structures – no more than that the autonomy of the first world would reduce the role of physicists to passive observation of physical states of affairs. On the contrary, the growth of mathematical knowledge is almost entirely due to the constant feedback or 'dialectic' between human creative action upon the third world and the action of the third world upon human thought.

Every theory, whether mathematical or scientific or metaphysical, is rational on Popper's view exactly

> in so far as it tries to solve certain problems. A theory is comprehensible and reasonable only in its relation to a given problem situation, and it can be discussed only by discussing this relation. (Popper 1969, p. 199)

In mathematics as in science, it is always problems and tentative problem solutions that are at stake:

> only if it is an answer to a problem – a difficult, a fertile problem, a problem of some depth – does a truth, or a conjecture about the truth, become relevant to science. This is so in pure mathematics, and it is so in the natural sciences. (*ibid*., p. 230)

Popper clearly did not view mathematics as a formal language game, but as a rational problem solving activity based, like all rational pursuits, on speculation and criticism.

Although they have no falsifiers in the logical sense (they do not forbid any singular spatiotemporal statement), mathematical as well as logical, philosophical, metaphysical and other non-empirical theories can nevertheless be critically assessed for their ability to solve the problems in response to which they were designed, and accordingly improved along the lines of the *situational* logic or *'dialectic'* indicated above. In particular, mathematical and other 'irrefutable' theories often provide a basis or framework for the development of scientific theories that *can* be refuted (Popper 1969, Chap. 8) – a view which later was to inspire Lakatos' notion of scientific research programmes with an 'irrefutable' hard core. Indeed, his *Methodology of Scientific Research Programmes* (Lakatos 1978a) was largely based on insights obtained through applying (in *Proofs and Refutations*) Popper's logic of scientific discovery to mathematics – and not merely in response to Kuhn's strictures, as has too often been claimed (compare Glas 1995).

Most characteristic of Popper's approach to mathematics was his focussing entirely on the dynamics of conceptual change through the dialectic process outlined, replacing the preoccupation of the traditional approach with definitions and explications of meanings. Interesting formalisations are not attempts at clarifying meanings but at solving problems – especially eliminating contradictions – and this has often been achieved by *abandoning* the attempt to clarify, or make exact, or explicate the intended or intuitive meaning of the concepts in question – as illustrated in particular by the development and rigorisation of the calculus (Popper 1983, p. 266). From his objectivist point of view, epistemology becomes the theory of problem solving, that is, of the construction, critical discussion, evaluation, and critical testing, of competing conjectural theories. In this, everything is welcome as a source of inspiration, including intuition, convention and tradition, especially if it suggests new problems. Most creative ideas are based on intuition, and those that are not are the result of criticism of intuitive ideas (Popper 1984, p. 69). There is no sharp distinction between intuitive and discursive thought. With the development of discursive language, our intuitive grasp has become utterly different from what it was before. This has become particularly apparent from the twentieth-century foundation crisis and ensuing discoveries about incompleteness and undecidability. Even our logical intuitions turned out to be liable to correction by discursive mathematical reasoning (*ibid.* p. 70). Nothing is entirely beyond doubt.

23.7 Conclusion

As said at the outset, my discussion of quasi-empiricism has been confined to the criticist-objectivist tradition connected with the names of Lakatos and Popper. Consequently all other approaches to the philosophy of mathematics that go under this or a similar heading have been omitted. One might think in particular of physicalist approaches such as collected in Irvine (1990) and various other studies focussing on science-like aspects of mathematics and of mathematical practice (for a small selection, see 'suggested further reading'). As it would have been impossible within the available space to do these other approaches sufficient justice, I have preferred to restrict myself to the said critical tradition. This choice enabled me also to present my subject as one coherent whole, rather than getting the discussion scattered in a wide diversity of directions.

Although Lakatos' seminal work on *Proofs and Refutations* was written in the form of a fictitious classroom dialogue, it was intended to represent a rational reconstruction of a particular historical development, and most certainly not as a recommendation for the teaching of mathematics in school. By the same token, the present article does not have any direct implications for the actual practice of classroom teaching. Its educational relevance lies in the *image* of mathematics that it conveys, which might inspire teachers in their practice, for instance, by taking a less rigid stance, eschew formalism, invoke practical experiences and insights, make room for exploration, the formation and testing of conjectures, etc. One example of a proposal concerning the teaching of geometry in this manner is given by Chazan (1990).

The idea of three rather than two ‘worlds’ – which moreover partially overlap and interact – is educationally important in several respects. Firstly, it enables us to overcome traditional dualisms such as between realism and constructivism. It is, for instance, perfectly well possible to be at once a constructivist and a realist with respect to the objective content of mathematics. For even if they are invented by ourselves, mathematical constructions are not arbitrary, nor are they entirely transparent even to their creators. We can make genuine discoveries of entirely unsuspected properties and relationships concerning our own creations.

Secondly, it evidently bears directly on our image of mathematics and the way in which it is culturally embedded. In order to acknowledge the social and cultural dimension of mathematics, there is no need to question the objectivity and partial autonomy of mathematical knowledge. It is sufficient to shift our focus, away from the ways in which new truths are derived, towards the ways in which new problems are conceived and approached. There is indeed much more to mathematics than mere accumulation of true statements. Mathematicians are not interested just in truths (let alone truisms), but in truths that provide answers to questions that are worthwhile and promising in the contemporary – socially and culturally contingent – scene of inquiry. In this way the quasi-empiricist trend in modern philosophy of mathematics may contribute significantly to the further humanisation of the discipline.

Chapter 24
History of Mathematics in Mathematics Teacher Education

Kathleen M. Clark

24.1 Introduction

The use of the history and in related ways philosophy of mathematics in teaching mathematics has been the subject of discussions in everything from the didactics of mathematics in primary and secondary mathematics teaching to its appropriate role in the education of teachers of mathematics at the primary and secondary[1] level. Given the narrower literature base in this field, the ways in which philosophy of mathematics plays a role in the preparation of mathematics teachers will not be addressed in this chapter. It is worth noting, however, that many contributions shed light on how philosophical perspectives can accurately capture and describe the development of mathematical thinking. For example, in a recent description of his research, Radford (2012) claimed that "algebraic thinking cannot be reduced to an activity mediated by notations" (p. 690). Furthermore, Radford has also described ways in which historical-epistemological analyses "provide us with interesting information about the development of mathematical knowledge within a culture and across different cultures," as well as information about "the way in which the meanings arose and changed" (Radford 1997, p. 32).

The chapter is organized into seven sections. First, a brief overview of arguments that advocate for the use of history in mathematics education and the research perspectives that correspond to this advocacy are presented. In Sects. 24.2 and 24.3, descriptions of the role that history of mathematics has played in mathematics teacher education in the United States (Sect. 24.2) and elsewhere (Sect. 24.3) are given. Section 24.4 elaborates on the reasons for using history of mathematics in

---

[1] Although various locations around the world may use "primary" and "secondary" differently, in this chapter, "primary" level corresponds to the school years or grade levels for pupils aged 5–11 and "secondary" level corresponds to years or grade levels for pupils aged 12–18.

teaching mathematics. Next, Sects. 24.5 and 24.6 discuss examples of empirical studies that were conducted with prospective teachers of primary mathematics and secondary mathematics, respectively. Finally, Sect. 24.7 outlines examples of research from the "next generation" of infusing history in mathematics education, that is, the accounts of practicing teachers who incorporated history of mathematics in teaching at the primary, secondary, and tertiary levels.

24.2 Arguing for the History of Mathematics in Mathematics Education

Lockhart (2008) posed the following questions in "A Mathematician's Lament":

> What other subject is routinely taught without any mention of its history, philosophy, thematic development, aesthetic criteria, and current status? What other subject shuns its primary sources – beautiful works of art by some of the most creative minds in history – in favor of third-rate textbook bastardizations? (Lockhart 2008, p. 9)

Although the main idea of his essay was to highlight the critical issues of a broken mathematics education system in the United States, Lockhart made frequent reference to the necessity of history in teaching and learning mathematics. In his criticism of mathematics in general and standardized curricula and assessments in particular, Lockhart complained about "the complete absence of art and invention, history and philosophy, context and perspective from the mathematics curriculum" (p. 13). Moreover, he condemned those who ask students to learn mnemonic devices (e.g., "SohCahToa" in geometry or trigonometry[2]) or "succumb to 'cutesyness'" to remember area and perimeter formulas for circles[3] (p. 9), rather than relating the real story of the development of a concept, such as "the one about [humankind's] struggle with the problem of measuring curves; about Eudoxus and Archimedes and the method of exhaustion; about the transcendence of pi" (p. 9).

Consideration of the value and importance of using history of mathematics in mathematics education has taken place over many decades. In the United Kingdom, encouragement for the inclusion of historical aspects of mathematical topics has appeared in documents for their National Curriculum – off and on – for over 100 years. Fauvel (1991) cited several excerpts from school curriculum documents, which included directives such as:

> …[P]ortraits of the great mathematicians should be hung in the…classrooms, and that reference to their lives and investigations should be frequently made by the teacher in his lessons, some explanation being given of the effect of mathematical

---

[2] This mnemonic device, SohCahToa, is employed by school mathematics teachers (and their students) to remember the basic right triangle ratios of **s**ine = **o**pposite (side)/**h**ypotenuse; **c**osine = **a**djacent (side)/hypotenuse; and **t**angent = **o**pposite (side)/**a**djacent (side).

[3] One such mnemonic device in the form of a "cutesy" anecdote is: "Mr. C, who drives around Mrs. A, and tells her how nice his two pies are ($C = 2\pi r$) and how her pies are square ($A = \pi r^2$)" (Lockhart 2008, p. 9).

> discoveries on the progress of civilization. (Report of Mathematical Association Committee 1919)

> The teacher who knows little of the history of Mathematics is apt to teach techniques in isolation, unrelated either to the problems and ideas which generated them or to the further developments which grew out of them. (British Ministry of Education 1958)

> The mathematics teacher has the task…of helping each pupil to develop so far as is possible his appreciation and enjoyment of mathematics itself and his realization of the role which it has played and will continue to play both in the development of science and technology and of our civilization (The Cockcroft Report 1982). (Fauvel 1991, p. 3)

Fauvel also noted, however, that beginning in the early 1990s, "the historical perspective [was] less noticeable… than in any official document about mathematics education for a century" (p. 3). The national mathematics curriculum in England today explicitly requires that the "historical and cultural roots of mathematics [be] part of the entitlement for every child's experience of mathematics" (Barbin et al. 2011, p. 37).

A similar "history" is mirrored in mathematics education documents in the United States. In the opening chapter of the thirty-first yearbook of the National Council of Teachers of Mathematics (1969), *Historical Topics for the Mathematics Classroom,* Phillip S. Jones described the struggle in using history in the mathematics classroom:

> Teaching so that students understand the "whys," teaching for meaning and understanding, teaching so that children see and appreciate the nature, role, and fascination of mathematics, teaching so that students know that men are still creating mathematics and that they too may have the thrill of discovery and invention – these are objectives eternally challenging, ever elusive. (Jones 1969, p. 1)

This elusiveness may be due in part because as the editors of the yearbook themselves admitted, their goal was to "emphasize the mathematical content of the material and to leave the method of bringing it into the individual classroom in the hands of the person most qualified to make this decision – the teacher" (Baumgart et al. 1969, pp. x–xi).

The opportunities for teachers to learn history of mathematics, particularly during their pre-service teacher preparation program, are the primary reasons why variability exists in how mathematics teachers are able to use history of mathematics in teaching. And, if teachers are not afforded the opportunity to study history of mathematics during teacher preparation programs, then upon entering the teaching profession they have a minute chance, if any, to participate in formal study of history of mathematics and why it is beneficial for using in teaching mathematics.[4] This is problematic when considering national standards for mathematics teachers that call for goals aimed at providing experiences for pupils that included historical and cultural perspectives.

---

[4] This observation is made with mathematics education in the United States in mind. France is an existence proof for greater opportunities for teachers to engage in history of mathematics in this way.

In 1989, the National Council of Teachers of Mathematics (NCTM) issued the *Curriculum and Evaluation Standards for School Mathematics*. In the document, the NCTM listed "learning to value mathematics" as the first goal for students. The goal specified that

> Students should have numerous and varied experiences related to the cultural, historical, and scientific evolution of mathematics so that they can appreciate the role of mathematics in the development of our contemporary society and explore relationships among mathematics and the disciplines it serves .... It is the intent of this goal – learning to value mathematics – to focus attention on the need for student awareness of the interaction between mathematics and the historical situations from which it has developed and the impact that interaction has on our culture and lives. (NCTM 1989, pp. 5–6)

Equivalent recommendations concerning the role of the history of mathematics are found in the NCTM's *Principles and Standards for School Mathematics* (2000), with the objective of students developing an appreciation of mathematics as "being one of the greatest cultural and intellectual achievements of humankind" (p. 4). Unfortunately, this objective is couched in significantly weaker language[5] than that of the 1989 *Curriculum and Evaluation Standards* – that of developing an appreciation of certain historical and cultural attributes of mathematics as opposed to engaging in mathematics from multiple perspectives, including those along historical and cultural dimensions. In either case, there has not been overwhelming evidence that the goal or objective from either version of *Standards* is being achieved (Liu 2003, p. 418). When examining the record of conference sessions offered at NCTM annual meetings and published materials available through NCTM – particularly recent offerings – it is difficult to find evidence of the rhetoric of the 1989 and 2000 *Standards* calling for increased attention to the historical development of mathematics.

The important volume, *History in Mathematics Education: The ICMI Study* (Fauvel and van Maanen 2000), included a summary of what was known about the contribution of history of mathematics to the knowledge and perspectives of teachers and pupils. From a survey of the literature at the time, Barbin and her colleagues (2000) identified five distinct outcomes, including the ability of using history to promote changes in teachers' mathematical conceptions, the students' mathematical conceptions, the role of the teacher, the way students view mathematics, and the students' learning and understanding (p. 67). Whereas accounts exist that document each of these outcomes, Barbin was careful to observe the lack of the field's ability to document "the attainment of objectives claimed for using history" (p. 66) because large-scale assessments do not exist for such measures. Instead, qualitative methods are much more appropriate to ascertain whether using history in teaching mathematics can achieve what is claimed.

---

[5] For example, in 1989, NCTM asked for students to have "numerous and varied experiences related to the cultural, historical, and scientific evolution of mathematics," which could have entailed learning mathematics from historical methods or reinventing such methods from guided explorations using historical problems. In 2000, however, the language was simplified to focus on the appreciation of mathematics.

24.3 History of Mathematics in Mathematics Teacher Education in the United States

In a similar manner, policy documents are used to impart standards on mathematics teacher preparation programs. In the United States, the jointly constructed National Council for the Accreditation of Teacher Education (NCATE) and the NCTM program standards, *Programs for Initial Preparation of Mathematics Teachers* (2003), described content standards[6] for seven mathematical strands at both the middle and secondary levels.[7] Consequently, for programs to achieve "National Recognition" under the NCATE model, "the program report must demonstrate that at least 80 % of all indicators are addressed and at least one indicator[8] is addressed for each standard" (NCTM 2007). The final indicator for each content standard called for teacher candidates to "demonstrate knowledge of the historical development of [topics] including contributions from diverse cultures" (NCATE 2003, p. 4).

The ability for a teacher education program to exhibit mathematics teacher candidates' history of mathematics content knowledge is important to achieve national recognition; however, mathematics teacher preparation programs may still achieve the status since only 80 % of indicators are needed for national recognition. This aspect of the program standards, which was aligned with the NCTM goal for students to develop an appreciation of the cultural and intellectual achievements represented in the development of mathematics, did serve to reinforce the argument that understanding and engaging in the study of the history of mathematics contributes to the mathematical and pedagogical preparation of mathematics.

In 2011, NCTM published its draft of the new initial certification program standards for middle- and secondary-level mathematics. Instead of one indicator within each of seven content standards dedicated to the provision that mathematics teacher candidates demonstrate knowledge of the historical development of particular mathematics content, the first draft of the standards asserted one indicator only. The proposed indicator appeared in Standard 6: Mathematics Teaching and Learning and was stated as, "Equity: Recognizing the cultural diversity that exists within classrooms, valuing the contributions of various cultures in the development of mathematics, and incorporating the historical development of mathematics and culturally relevant perspectives as tools to engage students" (NCTM 2011).

---

[6] In the NCATE/NCTM program standards, "content standards" represent the different strands of mathematical knowledge teachers are responsible for knowing for teaching, such as knowledge of number and operation and knowledge of geometries.

[7] This is language of the NCATE/NCTM program standards, where "middle level" is understood as grades 6, 7, and 8 (pupils aged 12–14) and "secondary level" is understood as grades 9–12 (pupils aged 15–18). Many consider this redundant (including the author) since two divisions seem sufficient (e.g., elementary and secondary, or primary and secondary).

[8] In the NCATE/NCTM program standards, an "indicator" is a specific objective within a given content standard, such as, "Exhibit knowledge of the role of axiomatic systems and proofs in geometry" in the knowledge of geometries content standard.

After initial public response to the draft certification program standards for middle and secondary mathematics,[9] however, a new draft of the standards appeared in April 2012. In this draft as with the 2003 program standards, a final indicator was added to each of the content standards for middle and secondary mathematics. An example from middle-level algebra reads: "All middle grades mathematics teachers should be prepared to develop student proficiency with …[the] historical development and perspectives of algebra including contributions of significant figures and diverse cultures" (NCTM 2012). The current draft standards remained open for public comment until June 2012, and the final versions of the program standards were presented to the NCATE Specialty Area Studies Board in October 2012.

At the same time that the standards for mathematics teacher certification programs in colleges and universities in the United States are being rewritten, another influential document, *The Mathematical Education of Teachers* (or MET1, published in 2001) is also under revision. The draft of MET1 was published in early 2012 and public comment was accepted until the end of April 2012. MET1 (Conference Board for the Mathematical Sciences (CBMS) 2001) argued that prospective mathematics teachers could improve their knowledge of the history of mathematics as one way for them to "undertake, and then be able to challenge their students in ways that will lead them to reason and make sense of mathematics" (p. 99). Recommendations found in MET1 called for the inclusion of historical content in the preparation of both middle grades and high school mathematics teachers and focused on providing the means for prospective teachers "to develop an eye for the ideas of mathematics that will be particularly challenging for their students" (p. 126). The primary mode of preparation advocated in MET1 was in the form of undergraduate courses in teacher preparation programs. However, the recommendations articulated in MET1 were not intended to outline potential routes for taking non-university level courses. Instead, the intention was that institutions of higher learning would develop programs and courses to meet the needs of teacher candidates within their own context while attending to the recommendations in MET1.

The role of history of mathematics in secondary mathematics teacher preparation is also strongly articulated in *The Mathematical Education of Teachers II* (MET2) (CBMS 2012). MET2 suggests that preparation programs for middle grades teachers include 24 semester hours of mathematics courses, some of which are courses to "strengthen prospective mathematics teachers' knowledge of mathematics and broaden…understanding of mathematical connections…" (p. 46). Furthermore, the writers claimed that "a history of mathematics course can provide middle grades teachers with an understanding of the background and historical development of many topics" (p. 48).

A course in history of mathematics is identified in MET2 as essential for future high school mathematics teachers:

> The history of mathematics can either be woven into existing courses or be presented in a course of its own. In both instances, it is important that the history be accurate; instructors

---

[9] Although many consider middle grades mathematics to be included in "secondary," these are the terms that NCTM uses.

> who have no contact with historians need to be aware that findings from historical research may contradict popular accounts…. It is particularly useful for prospective high school teachers to work with primary sources. Working with primary sources gives practice in listening to "wrong" ideas. Primary documents show how hard some ideas have been, for example, the difficulties that Victorian mathematicians had with negative and complex numbers helps prospective teachers appreciate how hard these ideas can be for students who encounter them for the first time.
>
> Finally, primary documents exhibit older techniques, and so give an appreciation of how mathematics was done and how mathematical ideas could have developed. (CBMS 2012, pp. 61–62)

MET2 also recognized the role of additional study in the history of mathematics for those preparing to teach high school mathematics:

> Many topics in the history of mathematics are closely related to high school mathematics, for example, history of statistics, history of trigonometry, and history of (premodern) algebra. It is important to make sure that the materials used for courses on these topics include a significant amount of mathematical content. (CBMS 2012, p. 67)

At the time of the writing of this chapter, however, the 2003 NCATE program standards were still in place, and substantial diversity exists among mathematics teacher preparation program requirements in the United States and as to whether a course on the history of mathematics should be included in such programs. For example, many programs do not include a separate history of mathematics course since programs can still be accredited by NCATE without specific attention to the historical development of mathematics. It is also possible for institutions to elect to not pursue program accreditation through the organization. Instead, teacher preparation programs within colleges and universities may opt for state accreditation only or follow other accreditation standards, such as those of the Interstate Teacher Assessment and Support Consortium (InTASC).

Alternatively, mathematics teacher preparation programs offer history of mathematics as an elective, with such courses often focusing more on the mathematical content and less on the cultural, philosophical, historical, and pedagogical elements. Still other programs, such as the UTeach program at the University of Texas at Austin, as well as its 34 replication sites, require that prospective mathematics teachers take "Perspectives on Science and Mathematics"[10] with fellow prospective science teachers.

In an effort to describe the extent to which mathematics teacher preparation programs include history of mathematics, information provided by universities and colleges was used to survey mathematics teacher preparation programs for their requirement (or not) of a history of mathematics course.[11] Two sources of information were used. First, a search using the Carnegie Foundation for the Advancement of Teaching (http://classifications.carnegiefoundation.org/lookup_listings/institution.php)

---

[10] The number of replication sites as of May 2013. Also, since faculty called upon to teach "Perspectives" are often historians of science, the course privileges a "history of science" perspective. Consequently, the breadth of the historical implications of school mathematics or nature of mathematics that students take away from such a course is in need of further research.

[11] I am grateful to Christopher Thompson, my graduate research assistant, for his invaluable assistance in collecting and analyzing this information in 2011.

returned a data set of 1713 universities or colleges whose basic classification was either (1) a research (doctoral degree granting) university (RU/VH, RU/H, or DRU)[12] or (2) a university that offered master's degrees (L, M, or S)[13] or (3) a university or college that offered only bachelor's degrees.

Next, the set of 1713 institutions were stratified by state (including the District of Columbia), and the indicator function *I* was composed with a value of "1" indicating that the institution included a mathematics education program and a value of "0" for those institutions not offering a mathematics teacher preparation program.[14] Institutions that offered a degree program in mathematics education were determined from searching the CollegeBoard (http://collegesearch.collegeboard.com/search/index.jsp) College MatchMaker database[15] and selecting the categories of "Education" and then "mathematics education" as search criteria. The search returned 569 institutions. Although a large-scale survey (of these 569 institutions) would have been optimal, the goal was to provide a snapshot of whether mathematics teacher preparation programs required or even offered a history of mathematics course. Consequently, institutions were randomly selected from the stratified sample (N = 569) – three institutions from each state and the District of Columbia, which constitutes one each corresponding to the three types of institutions according to the Carnegie levels (doctoral, master's, bachelor's).

The results of the survey revealed that of 153 potential institutions, the stratified random sample returned only 15 that did not offer a mathematics teacher preparation program meeting the criteria. Of the remaining sample, 62 programs representing 37 states required a history of mathematics course for their program. Also variable was the number of institutions that offered elective or optional history of mathematics courses – or no course at all – as well as whether the mathematics teacher preparation programs were housed in education or mathematics departments.

The United States is not alone in the variety of ways in which recommendations to include history of mathematics in mathematics teacher preparation programs are implemented. Elsewhere, there is evidence of a wide variety of established practices with regard to the role of the history of mathematics in the preparation of mathematics teachers.[16] In *History in Mathematics Education: The ICMI Study* (Fauvel and van Maanen 2000), an entire chapter was dedicated to the presence of history of mathematics in programs for trainee (i.e., prospective) teachers.

---

[12] The Carnegie basic classifications are RU/VH = Research Universities (very high research activity); RU/H = Research Universities (high research activity); DRU = Doctoral/Research Universities.

[13] These Carnegie basic classifications are Master's L = Master's Colleges and Universities (larger programs); Master's M = Master's Colleges and Universities (medium programs); Master's S = Master's Colleges and Universities (smaller programs).

[14] Only initial teacher certification programs at the undergraduate level were considered.

[15] CollegeBoard College MatchMaker database (http://collegesearch.collegeboard.com/search/index.jsp) was last accessed on 10 October 2010. The database has been replaced with a much more student-friendly website, BigFuture (https://bigfuture.collegeboard.org/), last accessed 27 December 2012.

[16] For the purposes of this chapter, we only consider initial teacher preparation programs, that is, undergraduate (tertiary) at the university or college level or postgraduate programs.

24.4 History of Mathematics in Mathematics Teacher Education Around the World

In the 2000 ICMI Study, Schubring and colleagues (2000) described the state of history of mathematics for teachers in the world based upon information available at the end of the twentieth century. In addition to accumulating prior views and documenting prominence of history of mathematics in mathematics teacher education, the authors described the "state of teaching history of mathematics to future mathematics teachers" (Schubring et al. p. 94) within several countries considered to be "a fairly representative sample" (Schubring et al. p. 94). Schubring and his colleagues also claimed that whereas history of mathematics in the mathematical education of any person pursuing a degree in mathematics was once more commonly found in locations where there existed "an extended tradition in mathematics history and a considerable mathematical community" (Schubring et al. 2000, p. 94), this was no longer the case.

Gathering information about cases beyond those available at the time of the ICMI Study proves difficult, however. For example, several attempts to contact those with keen interest in the history and pedagogy of mathematics (HPM) in 2012, particularly with regard to the role of HPM in mathematics teacher education, were left unanswered. In another attempt to gather such information at the International Congress on Mathematical Education (ICME) in Seoul, South Korea, in July 2012, it became apparent that many locations around the globe struggle with incorporating such courses in mathematics teacher education programs.

Schubring and his colleagues (2000) identified a wide variety of examples of the extent to which a historical component was a part of preparation of mathematics teachers. To facilitate the discussion of differences, they divided the examples (by country) into three types[17]: countries with smaller mathematical communities but which experienced success in establishing strong records in teaching history of mathematics, countries with a longer tradition of research and teaching in mathematics history but which struggle with establishing a historical component within mathematics teacher education programs, and countries on the "periphery."[18] So as not to repeat the work of Schubring and colleagues, examples of what is most recently known about the role of history of mathematics in mathematics teacher education in several different contexts are described here for a small sample of countries around the world.

---

[17] Only European countries were discussed in the analysis with regard to the first and second types of country identified in the ICMI Study.

[18] The ICMI Study defined countries on the periphery as those "where, comparatively recently, historians of mathematics, or mathematics educators with a strong interest in mathematics history, have achieved an academic position where they are able to introduce mathematics history courses into teacher training" (Schubring et al. 2000, p. 94).

24.4.1 Europe

At the Sixth European Summer University in Vienna in 2010, a panel was held on "The Role of the History and Epistemology of Mathematics in Teachers Training" (Barbin et al. 2011). Each panelist discussed the current status of both pre-service and in-service mathematics teacher education in their country. Barbin detailed the situation in France, which has always been considered to have a strong focus on history and epistemology in teacher training. Until 2010, the training of prospective mathematics teachers took place at each University Institute for Teachers Training (IUFM). Examples of the training for teachers that took place at the institutes included a 30-h course comprised of content in the history of mathematics. Currently, all future teachers must obtain a master's degree, and the course of study includes history and epistemology of mathematics.[19]

In Italy, as is the case in many other locations, primary teachers teach mathematics along with other subjects and obtain their university degree in an educational department, and there are no formal courses on history of mathematics. Although some university programs do include history of mathematics as components of other courses, this practice is not standardized. Secondary teachers who will teach lower secondary mathematics (to pupils aged 11–14) obtain a degree in science, mathematics, physics, or chemistry. Those who will teach upper secondary mathematics (to pupils aged 14–19) are required to obtain a degree in mathematics or physics. Italy enjoys a long tradition of a community of mathematicians who share a strong interest in primary and secondary school teaching. Furinghetti reported that "for about the last 50 years, the curriculum of mathematics in Italian universities encompasses special courses addressed to prospective teachers" (Barbin et al. 2011, p. 28); the content of some of these courses includes history of mathematics.

Austria[20] has a strong tradition of requiring history of mathematics course work for prospective teachers; it is a compulsory course at two of the country's seven universities and either an elective or optional course at five universities. Table 24.1 displays the seven universities and the category of requirement applicable to each. Regardless of level of requirement, course lecturers are free to construct a course in the history of mathematics as they choose.

24.4.2 Africa

The Moroccan situation is an example of the changing role of history of mathematics within the preparation of prospective mathematics teachers. Previously, the training of teachers was under the direction of specific educational institutes that were mainly involved with the educational and didactical dimensions of pre-service

---

[19] There exists variability in the importance placed on teaching these subjects in France.

[20] The author is grateful to Manfred Kronfellner for providing this information.

Table 24.1 Types of history of mathematics courses in Austria: compulsory, elective, or optional

University	Required	Elective or optional[a]
University of Innsbruck	Compulsory course, lecture, with final examination	
University of Klagenfurt	Compulsory course, seminar, with immanent assessment	
Vienna University of Technology		Elective course, lecture
University of Vienna		Elective course, lecture
Johannes Kepler University of Linz		Elective course, seminar
University of Salzburg		Elective course, lecture, and seminar combination
University of Graz		Optional course, when available

[a] "Elective course" means that history of mathematics is one of several courses students must select from a collection of options. They must select a certain number of elective courses from the collection, but they do not have to select all in their course of study. An "optional course" may not always be available as an elective option

teacher training. Consequently, the history of mathematics held a reduced role and was evoked during the study and didactical analysis of concepts. A few exceptions existed. For example, in the *École Normale Supérieure* of Marrakech, courses on the history and philosophy of mathematics were always taught. Currently and according to the new reforms in Morocco, the training institutes for prospective secondary teachers were moved to universities. This aspect of the reforms enables universities to organize and implement courses for prospective teachers and, as a result, aids in providing more substantial pedagogical training of teachers. In 2012 prospective teacher training programs were under revision, and those involved with the work are hopeful that the historical and cultural dimensions of mathematics will receive particular attention and that such dimensions will help develop and reinforce learning of scientific concepts, citizenship, and critical thinking of students.[21]

24.4.3 Asia

Whereas much of the Western world seeks to increase attention to mathematical contributions of non-Western cultures in history of mathematics courses (and history of mathematics courses for prospective mathematics teachers), a similar phenomenon occurs in many Asian contexts. In many Asian countries there are efforts to highlight Western developments and to compare them with methods, algorithms, and examples found in ancient texts and manuscripts. However, well-developed courses or units within courses in mathematics teacher preparation programs are still absent, as in

---

[21] The author is grateful to Abdellah El Idrissi for providing this information.

the case of South Korea.[22] A trend that may prove to be influential in the near future is the increased attention to history of mathematics in the preparation of mathematics teachers in South Korea (and other proximal countries), especially after the introduction of the International Study Group on the Relations between the History and Pedagogy of Mathematics (HPM Group) to several mathematicians and mathematics teacher educators as a result of HPM 2012 in Daejeon.

24.5 Development of Theoretical Claims: Why Use History in Teaching Mathematics

Although there has been strong interest in the question of how history of mathematics benefits teachers and learners of mathematics since the 1890s (Fasanelli 2001), significant international activity directed at addressing the question began in the 1970s. Key to this activity was the creation of the International Study Group on the Relations between the History and Pedagogy of Mathematics (HPM Group), which was officially established as a satellite group of the International Congress on Mathematical Education (ICME) in 1972. Henk Bos, Barnabas Hughes, Phillip Jones, Leo Rogers, and Roland Stowasser were among the group of mathematicians, mathematics historians, and mathematics educators gathered at the first sessions held in association with in 1976 at ICME-3 in Karlsruhe, Germany. As a result of these initial sessions, the HPM Group was established and the official aims of the Study Group were established. The group sought to:

1. Promote international contacts and exchange information concerning:
    (a) Courses in history of mathematics in universities, colleges, and schools
    (b) The use and relevance of history of mathematics in mathematics teaching
    (c) Views on the relation between history of mathematics and mathematical education at all levels
2. Promote and stimulate interdisciplinary investigation by bringing together all those interested, particularly mathematicians, historians of mathematics, teachers, socialscientists, and other users of mathematics
3. Encourage a deeper understanding of the way mathematics evolves and the forces that contribute to this evolution
4. Relate the teaching of mathematics and the history of mathematics teaching to the development of mathematics in ways that assist the improvement of instruction and the development of curricula
5. Produce materials that can be used by teachers of mathematics to provide perspectives and to extend critical discussion of the teaching of mathematics
6. Facilitate access to materials in the history of mathematics and related areas
7. Promote awareness of the relevance of the history of mathematics for mathematics teaching in mathematicians and teachers

---

[22] The author is grateful to Sang Sook Choi-Koh for describing the South Korean context.

8. Promote awareness of the history of mathematics as a significant part of the development of cultures (Fasanelli 2001, p. 2)

The influence of the articulated aims can be found in the preponderance of theoretical literature published during the first 25 years of the existence of the HPM Group. For example, Fauvel (1991) provided a list of 15 reasons that are used to promote using history in mathematics education:

> … helps to increase motivation for learning; gives mathematics a human face; historical development helps to order the presentation of topics in the curriculum; showing pupils how concepts have developed helps their understanding; changes pupils' perceptions of mathematics; comparing ancient and modern establishes value of modern techniques; helps to develop a multicultural approach; provides opportunities for investigations; past obstacles to development help to explain what today's pupils find hard; pupils derive comfort from realizing that they are not the only ones with problems [with mathematics]; encourages quicker learners to look further; helps to explain the role of mathematics in society; makes mathematics less frightening; exploring history helps to sustain [teacher] interest and excitement in mathematics; and provides opportunity for cross-curricular work with other teachers or subjects. (Fauvel 1991, p. 4)

In the current educational context that often includes a heightened emphasis on standards and high-stakes accountability, many of Fauvel's reasons are easy to ignore – particularly if educators perceive the actions of the proposed reasons to not be aligned to content and practices of the curriculum or assessments. Examining one reason as an example, most mathematics teachers agree that "showing pupils how concepts have developed" may have a role in pupils' understanding of particular mathematical concepts (e.g., operations with integers, complex numbers). However, mathematics teachers may be skeptical that employing historical methods to show this to pupils is a viable pedagogical tool.

Furinghetti (2002) observed that history can be used "as a mediator to pursue the objectives of mathematics education" (Abstract). Furthermore, Furinghetti proposed that enabling students to work with topics at an informal level before formally investigating topics was similar to Freudenthal's view that contextual problems provide efficient opportunities to allow formal mathematics to emerge. In this way Furinghetti claimed using "history may reveal itself fruitful and [a] sense-carrier" (p. 3).

There is important evidence that the membership and interested colleagues of the HPM Group are making progress towards achieving many of the official aims. Not only do the Topic Study Groups of the International Congress meetings (since 1972) and the HPM Satellite meetings produce peer-reviewed, published proceedings, but the European Summer University on the History and Epistemology in Mathematics Education meetings (now held every 2 years, not including the years in which the ICME and HPM Satellite meetings are held)[23] and now a working group of the Congress of the European Society for Research in Mathematics Education (CERME)

---

[23] The European Summer University on the History and Epistemology in Mathematics Education (ESU) was held every 3 years from 1993 until 2010. Subsequent ESUs will be held every 4 years (e.g., the Seventh ESU will be in 2014), but not in years when ICME meetings are held.

since 2009 also add "substantially to the amount of papers on history in mathematics education" (Jankvist 2012, p. 296). Moreover, special publications have appeared as a result of increased attention to the inclusion of history of mathematics in mathematics education. Among these are several books published by The Mathematical Association of America (e.g., *Using History to Teach Mathematics: An International Perspective* (Katz 2000), *Recent Developments on Introducing a Historical Dimension in Mathematics Education* (Katz and Tzanakis 2011)) and other important volumes such as *History in Mathematics Education: The ICMI Study* (Fauvel and van Maanen 2000) and *Crossroads in the History of Mathematics and Mathematics Education* (Sriraman 2012).[24]

Even with this increased attention, however, many contributions to these edited volumes are what Siu and Tzanakis referred to as "propagandistic" (2004, p. vii); that is, it is evident that a critical mass of teachers and scholars alike attest to the worthiness of history in mathematics education. As a result, such contributions remain theoretical as opposed to providing empirical results of what happens when history of mathematics is part of the instructional program. The proportion of contributed chapters in such volumes that are focused on history of mathematics in mathematics teacher education is also a concern. For example, in Katz and Tzanakis (2011), only four of 24 chapters were devoted to this theme and none of the 25 chapters in Sriraman (2012) were.

One possible reason for the abundance of theoretical descriptions of the importance of using history of mathematics in teaching is the obstacle of adequately preparing primary and secondary mathematics teachers to use the history of mathematics in meaningful ways in their teaching. Jones (1969) claimed, "the history of mathematics will not function as a teaching tool unless the users (1) see significant purposes to be achieved by its introduction, and (2) plan thoughtfully for its use to achieve these purposes" (p. 5). Although Jones' claims were made over four decades ago, most mathematics teacher educators would find it difficult to summarize two key issues more succinctly. Furthermore, many argue that the lack of opportunity for history of mathematics course work in mathematics teacher preparation programs – whether primary or secondary – is intimately connected to the lack of strong mathematical knowledge of teacher candidates.

Finally, it is important to keep in mind that a "domino effect" may be at work here. For example, it may be difficult to identify literature describing accounts of elementary and secondary teachers incorporating history of mathematics in their mathematical instruction because of the absence of history of mathematics in mathematics teacher education.

The remainder of this chapter discusses a variety of empirical investigations that establish a premise for why so many advocate for the inclusion of history of mathematics in teaching and that motivate future investigations. First, and because the focus of the chapter is on the role of history of mathematics in mathematics teacher education, studies about the influence of studying history of mathematics on prospective primary and secondary mathematics teachers are described. Next,

---

[24] For a more comprehensive list, see Jankvist (2012).

accounts of the ways in which teachers – having previously studied history of mathematics to some extent – incorporate history of mathematics in their teaching are presented.

24.6 History of Mathematics in Primary Mathematics Teacher Education

The lack of guidelines that call for history of mathematics in primary mathematics teacher[25] education programs around the world makes it difficult to identify empirical investigations that involve this population. Exemplars of empirical work conducted with prospective primary mathematics teachers tend to focus on attitudes and beliefs. Primary mathematics teacher preparation programs vary in number of hours, courses, seminars, or lectures in both mathematics content and pedagogy (i.e., didactics). Additionally, primary mathematics teacher education programs typically prepare teachers responsible for multiple subject areas – and often for all academic and specialty areas (e.g., art, music). Secondary mathematics teacher education programs, however, focus on preparing teachers of mathematics and in some cases, a second subject area. Consequently, when and how history of mathematics is employed in the preparation of primary mathematics teachers varies. Much of this variability may result from program expectations for the mathematics content required for prospective primary teachers compared to the content expectations for prospective secondary teachers.

24.6.1 First Example

Fleener and colleagues (2002) studied the influence of a mathematics education curriculum that incorporated historical topics in each of three different courses on prospective elementary mathematics teachers' "meaning-making efforts" (p. 73). A series of questions were asked of prospective teachers in three courses, representing three different time points in their teacher preparation program: a mathematics course required for elementary education majors taken early in the second year of the elementary education program, the first mathematics education teaching and learning course, and the mathematics methods taken in the last semester before the teaching internship. The extent of history of mathematics in each course is given in Table 24.2.

The researchers collected responses to a variety of prompts about prospective elementary teachers' experiences with history of mathematics during the three courses.

---

[25] In general, the terms "primary mathematics teachers" and "elementary mathematics teachers" are used interchangeably to describe teachers of pupils aged 5–11 years of age. And, regardless of the term used, such programs are those that prepare generalists, or teachers who teach most if not all of the academic subjects.

Table 24.2 Course descriptions (Fleener et al. 2002)

Course description	When taken	History content
MATH 3213: General mathematics course ($n=48$)	Second semester of second year of elementary mathematics education program	Students conduct research on a topic from the history of mathematics, write a two-page paper, and deliver a brief presentation in class
EDMA 3053: First mathematics education teaching and learning course ($n=37$)	After admission to teacher education program (typically in the third year of a 4-year program)	Students conduct research on a historical figure or historical topic, write a formal paper, and prepare a one-page handout to accompany a presentation delivered to the class. "Students are required to develop activities for elementary students that incorporate an inquiry approach using historical topics or individuals" (Fleener et al. 2002, p. 75)
EDMA 4053: Math methods ($n=12$)	Last semester of course work (taken just before teaching internship)	Content includes: Select a mathematician, conduct research, role-play their mathematician Tested on historical contributions, significance of historical figures, and topics on midterm exam Discussions, readings, and activities to encourage planning of historical activities in future teaching

The prompts asked for prospective teachers to reflect on how learning about the history of mathematics affected their understanding of mathematics and how the preparation of their report on a historical topic or figure aided in understanding mathematics and strategies for teaching mathematics. The participants were also asked about their experiences after participation in each course, including whether they retained handouts from any peers' historical topic presentation or whether they used ideas from their own or others' presentations when preparing classroom activities.

In the analysis of the data, Fleener and her colleagues (2002) were interested in which orientation towards learning mathematics each prospective teacher favored. In particular, they examined participant responses for evidence of knowledge informed by the technical, practical, or emancipatory interests. Grundy (1987) defined the technical interest as "a fundamental interest in controlling the environment through rule-following action based upon empirically grounded laws" (p. 12): the practical (or, hermeneutical) interest as "a fundamental interest in understanding the environment through interaction based upon a consensual interpretation of meaning (p. 14), and the emancipatory (cognitive) interest as "a fundamental interest in emancipation and empowerment to engage in autonomous action arising out of authentic, critical insights into the social construction of human society" (p. 19).

Fleener and colleagues (2002) found that the prospective elementary teachers favored a technical perspective when studying history of mathematics for their own learning and for use in teaching. They also claimed that real-life experiences and historical connections may not equip future teachers with necessary tools to overcome long-held traditional beliefs about mathematics and mathematics learning, and that the prospective teachers in the study were over-reliant on algorithms, which in turn prevented them from exploring deeper meanings within mathematics. Although Fleener and her colleagues (2002) claimed that "critical and historical approaches, even sustained over several semesters of mathematics instruction, are not sufficient for students to develop an emancipatory approach" (p. 80), it is possible that the orientation of the history of mathematics instruction in the three courses favored a technical perspective as well.

Details about the topics or mathematicians that the prospective teachers selected for their research or the content of focus during the mathematics methods course were not provided by the authors, and consequently, it is difficult to further interpret the outcomes they discussed. In research where more details are provided about historical content, potential solutions to improve the ways in which history of mathematics is incorporated in the preparation of primary mathematics teachers are easier to identify, as in the case of Charalambous et al. (2009).

24.6.2 Second Example

Charalambous and colleagues (2009) quantitatively described how prospective primary mathematics teachers' attitudes and beliefs were impacted as a result of participating in a teacher preparation program that contained two content courses grounded in the history of mathematics. The courses, designed and implemented at the University of Cyprus, have been in place for more than a decade. Each three-credit-hour course lasted 13 weeks was taken consecutively, and together the courses were considered the only mathematics-oriented courses in the program for the prospective primary mathematics teachers.

There were 94 prospective primary mathematics teachers who were surveyed four times (pre- and post-surveys for each of the two courses), and six participants (a convenience sample) were interviewed for additional insight after quantitative results were compiled. The authors divided the participants into two groups, according to their acceptance into the pre-service teacher program at the University of Cyprus. The first group ("G1" in the study, with 52 participants) opted to take the mathematics entrance examination and the second ("G2," with 42 participants) did not.[26]

The authors reported that in many ways, the survey results pointed to the finding that the two courses grounded in the history of mathematics were a failure. For example, "the G2 participants exited the program with increased negative attitudes toward mathematics" (Charalambous et al. 2009, p. 177). And G2 participants were unable to "see many connections between the content and the activities of the two

---

[26] At the University of Cyprus, entrance into the preservice teacher program is highly competitive and students must take four entrance exams: one in language and three others in different subject areas of their choice.

courses and the content considered in elementary grades" (Charalambous et al. 2009, p. 177). Each of these results counters much of the rhetoric about why history of mathematics should be used in teaching mathematics. Consequently, the authors used interview data to aid in understanding the quantitative results. They found that the teacher candidates shared that their previous mathematical experiences were all too common, namely, that such experiences "did not help [them] learn how to think" (p. 174) – but merely honed their test-taking skills.

An important outcome from Charalambous and his colleagues (2009) is the identification of three limitations in the approach employed – all of which may serve future research and development of mathematics teacher education programs well. First, they recognized that not sharing the intention to ground the two courses in history of mathematics was a mistake. Second, the authors anticipated that an elementary teacher preparation program grounded in the history of mathematics would impact the participants in such a way that they would begin to view mathematics differently than they did before studying at university. Unfortunately for many of the pre-service teachers, their experiences with the two courses were too similar to their prior experience with learning mathematics: that certain complex mathematical problems were challenging and stressful and the grounding in history failed to matter in a positive way. Lastly, opportunities to genuinely experience the development of mathematics were insufficient for the six participants interviewed. Indeed, this is one of the most challenging issues with implementing history of mathematics in teacher preparation programs. Even with careful planning, knowledgeable instructors, and appropriate resources, such a course can still feel as a whirlwind of historical activity, punctuated by (in the case of many of the G2 participants) difficult mathematical ideas and methods.

Finally, there are three cautions provided by Charalambous and colleagues (2009) that must be heeded when considering similar experiences for future primary mathematics teachers. First, the decision to implement a content course for prospective mathematics teachers grounded in the history of mathematics should be shared with them. Perhaps the most important reason for this is that their prior experience with history of mathematics may be limited, and predetermined attitudes towards mathematics may serve as an obstacle for learning in the course. Second, the difficulties prospective teachers experience with the content of courses based upon the history of mathematics "need to be acknowledged and addressed" (p. 178). And third, to prevent spending insufficient time on the evolution of key mathematical ideas, the authors suggested designing "guided explorations of important mathematical ideas that will support pre-service teachers in their work of teaching" (p. 178). Furthermore, the authors recognized the potential for history of mathematics in teacher education program to contribute to the development of knowledge "that is both useful and usable for the work of teaching mathematics" (p. 179). An important means to this end is the identification of the content of the two courses Charalambous and colleagues (2009) implemented (Table 24.3).

The content of the second course identified by Charalambous and his colleagues (2009) raises an additional concern. Many of the topics identified are well beyond the content that many prospective primary mathematics teachers are familiar with,

Table 24.3 Topics for courses grounded in history of mathematics: Charalambous et al. (2009, p. 179)

Course	Unit 1	Unit 2	Unit 3	Unit 4	Unit 5
First course	First arithmetic systems Arithmetic systems with/without zero Contemporary place value system Two methods multiplication	Transition to systematic proof Applications of similar triangles Different proofs of the Pythagorean theorem Pythagorean mathematics Applications of Pythagorean mathematics in elementary school	Three famous problems of antiquity Attempts to solve the problems (and their contribution to the expansion of mathematical knowledge)	Euclid and his contributions to mathematics	Contribution of other renowned mathematicians (Archimedes, Apollonius, Pascal)
Second course	Zeno's paradox and the principle of exhaustion Development of the notion of limits Limits, differentiation, integration (including applications in real-life situations) Contribution of Newton and Leibniz to modern mathematics	The liberation of geometry: Attempts to prove the 5th Euclidean axiom When is the sum of the angles of a triangle not equal to 180°? Bolyai and Lobachevsky and the development of hyperbolic geometry Riemann and elliptic geometry	The liberation of algebra: Peacock's contribution Hamilton and his quaternions Cayley and matrix algebra Applications in real-life situations	Sets and binary relationships: Notion of sets and associated paradoxes Operations on sets and their properties Cartesian product and its applications to elementary school	A sample of more advanced mathematics: Mathematical logic and applications Boolean algebra Computers and mathematics

and as a result, whatever knowledge prospective mathematics teachers are expected to gain through history of mathematics may not be seen as useful and usable for the work of teaching mathematics. The design of such courses cannot ignore the importance of topics most associated with the work of future primary teachers.

24.6.3 Third Example

In an effort to establish a reliable instrument to measure attitudes and beliefs towards using history of mathematics in teaching, Alpaslan and colleagues (2011) constructed, administered, and evaluated the underlying factor structure of their instrument, *Attitudes and Beliefs towards the Use of History of Mathematics in Mathematics Education Questionnaire*. The instrument was constructed from a variety of available survey questions and was administered to a purposive sample[27] of 237 pre-service primary mathematics teacher candidates in 2010–2011. The authors conducted factor analysis and identified three factors "by considering the field of history in mathematics education and…instrument development studies about social sciences" (Alpaslan et al. 2011, p. 1666): positive attitudes and beliefs towards the use of history in mathematics education, negative attitudes and beliefs towards the use of history in mathematics education, and self-efficacy beliefs towards the use of history in mathematics education. After problematic items were removed from the instrument, the same validity and reliability analyses were conducted again. The final survey contains 35 items; 22 items are included in the positive attitudes and beliefs component, nine items are contained in the negative attitudes and beliefs component, and four items are contained in the self-efficacy component.

The instrument developed by Alpaslan and his colleagues suggests important opportunities for future empirical work in the field of history in mathematics education. As they posited:

> … the results gained by using the instrument by future research projects would have valuable implications for teacher educators in different universities, education policy makers and curriculum developers of different countries in designing curriculum for mathematics education [at] different levels. (Alpaslan et al. 2011, p. 1669)

Furthermore, research regarding the problematic trends in prospective teachers' beliefs about mathematics and attitudes towards learning mathematics via the history of the important development ideas revealed by Charalambous and colleagues (2009) would also be informed by use of the instrument on a larger scale. For example, pre- and post-administrations of the instrument have the power to "reveal potential effects of interventions on the attitudes and beliefs towards the teaching approach in question" (Alpaslan et al. 2011, p. 1669). Future use of the instrument

---

[27] In qualitative research, a purposive sample is one in which a particular participant population is targeted, especially when there is a special nature of the study or participants are difficult to find. This was the case of Alpaslan's and his colleagues' research, where new reforms were in place in Turkey's higher education institutions.

can help reveal gaps in learning and knowing mathematics for teaching and will enable researchers to investigate ways in which history of mathematics may fill such gaps. Furthermore, the populations available to use the instrument are extensive, including pre-service teachers, in-service teachers, and with further development and modifications, primary school pupils.

24.6.4 Fourth Example

Certainly an abundance of empirical studies that rely upon survey data – and thus, self-report data – is a concern for the field of history in mathematics education. Although survey data provide important descriptive information about the research questions posed and establish the landscape of future research directions, the field requires rigorous and extensive empirical study. One promising study, proposed by Alpaslan and Haser (2012), will "provide…teacher educators with possible effective presentations of the history of mathematics knowledge for teaching mathematics" (p. 2). In the pilot study they described, Alpaslan and Haser will conduct a case study on the implementation of a "History of Mathematics" course for lower secondary prospective mathematics teachers (who will be trained to teach 6th, 7th, and 8th grade mathematics in Turkey).

In their future research Alpaslan and Haser (2012) plan to investigate the extent to which the history of mathematics content within the course is used both "as a tool" and "as a goal" (Jankvist 2009) in the course. Furthermore, they will examine whether the content of the history of mathematics course will be addressed from an illumination approach, module approach, or history-based approach (Jankvist 2009). Finally, Alpaslan and Haser will describe how the course content and experiences are reflected in the instructor's and prospective teachers' views.

The results of the study can prove promising for several reasons. First, the researchers plan for multiple data sources, including "observation of the natural course process, content, tasks, and experiences, the nature of the content-related communication between the pre-service teachers and the instructor, and the participation of pre-service teachers in the course experiences" (Alpaslan and Haser 2012, p. 3). A study on the impact and results from implementing a history of mathematics course in mathematics teacher education has not yet been treated to the extent proposed here.

Second, the potential to inform the construction or modification of courses in the history of mathematics for prospective teachers (particularly for future teachers of upper elementary and lower secondary pupils) as a result of the pilot and full-scale study is extensive. Whereas the topics of the two-course sequence implemented by Charalambous and his colleagues (2009) represent an important contribution, Alpaslan and Haser's (2012) investigation has the potential to produce a substantial publication outlining solutions to several obstacles regarding the construction, implementation, and outcomes of history of mathematics courses for prospective mathematics teachers.

Finally, Alpaslan and Haser (2012) will use Jankvist's (2009) recent and influential distinctions of "hows" and "whys" as a framework[28] for the research questions, data collection, and data analysis. The attention to considering these distinctions in investigations such as the study being conducted by Alpaslan and Haser continues to strengthen the field of history in mathematics education. The working group on "History in Mathematics Education" at the seventh Congress of the European Society for Research in Mathematics Education (CERME-7) identified several key issues as crucial for the domain of history in mathematics education, including:

> the need for developing theoretical constructs that provide some order in the wide spectrum of research and implementations done so far; to somehow check the efficiency of introducing a historical dimension; and to develop appropriate conditions for designing, realizing, and evaluating our research…. (Jankvist et al. 2011, p. 1636)

Thus, in an effort to connect content from a history of mathematics course to the extent in which tools, goals, and approaches are addressed – as well as what such content and experiences mean for developing prospective mathematics teachers – Alpaslan and his colleagues may in fact develop a research agenda that informs each of the key issues for the field.

24.6.5 Summary

This section discussed four studies pertaining to the role of history of mathematics in primary mathematics teacher education. Certainly this is not a comprehensive description of literature on research about the effect (e.g., attitudes and beliefs) or inclusion (e.g., history of mathematics courses or content within teacher preparation programs) of history of mathematics. However, there is an abundance of survey research focused on the topic in primary mathematics teacher education and to include additional descriptions is an exercise in repetition.

To be fair, extensive variability exists with respect to programs preparing future primary mathematics teachers. In the United States alone, a key variable is the mathematics content required of these future teachers. For example, it is not uncommon for primary teacher preparation programs to require only one or two lower division[29] mathematics courses for prospective elementary education candidates. In other programs, however, and in some cases for every elementary teacher preparation program in a given state in the United States, a sequence of "Mathematics for …" courses are required for those preparing to teach elementary school.[30]

---

[28] The influence of Jankvist (2009) has been extensive; see examples in Clark (2011), Kjeldsen and Blomhøj (2009), and Tzanakis and Thomaidis (2011).

[29] Lower division courses are courses taken during the first and second year at universities and colleges in the United States.

[30] In the United States, Maryland represents an example of this. Prospective elementary teachers are required to take a sequence of mathematics courses, though these may vary by institution.

The variability in mathematics course requirements for prospective elementary mathematics teachers may be the cause for the limitation of literature (either descriptive or empirical). For those preparing to teach secondary mathematics, a wide range of preparation programs also exists. However, the number of mathematics courses necessary for teaching mathematics at the secondary level (e.g., to pupils aged 12–18) is typically greater than that required for elementary teachers. Consequently, there are an increased number of possibilities within a teacher preparation program of which history of mathematics can be part.

24.7 History of Mathematics in Secondary Mathematics Teacher Education

In this section a representation of both theoretical work about and empirical studies conducted with prospective secondary mathematics teacher populations are discussed. For ease in presentation, the studies are divided into two types. First, descriptions of the perceptions of history of mathematics that is part of a teacher preparation course are given, where the influence of history of mathematics is primarily the "story" of mathematics. Secondly, examples of research are given in which the history of mathematics influenced prospective teachers' mathematical knowledge, as a result of an experience in history of mathematics as part of a teacher preparation program.[31]

24.7.1 History of Mathematics: Influences of Telling the "Story" of Mathematics

Many examples of published research literature in the field of history in mathematics education describe experiences in the history of mathematics for those preparing to teach secondary mathematics. Of these there are two main types of contributions. A large proportion of published accounts describe prospective teachers' attitudes towards history of mathematics or using history of mathematics in teaching, as was the case with research involving prospective elementary mathematics teacher populations. A second type[32] of contribution explains results anecdotally, punctuated by comments from students enrolled in the course.

At the University of Maryland, Baltimore County, for example, prospective teachers take Statistics, Mathematics for Elementary Teachers I, and Mathematics for Elementary Teachers II.

[31] In some contexts the preparation of mathematics teachers entails an undergraduate degree in mathematics, as in the case of Italy (Furinghetti 2000).

[32] Of course, it is possible to see both types represented in the same publication.

24.7.2 First Example

Burns (2010) examined how prospective secondary mathematics teachers at a small private university in the northeastern United States viewed the role of history of mathematics in the curriculum. The mixed methods study also included a brief description of key history of mathematics assignments pre-service that mathematics teachers were asked to complete as part of a secondary mathematics methods course. Post-administration of a five-question survey (when compared to pre-administration responses) indicated that they were more amenable to integrating history of mathematics in future teaching and felt more comfortable with their ability to incorporate history of mathematics.

Responses to the open-ended question, "What should the role of 'history of mathematics' play in the high school mathematics curriculum?" at the beginning of the study revealed that the majority of the prospective mathematics teachers in Burns' sample favored a minor or moderate role. Only three responses indicated a major role for history of mathematics in teaching. When the final questionnaire was administered, Burns found that the students felt more favorable, with only three students attaching a minor role to the history of mathematics. However, these results are somewhat problematic.

The secondary mathematics methods course provided "activities designed to enhance [participants'] exposure to the history of mathematics" (Burns 2010, p. 3), yet each activity described in the article focused on history as the "story of mathematics." For example, the prospective mathematics teachers in the course kept "track of mathematicians" and the mathematics they were famous for from their reading of *Fermat's Enigma* (Singh 1998), selected their "favorite mathematician" and created a short presentation about them, and finally, chose a unit within a high school mathematics course and described what history of mathematics content they would be able to incorporate into the unit. When the course activities are considered along with the pre-service mathematics teachers' responses indicating that they believed history of mathematics should have a major role in the high school curriculum, a contradiction arises. That is, if "history as story" (or, "history as anecdote")[33] is assessed as a minor way in which history is used in teaching mathematics, then the observation that "…basically I feel like history of mathematics should be 'sprinkled' on top of the lesson" (Burns 2010, p. 5) should not be coded as history having a major role in teaching.

Burns (2010) provided an example of research on exposing prospective teachers "to topics from history of mathematics and methods that could be used to teach these topics" (p. 2), but the exposure described lacked attention to strategies in which historical methods (e.g., mathematical procedures and techniques), historical problems, and primary sources are integrated when teaching mathematics. Indeed, she called attention to the need for more "to be done to develop a deeper understanding

---

[33] Three modes of using history in teaching mathematics were given in Clark (2011): history as anecdote, history as biography, and history as interesting problems.

of [history of mathematics] before students get to a methods course" (p. 7), which is intimately connected to policy and standards that recommend history of mathematics courses for prospective secondary mathematics teachers.

24.7.3 Second Example

A similar intervention in a secondary mathematics methods course in Turkey was "designed to improve competencies regarding the integration of history of mathematics" in teaching mathematics courses (Gonulates 2008). The small intervention study involved 14 senior-level students over a 14-week period during the course. The intervention required the mathematics methods students to read assigned articles, which were chosen using the criteria of Gulikers and Blom (2001). Using the criteria, articles were selected if they fulfilled the aims of the study to portray the usefulness of historical materials when teaching mathematics, as well as the variety in which history of mathematics may be incorporated in teaching. The students were also required to participate on a class discussion board weekly by submitting a report that detailed their ideas about the weekly article and proposed use of history in teaching mathematics. Finally, "brainstorming and discussion" during the final week of the intervention enabled students to share their overall ideas about using history in teaching.

Two instruments were developed for the study, an attitude scale and a questionnaire. The attitude scale asked students to "state teaching strategies or instructional procedures that they [thought] they [could] use [history of mathematics] in [mathematics teaching]," and an accompanying questionnaire asked them to provide examples for each strategy (Gonulates 2008, p. 5). The results from the two instruments revealed that although the students' attitudes about integrating history of mathematics in teaching increased, the increase was not significant. Of greater interest, however, were results related to the extent to which the pre-service teachers were able to name ways in which they could integrate history of mathematics in teaching and the quality of the examples they identified. The pretest and posttest results for the total number of teaching strategies for incorporating history of mathematics were 55 and 73, respectively; the increase in the total number of examples for the strategies identified pre- and posttest was 53 and 69, respectively. Neither increase was significant. However, the increase in the quality of the examples as judged by three different juries was significant.

Gonulates' investigation raises several important issues for the field of history in mathematics education. The students' comments on the discussion board revealed that they held the belief "that the history of mathematics could be used more for motivational than for conceptual purposes" (2008, p. 9), which is a common theme for the investigations described in this section. The view that using history promotes mathematics (Furinghetti 1997) is a frequent outcome when "history as story" dominates pre-service teachers' experience with history of mathematics. Consequently, this view presupposes that the future practice of prospective teachers will entail using history to enrich their teaching in social, affective, and cultural ways, but will not be robust enough to aid in the learning of mathematical content. A potential solution to prompt the use of history of mathematics for the purpose of reflecting on mathematics (Furinghetti 1997) is to incorporate opportunities for prospective mathematics teachers in which they experience a quantifiable change in their own learning of mathematics through historical content, resources, and methods.

24.7.4 Third and Fourth Examples: Design of "History of Mathematics" Courses

Descriptive accounts for designing and implementing history of mathematics courses for prospective secondary mathematics teachers are abundant in the literature. Toumasis (1992) is an early example of proposing formal experiences in the history of mathematics in the training of secondary school mathematics teachers in Greece.

At the time, Toumasis observed that the content training of secondary mathematics teachers was "sound and supersufficient…, whereas the pedagogical training [was] quite inadequate" (1992, p. 289). Toumasis claimed that "teachers should be acquainted with the history of mathematics and mathematical ideas and its relation to science, and should acquire some familiarity with the way mathematicians work today" (p. 291). Furthermore, he claimed that prospective secondary mathematics teachers needed to receive training on "the role of the subject in history and the society" (p. 291), in addition to being taught mathematics content. Specific content of a course in the history or mathematics for prospective secondary mathematics teachers was not given; however, Toumasis outlined several tenets for teacher education programs, including a sample pre-service program structure and attention to such elements as providing students with opportunities to connect theory and practice.

Still other descriptions detail course content, required materials, and assignments for history of mathematics courses intended for prospective mathematics teachers, including Clark (2008) and Miller (2002). Miller designed and implemented a course that focused on the mathematics of five ancient cultures and which used two course texts on the history of mathematics from which to draw content and exercises. Miller's experience with teaching a history of mathematics course for the first time was the impetus for her "trial by fire" article; however, much of what she shared from her experience outlines many of the reasons why history of mathematics courses is not offered in teacher education programs.

Miller identified the lack of sufficient homework problems in any one text as a major obstacle in the implementation of the course. This, coupled with the realization that she was "not as prepared to teach the material" as she thought (2002, p. 339), made for a labor-intensive teaching experience. Furthermore, the curriculum committee at the State University of New York (SUNY) Potsdam established the mathematics course prerequisite at precalculus, thus potentially limiting the mathematical content and rigor of the course. The course was implemented at Miller's institution in anticipation of future NCATE accreditation to meet the program standard needs for prospective teachers to possess knowledge of the historical and cultural development of mathematics. Thus, developing foci for such a course, selecting appropriate materials and textbooks, identifying qualified and willing faculty, and setting the course prerequisite(s) may very well serve as the same obstacles for other institutional contexts.

24.7.5 History of Mathematics: Potential for Teachers' Mathematical Learning

Thus far there has not been explicit focus on why prospective teachers must know something of the history of mathematics, either for the development of their own knowledge or for learning concrete, innovative, or interesting ways to teach mathematics to pupils. Instead, the focus has been to summarize key activities that have taken place in the field regarding the existence of history of mathematics in mathematics teacher preparation. Perhaps the most essential aspect of the role of history of mathematics in mathematics education is what potential it holds for impacting the learning of the subject. In his text, *Elementary Mathematics from an Advanced Standpoint* (1908), Felix Klein wrote:

> …I shall draw attention, more than is usually done…to the *historical development of the science*, to the accomplishments of its great pioneers. I hope, by discussions of this sort, to further, as I like to say, your general *mathematical culture*: alongside of knowledge of details, as these are supplied by the special lectures, there should be a grasp of subject-matter and of historical relationship. (Klein 1908/1939 Pt. II, p. 2, emphasis in the original)

The importance of knowing and studying the accomplishments – in this case, mathematical accomplishments – as part of the (history of) mathematical education of prospective teachers has been valued and conjectured for over a century. It is vital to begin work on providing evidence in support of such conjectures.

24.7.6 First Example

Fulvia Furinghetti's work with prospective mathematics teachers in Italy provides important examples of how history of mathematics can be incorporated into teacher preparation programs with particular attention to "the conception of mathematics and its teaching…that students develop through their mathematics studies in university" (Furinghetti 2000, p. 43). As Furinghetti observed (and many would agree), university students with strong mathematical training become far removed from the mathematics they are required to teach and once arriving in the classroom their own teaching is similar to how they were taught mathematics in secondary school. In an effort to combat prospective mathematics teachers' falling back on old conceptions of teaching, Furinghetti asked her prospective teachers to "reflect on their mathematical knowledge, in particular on their beliefs about mathematics and its teaching" (p. 46). The activity used in the study focused on "definition," due to its critical role in learning mathematics.

The main component of the prospective teachers' work in the activity was to analyze definitions found at the beginning of old geometry books, including Italian translations of Euclid, Clairaut, and Legendre. Furinghetti (2000) outlined the outcome of the students' exploration of various geometric definitions (e.g., line, quadrilateral, square, trapezia), noting that "students became aware of the fact that definition has three different aspects" (p. 48) in that definitions must be logical, epistemological, and didactic (p. 49). Although the prospective teachers focused only on the didactic aspect of definitions, this in itself was an important mathematical orientation for the students and for this particular study. Here, the examination of various historical resources prompted prospective teachers to investigate questions about what is necessary, sufficient, and preferable information for a definition. In this way, the analyses in which the prospective teachers engaged were linked to proof, further strengthening their mathematical knowledge for teaching.

There are several important observations to make about this example of using historical content and resources with prospective teachers. It is important to note that they possessed strong mathematical backgrounds. However, insufficient research has been conducted on the mathematical background needed to study history of mathematics, particularly with respect to intentions for its use in mathematics teacher education and mathematics teaching.[34] However, it is significant that Furinghetti began the research with the goal that the prospective teachers would reflect on their mathematical knowledge. This difference sets Furinghetti's investigation apart from the research described in the first part of this section, most of which discussed outcomes primarily focused on the story of mathematics and learning to use history of mathematics as anecdote (Siu 1997). The important difference in the investigation Furinghetti conducted was how prospective teachers used history as

> a kind of 'magnifying glass' for the conceptual nodes of a certain theory, a means to identify critical points, to stop at the difficult concepts and to analyse them through the words of past authors. (Furinghetti 2000, p. 50)

24.7.7 *Second Example*

Prospective mathematics teachers' reflections are also the data source for Furinghetti (2007). In the experiment, 15 prospective secondary mathematics teachers were tasked with producing a sequence for teaching a particular concept in algebra for 9th and 10th grade students in Italy. The perspective from which Furinghetti designed the experiment was that the use of history of mathematics enables *reorientation*, that is, "that prospective mathematics teachers experience again the construction of mathematical objects" (p. 133). There were several phases in the experiment, including (1) analysis of the national mathematical programs from elementary school through the end of high school; (2) work with the history of mathematics to identify and study "the cognitive roots of algebra"; (3) design of the teaching sequence, applying both historical and theoretical perspectives from their course

---

[34] Furinghetti noted that she served as the historian "guide" for students, providing "historical information…needed to interpret authors" (2000, p. 47).

work; and (4) discussion of the outcome of the teaching sequences produced, using both historical and classroom contexts to discuss how cognitive roots may emerge in the teaching sequence (Furinghetti 2007, pp. 135–136).

The prospective mathematics teachers' construction of teaching sequences for an algebraic concept produced a variety of artifacts. In addition to the planned sequences, the prospective teachers also produced exercises and problems for pupils and reports on implementation of excerpts from the teaching sequences. The significant finding of the study was the identification of the ways in which history of mathematics impacted these artifacts. Furinghetti (2007) identified two modes of impact: using history as a way of looking at the evolution of a particular concept and the reading of original sources. For each of these modes of impact, Furinghetti yet again provided empirical evidence for the power of history of mathematics to influence prospective mathematics teachers' mathematical knowledge. For example, for the "evolutionary" mode she observed that the prospective teachers held the idea that

> History provides meaningful examples of algorithms and methods that allow exploitationof the operational nature of mathematical objects;
>
> History suggests the development of the concepts in a visual/perceptual environment such as that provided by geometry. (Furinghetti 2007, p. 137)

Finally, it is important to again comment on the orientation from which Furinghetti conducted this experiment. As in the context with prospective mathematics teachers working on the notion of "definition" in mathematics, Furinghetti made it clear that guiding students in how to "do" history of mathematics was a primary concern. As part of her work with the 15 prospective teachers, she provided different types of sources and guidance on how to "look for information, to choose among different sources, to interpret original historical passages, to evaluate many elements, and to make their own choices" (p. 136). In this way, the varying background experiences of the participants were leveled out and this afforded opportunities for collaboration and discussion. Most importantly, "the participants were provided with motivation to learn some history of mathematics" (p. 141).

24.7.8 *Third Example*

Although history of mathematics received prominent attention in the 1997 new national curriculum in Norway, its role in mathematics teacher education did not receive similar attention. Smestad (2012) described the development and revision of a 6-h history of mathematics course he developed as part of a new course for prospective lower secondary mathematics teachers. Smestad established several goals for the students, all of which were focused on future pedagogical practices. The course:

> …should give the students examples of different ways of teaching with history of mathematics, it should be connected to the students' curriculum, it should give ideas that are suitable for different age levels in the 11–16 bracket, it should show how mathematics has…developed. (Smestad 2012, p. 1)

The students' evaluation of the first iteration of the course revealed that it was difficult for them to glean anything from the potpourri of topics. For the second iteration, Smestad focused entirely on the history of probability. Although Smestad provided a list of topics and a brief description of several examples from the course, of the outcome of the second iteration he stated only that "the mathematical learning was more obvious to the students" (2012, p. 3). Quantification of the extent of the mathematics learned and why it was more obvious to the students or what evidence supported either of these critical pieces of information are not known.

24.7.9 Fourth Example

Clark (2012) sought to qualify mathematical learning as a result of studying history of mathematics. In a history of mathematics course for prospective secondary mathematics teachers, students studied and used translations of primary sources as well as historical methods to solve problems connected to the mathematical content they would be responsible for in their future teaching. After studying the method of completing the square from al-Khwarizmi's famous text (ca. 825 CE), prospective teachers' journal reflections from four different semesters of the course were analyzed to identify key themes indicative of changes in their mathematical knowledge.

Excerpts from 80 of 93 student reflection journals provided insight into the ways in which the study of historical examples of solving quadratic equations using the method of completing the square revealed that the prospective teachers experienced two changes in their understanding of this mathematical idea. The prospective mathematics teachers came to understand the method of completing the square as a result of the geometric representation motivated by al-Khwarizmi's method. And they claimed that their previous experience with this mathematical topic was firmly situated in rote understanding of the quadratic formula emerging from the method of completing the square.

It was difficult to definitively identify whether the historical tasks, content, and historical sources were the primary influences of the changes in mathematical understanding experienced by the prospective mathematics teachers participating in the study. However, the reflections about the perspective on their own mathematical learning also influenced the prospective teachers' conceptions for how to incorporate history of mathematics in their future teaching. This prompts attention to Schubring's and his colleagues' (2000) concern that "…there is only scattered evidence about the effectiveness of the historical training in the later teaching practice" (p. 142) – and which continues to be of concern.

24.7.10 Summary

Each of the examples summarized in this section serves to remind the field that conducting research that details a clearer picture of what the role of history of mathematics in secondary mathematics teacher education is, and how teacher educators can best capitalize on what it offers to future educators, is difficult work. On the one hand, the extent to which the guidelines provided in MET1 – and now, MET2 – were or will be instituted in the United States remains unclear. Furthermore, the introduction of the Common Core State Standards Initiative in Mathematics (CCSSI-M) will have significant impact on mathematics teacher education. The newly created Mathematics Teacher Education Partnership (MTE-Partnership), a partnership of institutions of higher education, K-12 schools, school districts, and other stakeholder organization, has launched a collaborative effort to redesign secondary mathematics teacher education. The MTE-Partnership will identify best practices and guiding principles underlying such teacher education programs and the efforts of the partnership are intimately connected to CCSSI-M and common assessments that are attached to the Common Core State Standards. Finally, the extension of similar concerns and efforts applies to many, if not all, locations around the world, as the (largely unknown) outcomes of history of mathematics on mathematics teaching and learning will certainly influence its role in mathematics teacher education.

In order for teacher educators who advocate for the role of history of mathematics in mathematics teacher education to impart influence in the future, the broader field of mathematics education will demand evidence of positive impact of the integration of history of mathematics on pupils' learning of mathematics. The final section highlights several examples of interventions that have taken place in primary and secondary classrooms and which provide promise for imparting the influence needed in the future.

24.8 What Next: Teachers Using History of Mathematics in Teaching

This chapter was intended to provide an overview of the "state of the field" of history in mathematics education pertaining to the preparation of mathematics teachers. The previous sections described examples in the literature of the design and implementation of history of mathematics courses for prospective mathematics teachers, research on prospective teachers' attitudes towards learning history of mathematics, and teaching using historical perspectives, as well as qualitative research on how and what prospective teachers learn as a result of experiences with historical content. In addition to providing a representation of the field, suggestions of what is further needed to quantify responses to questions of why history of mathematics is necessary for the mathematical and pedagogical education of future mathematics teachers were offered. This final section offers a brief look at "what next?"; that is, after prospective teacher transition into classroom teaching, what are examples of efforts to incorporate the history of mathematics in teaching and what can be learned from them to further inform mathematics teacher education programs?

Table 24.4 displays a collection of six studies for which some element of history of mathematics was employed in a classroom intervention with pupils. The summaries

Table 24.4 Summary: recent examples of ways in which history of mathematics is used in classrooms

Author(s)	Age level, topic, and location	Intervention (including materials)	Methodology (data sources)	Outcomes and comments
Clark (2010)	46 pupils, grades 4 and 5 Contextual word problems involving multiplication, division, and conversion of units United States	Classroom teachers and school district mathematics specialists participated in professional development on an instructional unit created from two cuneiform tablets owned by Florida State University (FSU22 and FSU23). Pupils participated in an extended mathematics lesson using the materials, photos of FSU22 and FSU23, and local history	Qualitative; field notes, student work, teacher and mathematics specialists post-implementation survey	Classroom teachers participated with and observed their pupils' engagement with the instructional unit and reported increased student interest and attention. They also observed that pupils appeared to experience less difficulty with unfamiliar units (e.g., *eshe*, *bur*) and less anxiety with "word problems" that were situated in the ancient Babylonian context
Papadopoulos (2010)	20 pupils, grade 6 (two different Classroom environments: one computer lab, one paper-and-pencil classroom) Area of irregular shapes Greece	Inspired by the evolution of the Concept of area found in textbooks from the eighteenth to twentieth centuries, the author designed tasks and guided them to "reinvent" the methods for estimating the area of irregular shapes, for which they had no prior instruction	Qualitative; student work Artifacts from paper-and-pencil group and screen captures from computer lab group	The pupils applied Techniques that were the same as those given in the textbooks and some of the techniques developed by pupils were completely new
Ng (2006)	414 pupils in 8th year (177 in the experimental group; 237 in the control group) Relevant problems from ancient Chinese mathematical texts Singapore	Ancient Chinese Mathematics Enrichment Programme (ACMEP) entailed pupils' translating and solving problems taken from the *Nine Sections*. The intervention was 7 months in duration	Quasi-experimental (no random assignment: pupils selected which group they would be part of) assessments	Although there was an overall significant difference in academic achievement in mathematics between the experimental and control groups (favoring the experimental group), the difference could not be completely attributed to the ACMEP

Rowlands (2010)	36 gifted and talented pupils aged 14–15 and two groups of about 30 mixed ability pupils aged 16–17 Deductive geometry England	Pupils were introduced to the six levels of abstraction through the intervention containing two primary events	Qualitative; observations by one teacher and an academic, feedback questionnaires, formative assessment	Success of the pilot stage was judged primarily by the engagement of the learners
Thomaidis and Tzanakis (2007)	Two classes of 16-year-old students Ordering on the number line Greece	Pupils were taught according to the official syllabus and textbook for the first three chapters of the text. Regarding the fourth chapter, pupils were divided into two groups: those who had been taught “algorithmic” tools for solving quadratic inequalities (28 pupils) and those who had not (30 pupils)	Mixed methods; student responses to a three-item questionnaire, along with accompanying work	No significant difference was found between the post-“algorithmic” group and the pre-“algorithmic” group. Qualitative differences did point to the notion that some student difficulties paralleled the obstacles encountered in history regarding the conception of and ordering of negative numbers
Jankvist (2010)	Upper secondary pupils Public-key cryptography and RSA Denmark	A 67-page teaching module was prepared to introduce pupils to the historical case and the mathematics involved. Essay assignments were implemented in groups of three to five pupils	Qualitative; pre-implementation questionnaire involving historical, developmental, sociological, and philosophical questions and interviews conducted with a subset of the original group and five students from the 12 interviewees were interviewed during the module implementation	An existence proof for a module approach for history as a goal to occur with Danish upper secondary pupils

highlight the pupil age level and if appropriate, mathematical topic, what the intervention entailed, the methodology employed, and reported outcomes of the research.

The collection of studies highlighted here represents a broad range of pupil age levels, historical and mathematical content, and study design. What the analysis of the research revealed, however, is that most of the interventions were the result of ideas and research generated by scholars or mathematics teacher educators, not the result of classroom teachers who studied the history of mathematics (e.g., as a result of their pre-service mathematics preparation program) and then collaborated with others to conduct research of what occurred when using history in teaching. Finally, although progress is evident, questions and challenges regarding the role of history of mathematics in mathematics teacher education remain.

Kathleen M. Clark is an associate professor in the College of Education at Florida State University. She received her doctorate in Curriculum and Instruction (with an emphasis in Mathematics Education) from the University of Maryland, College Park, Maryland, United States, in 2006 and was the same year appointed assistant professor of Mathematics Education in at Florida State University. In 2009 she was awarded a 1-year research fellowship in the history of mathematics in the Department of Mathematics and Statistics at the University of Canterbury in Christchurch, New Zealand. Her primary research interests lie in two fields, mathematics education and history of mathematics. In the former, her research investigates ways in which prospective and in-service mathematics teachers use history of mathematics in teaching and the ways in which the study of history of mathematics impacts mathematical knowledge for teaching. In the latter, her historical research is focused on the seventeenth- and eighteenth-century mathematics, with a particular emphasis on the early development of logarithms. Dr. Clark serves a variety of national and international organizations concerned with the history of mathematics, including coeditor of the online journal *Loci: Convergence* (part of the Mathematical Sciences Digital Library (MathDL)), advisory board member and newsletter editor for the International Study Group on the Relations between the History and Pedagogy of Mathematics (HPM Group), and executive committee member of the HPM-Americas Section.

Chapter 25
The Role of Mathematics in Liberal Arts Education

Judith V. Grabiner

25.1 Introduction

> World-famous golden-thighed Pythagoras
> Fingered upon a fiddle-stick or strings
> What a star sang and careless Muses heard
>
> –William Butler Yeats (1865–1939), "Among School Children"

Ireland's great poet beautifully reminds us how a legendary mathematician of antiquity not only discovered that musical harmony results when the lengths of vibrating strings are in the ratios of small whole numbers but also taught that the same mathematical harmonies produce the music of the heavenly spheres. Yeats expects his readers to know this history. The surrealist artist Salvador Dalí (1904–1989), in his painting "The Last Supper," places Jesus and his twelve disciples in part of a wooden dodecahedron, resembling the wooden model of this twelve-sided figure pictured in a famous drawing by Leonardo da Vinci (1492–1519). Plato in his *Timaeus* had said that the dodecahedron was the shape of the universe. Dalí's painting gains in power for those viewers who understand this symbolism.

Furthermore, not only ideas about numbers and shape but the very technical terms that underlie mathematics pervade Western culture from the "postulata" with which Thomas Malthus begins his "Essay on Population" of 1798 to the "algorithms" which humanists and scientists alike know are the basis for Internet search engines. Nor is this just in the Western tradition. Mathematics is found in virtually every human society, from ancient civilizations to contemporary cultures, both literate and nonliterate, all over the world. In Greece almost two and a half millennia ago, Plato wanted the rulers of his ideal Republic to study arithmetic, geometry, astronomy, and the mathematics of musical harmony, and those four subjects, along

with grammar, rhetoric, and logic, made up the classical Seven Liberal Arts. In traditional Hindu architecture, numerical ratios are used to represent the mathematically determined structure of the universe. In classical India, not only was mathematics used to analyze poetic meter, mathematical results themselves were expressed in poetic form. In premodern China, mathematical writings were part of the canon of literary texts studied for the examinations to enter the civil service. At present, most universities in the United States require all students, whether these students aspire to be artists, social workers, or technologists, to take courses in mathematics. Mathematics, then, has played and still plays a central role in liberal arts education.

Yet mathematics is too often taught, and too often thought to be, a series of formulas, or a set of arbitrary rules for solving contrived and irrelevant word problems. It often acts as an instrument to keep less proficient students from entering certain fields. And though mathematics classes are often justified as helping teach students to think, or to think abstractly, much actual mathematics instruction teaches neither of these, instead producing frustration and a fear so pronounced that it has been given its own name, “mathematics anxiety” (Ashcraft 2002; Tobias 1993; Zaslavsky 1994). People who are otherwise well educated say, when confronted with the quantitative statements so pervasive in modern life, “Oh, I’ve always been bad at math.”

The present essay has four goals. First, it will briefly sketch the history of the continuous inclusion of mathematics in liberal education in the West, from ancient times up through the modern period; the focus on the West stems from the continuing influence of the idea reflected in the words of the title assigned to the author for this essay: “liberal arts education.” Second, it will elaborate on the brief remarks in this introduction to delineate the central role mathematics has played throughout the history of Western civilization, demonstrating that mathematics is not just a tool for science and technology (though of course it is that) but continually illuminates, interacts with, and sometimes challenges fields like art, music, literature, and philosophy – subjects now universally considered to be liberal arts.[1] Third, it will

---

[1] In modern discourse about education, the term “liberal arts” has been defined and characterized in a variety of ways. It is of course built into the history of Western education. The influential Carnegie Foundation for the Advancement of Teaching has provided a list of contemporary “liberal arts” that goes beyond the traditional Western canon: English language and literature, foreign languages, letters, liberal and general studies, life sciences, mathematics, physical sciences, psychology, social sciences, visual and performing arts, area and ethnic studies, multi- and interdisciplinary studies, philosophy, and religion (Carnegie 1994, p. xx; Ferrall 2011, p. 9). In antiquity, as the next sections of this paper will describe, the list came to have seven items: arithmetic, geometry, astronomy, and music theory (the quadrivium), and grammar, rhetoric, and logic (the trivium) (Stahl 1977; Wagner 1983b). Those who compile such lists characterize liberal arts education as study undertaken for its own sake, as opposed to vocational education. As for the purpose of liberal arts education, it has been described as educating a free person, or as liberating the mind to pursue the truth, or as producing a cultivated person who can be both a good citizen and a leader of society. Liberal arts instruction has sometimes focused on the canonical texts of Western civilization as ways to build and reinforce the shared values of society. But such instruction has also been championed as suitable for the education of free individuals to be citizens in a democracy by developing the capacities for independent and critical thinking, logical analysis, effective communication, an understanding of the interrelations between different fields of learning, and imagination (Ferrall 2011; Kimball 1995; Nussbaum 2010; Sinaiko 1998). The present chapter recognizes and appreciates these

add a more global perspective to the contemporary liberal arts story, by showing how the mathematics present in many cultures – an important part of global history – can enhance the teaching of modern mathematics. Fourth, it will address some ways that mathematics teaching could take the subject out of the toolbox and bring it back to the university, replace frustration with appreciation and understanding, and reestablish mathematics as a liberal art.

25.2 Mathematics and Liberal Education in Western History

25.2.1 The Ancient World

The tradition of liberal arts education in the West goes back to antiquity. A liberal arts education was intended not to prepare one for a vocation or to accomplish some practical goal but to educate a free human being and citizen – though what “free human being” and “citizen” meant has changed over the years. And mathematics virtually always was counted among the liberal arts (Jaeger 1944; Marrou 1956).

In the Greek-speaking world, even before Plato’s time, mathematics was entwined with philosophy. A new attitude toward mathematics and science, detaching them from the practical or the metaphysical, is often dated from the time of Thales of Miletus (late sixth century BCE), who is said to have proved some basic geometric results and to have begun the Greek practice of understanding nature in terms of fundamental rational principles. To the pre-Socratic question “what is the basic unifying principle of the universe?” Thales answered that “all was water.” Then, Anaximander answered that all was the unbounded, Anaximenes that all was air, and Democritus that all was made of atoms. The Pythagoreans answered the question by teaching that “all is number.” Proclus (fifth century CE) credits Pythagoras himself with having transformed the study of mathematics into “a scheme of liberal education, surveying its principles from the highest downwards and investigating its theorems in an immaterial and intellectual manner”; this transformation, initiated by the Pythagorean school, was well established by the fifth century BCE.[2] The subdivision of mathematics into the four canonical sciences of arithmetic, geometry, astronomy, and music goes back at least to the prominent Pythagorean Archytas of Tarentum (early fourth century BCE) (Huffman 2011; Fauvel and Gray 1987, p. 57).

Plato himself in Book VII of his *Republic* gave mathematics a central role in the education of the rulers of his ideal state, who were to be philosophers as well as

---

disparate views. The Carnegie list is useful to illustrate the types of subjects that constitute a liberal arts education today, and the present essay shares the view that modern liberal education’s most important goal is to educate independent and thoughtful citizens.

[2] For Proclus, see Proclus (1970, p. 53). The term “mathematics” itself reveals a liberal arts origin; the Greek root “mathema” was first more general, connoting merely “something learned,” and the “mathematikoi” were the inner initiates of the Pythagorean school. For pre-Euclidean logically structured geometry, see Knorr (1975, esp. p. 7) and McKirahan (1992, pp. 16–18).

kings. Plato acknowledged that mathematics is useful, but the needs of shopkeepers and generals are not why it is important. It is because the objects of mathematics are unchanging and eternal that their study is at the heart of liberal education. The study of mathematics, Plato said, compels the soul to look upward, drawing it from the changing to the real, from the uncertain to the certain, and from the world of illusion toward the truth (Plato, *Republic*, Book VII, 521c, 525d-529c; Plato 1961, pp. 575–844). Thus, mathematics is a "liberal" subject for Plato and his followers. Plato's outline for the education of the philosopher-rulers begins with arithmetic, followed by geometry, followed by astronomy, and is capped by the study of harmony. Astronomy goes beyond the study of the visible heavenly bodies to their pure mathematical shapes and motions, and harmony goes beyond physical music to the mathematical proportions involved (Plato, *Republic*, Book VII, 524e-531c; Plato 1961, pp. 575–844). Moreover, Plato often explained his philosophy using mathematical examples, most famously in the parable of the Divided Line, a geometric metaphor encompassing all of reality, from shadows to the Form of the Good (Plato, *Republic*, Book VI, 510d-513e; Plato 1961, pp. 575–844).

Aristotle, like Plato, distinguished learning for its own sake from more practical activities, and, also like Plato, put mathematics in the former category. Once there were people with leisure, said Aristotle, "those of the sciences which are directed neither to pleasure nor to the necessities of life were discovered" (Aristotle, *Metaphysics* 981b20-24; Aristotle 1941, pp. 689–926). Aristotle classified studies as theoretical, where the goal is knowledge; productive, where the goal is a product; and practical, where the goal is action. For him, mathematics, physics, and metaphysics are the theoretical sciences, and his theory of demonstrative science is illustrated by, and modeled on, the logically structured "elements of geometry" that existed before Euclid's definitive books drove out all previous competitors (Heath 1949, pp. 1, 5; McKirahan 1992, pp. 16–18). For Aristotle, the objects of mathematics are abstractions from sense experience (Aristotle, *De anima* 431b13-19; Aristotle 1941, pp. 535–603; Heath 1949, p. 65), a characterization that underlines the theoretical status of the subject. Aristotle also appreciated the aesthetic qualities of mathematics, saying "The chief forms of beauty are order and symmetry and definiteness, which the mathematical sciences demonstrate in a special degree" (Aristotle, *Metaphysics* 1078a37-b2; Aristotle 1941, pp. 689–926). Thus, for Aristotle as for Plato, mathematics shares goals and other characteristics with the liberal arts.

There were of course other subjects in Greek education, notably rhetoric, philosophy, and politics. Indeed, rhetoric, as championed by the Sophists such as Hippias of Elis (fifth century BCE), though criticized by Plato as the art of making the worse argument appear the stronger, was an important topic throughout antiquity. But the Sophists did not neglect mathematics. In fact Werner Jaeger credits the Sophists, beginning with Hippias, with having "altered the history of the world" by introducing mathematical instruction to their students, changing it from a subject of scientific research to a valuable part of education, with its value being the cultivation of the intellect (Jaeger 1944, vol. I, pp. 313–315). There was no unanimity on this point; the influential Greek orator and teacher Isocrates (436–338 BC) emphasized rhetoric and philosophy in his highly influential program of instruction, which, in the Hellenistic age, was often preferred to that of Plato and which was emphasized in the more literary and rhetorical educational ideal adopted by the Romans (Jaeger 1944, vol. 3, pp. 46–47; Kimball 1995, p. 19; Marrou 1956, pp. 119–120).

Education in the Roman period generally emphasized politics and rhetoric. Still, even the champion of oratorical instruction Quintilian (40–118 CE) conceded that mathematics sharpens the intellect and teaches how to construct an argument (Grant 1999a, p. 99). The Greek term "Enkuklios paidaea" that described higher education in antiquity was always taken to include mathematics, and the Latin phrase "artes liberales" was seen as similar to "enkuklios paidaea" (Kimball 1995, p. 21; Marrou 1956, pp. 243–245; Morrison 1983, p. 32). "Liber" – free – meant the arts of the mind of the free individual as opposed to the mechanical arts.

The influential orator Cicero held that to be truly human, one needed to have been "perfected in the arts appropriate to humanity" (Cicero, *De re publica* I.xvii.28), and, although mathematics was not foremost in his educational agenda, he included it on the list of "artes liberales" essential to the liberal education of a gentleman (Cicero, *De oratore* III.xxxii.127; Grant 1999a, p. 100). Cicero also reported that Plato became convinced of a country's intellectual nature by seeing that it had produced geometrical drawings, rather than just by observing that its land was cultivated (Cicero, *De re publica* I.xvii.29).

Throughout the Graeco-Roman period, then, mathematics remained part of education. Of course, sometimes the mathematics taught did not go very deep. Still, at least lip service was paid to its role, and even lip service keeps a tradition alive and capable of fuller resurrection.

25.2.2 The Middle Ages

The idea of the liberal arts continued into the medieval period. The Latin encyclopedists of the fifth through seventh centuries hoped to preserve the intellectual heritage of classical learning. They combined the intellectual traditions of Neoplatonism with Christianity and linked these with the handbook tradition of popular culture. The encyclopedists needed an organizing principle for all these topics, and the principle chosen was the concept of the liberal arts, a principle that continued to organize knowledge into the twelfth-century Renaissance and beyond.

Martianus Capella's fifth-century *Marriage of Philology and Mercury* is the first work to fully present the Seven Liberal Arts (Stahl 1977, pp. 21–39). Martianus's Seven Liberal Arts, described allegorically as seven bridesmaids, were grammar, rhetoric, logic, arithmetic, geometry, astronomy, and harmony or music. Martianus explicitly ruled out medicine and architecture, classifying them as "mundane matters," that is, professional pursuits, not liberal ones, pursued for their own sake (Stahl 1977, vol. 1, p. 93). Sometimes in medieval teaching, logic was assimilated into rhetoric, and often the mathematics was superficial, but Martianus's classification ensured that mathematics would remain part of the "arts of free people" (Stahl 1977; Wagner 1983a).

Although the Christian Roman Emperor Justinian closed the pagan philosophical schools, including Plato's Academy in Athens, in 529 CE, the Greek version of the liberal arts did not die. The early Church fathers had been interested. Clement of Alexandria (150–215 CE) was willing to include the liberal arts as a first stage in education that ultimately led to philosophy and Christian wisdom (Grant 1999a, p. 101), while Augustine (354–430 CE), much influenced by Neoplatonism, saw the liberal arts as pathways to the divine order underlying creation, especially, he said, "in music, in geometry, in the movements of the stars, in the fixed ratios of numbers" (Grant 1999a, p. 101). Cassiodorus (c. 480–c. 575 CE) also included the liberal arts in Christian education. In sixth-century Spain, Isidore of Seville wrote that mathematics is a legitimate and important component of Christian culture, supporting his view with a text from the *Apocrypha*: "Not in vain was it said in the praise of God: You made everything in measure, in number, and in weight" (*Wisdom of Solomon* XI, 20; Høyrup 1994, pp. 177–178).

In the monasteries, monks copied and preserved both Greek and Latin manuscripts. Beginning in the eighth century, notably under Alcuin of York, cathedral schools taught both the trivium and quadrivium. For the quadrivium, texts included arithmetic based on the work of Nicomachus of Gerasa, the first four books of Euclid's *Elements of Geometry* as adapted and abridged by Boethius, some astronomy based on an abridgement of Ptolemy's *Almagest*, and various Greek materials on music. Mathematics was needed in this period to determine the calendar in general, and the date of Easter in particular, and of course to solve various practical problems, but otherwise there was little interest in further research. Still, as a beginning of medieval education, the cathedral schools were important in preserving the role of mathematics, and Pope Sylvester II (999–1003) even began to introduce the Hindu-Arabic number system, as well as basic geometry and astronomy, in the cathedral school at Rheims (Katz 2009, pp. 325–327).

The twelfth century marked the high point of the Seven Liberal Arts in medieval education. Hugh of St. Victor, best known as the writer of an influential educational handbook for theology students, stressed the Seven Liberal Arts as appropriate for the liberated mind, calling them "the best instruments…for the mind's complete knowledge of philosophic truth" (Grant 1999a, p. 103). The celebrated cathedral school in Chartres, France, was marked by a Platonic orientation, and its chancellor, Thierry of Chartres, argued that the study of mathematics led directly to the knowledge of God (Grant 1999a, p. 104; McInerny 1983, pp. 254–255).

Yet though these educators knew that there was a great ancient tradition in mathematics, they did not know much about its substance. This situation changed with the flowering of translation activity in the twelfth century that has become known as the Twelfth-Century Renaissance (Haskins 1927). Europeans came to know about Greek works, mostly in their Arabic versions as studied in the Islamic world, through travel, contacts in southern Italy, and the European reconquest of parts of Spain. Because of the prestige of mathematics in the liberal arts tradition and also because of the importance of mathematics and astronomy and astrology for social and religious needs, major translators like Gerard of Cremona and Adelard of Bath assiduously searched for the principal works of men like Ptolemy and Euclid to translate from Arabic into Latin.

By the end of the twelfth century, major works of Greek mathematics and astronomy in their entirety, most of Aristotle's philosophy, and the books on algebra and arithmetic of Muḥammad ibn Mūsā al-Khwārizmī were all available in Latin. In the thirteenth century and beyond, with the rise of medieval universities, scholars worked to assimilate the expanded ancient traditions into medieval Christian culture. Aristotle in particular presented a sophisticated approach to philosophy and a range of subjects, from biology to metaphysics, that did not fit the old patterns. The new materials needed to be integrated with the old liberal arts as well as with Christian thought and practice.

Still, though the educational ideal may no longer have been the study of liberal arts for their own sake (McInerny 1983, pp. 248–9), many medieval thinkers from the thirteenth century on continued to value the traditional liberal arts, including mathematics, at least as stepping-stones to a religiously meaningful life. Thomas Aquinas (1225–1274) explicitly recognized the Seven Liberal Arts in general and mathematics in particular as "paths preparing the mind for the other philosophical disciplines," although he equally explicitly said that they were by no means sufficient for the Christian studying philosophy (Kimball, pp. 66–67; McInerny 1983, p. 251). Men like Roger Bacon (1214–1294) advocated mathematical instruction, saying that without mathematics "nothing of supreme moment can be known" in any other science – a more applied kind of mathematics, perhaps, but still seen as essential for learning (Grant 1999b, p. 199; Masi 1983, p. 151). Research in fields like geometrical optics, infinite series, and the graphing of variable magnitudes was undertaken in the fourteenth century by men like Robert Grosseteste, Richard Swineshead, and Bishop Nicole Oresme (Katz 2009, pp. 324–363).

However distinguished medieval mathematical research was, though, scholars of the Renaissance self-consciously reached back beyond it in their enthusiasm to revive the glories of the ancient mathematical traditions.

25.2.3 The Renaissance and After

The glories Renaissance thinkers saw themselves reviving included Plato as well as Aristotle and also included considerably more mathematics. Especially striking in light of what we now call the liberal arts is the use of geometry in perspective in painting, with men like Piero della Francesca, Leonardo da Vinci, and Albrecht Dürer highly proficient in both geometry and art (Field 1997). Also striking is the new mathematization of music, again based on supposed Greek models (Fauvel et al. 2003). And the ideal of the Renaissance man, competent in many areas of knowledge, foreshadows the modern idea of a well-rounded student with a general liberal education. In urban and court culture, liberal education was occasionally extended also to women (Cruz 1999, pp. 250, 252; Grendler 1989, pp. 93–102; Schiebinger 1989, p. 12).

One influential Renaissance educational theorist, Pier Paolo Vergerio, wrote a treatise in 1404 that emphasized the importance of liberal studies, encompassing history, moral philosophy, poetry, but also the traditional Seven Liberal Arts

(Cruz 1999, p. 243). Later on as artists became more prestigious, drawing and thus a bit of geometry became more important liberal subjects. What came to be called humanist education was linked both to Christian piety and to civic values and public service. It is true that Renaissance mathematical teaching was at first quite practical and carried out in the so-called abacus schools, but for many aristocrats such teaching was too closely associated with business and trade and too marked by rules of thumb. So in courts and in the households of the social elite, men of the stature of Luca Pacioli and Mauricio Commandino taught more theoretical mathematics, and courtly patrons of humanists included mathematicians at their courts as well (Rose 1975, p. 293). Influential humanist teachers like Vittorino da Feltre (1378–1446) of Mantua regarded mathematics as a crucial component of humanistic education, and he even included some women among his students (Cruz 1999, p. 251; Rose 1975, p. 16).

University mathematics teaching in Renaissance Italy used texts like Euclid, Sacrobosco's *Sphere*, Ptolemy's *Almagest*, and the Alphonsine astronomical tables (Marr 2011, pp. 62–64). And as the humanist curriculum expanded from Italy into France, England, and Germany, mathematics came with it (Cruz 1999, p. 249). In Germany, Philipp Melanchthon in the 1520s gave special emphasis to the place of mathematics and astronomy in the university curriculum (Cruz 1999, p. 240; Westman 1975, p. 170). Johann Sturm (1507–1589) in Strasbourg also went beyond grammar and rhetoric and Biblical texts in having his students study mathematics and science (Cruz 1999, p. 249).

Humanism was not the only impetus to expanding the teaching of liberal arts. There was a Catholic response to these new trends. In the mid-sixteenth century, the Jesuits begin to conduct schools, teaching not only grammar, philosophy, and theology but also mathematics, geography, history, and astronomy, often using original texts. Jesuit schools grew in number, importance, and influence; by 1600 there were 236 Jesuit colleges, some outside of Europe, and by 1750 there were 669 Jesuit colleges and 24 universities;[3] the Jesuits number Descartes, Voltaire, and Condorcet among their influential pupils. Mary Ward (1585–1645) established a network of humanist schools for girls patterned on the Jesuit model; by 1631 there were many such schools and hundreds of pupils, who were taught mathematics as well as Latin and Greek (Cruz 1999, pp. 252–253). Thus, the sixteenth century produced an educated elite, people who communicated and were grounded in a cultural heritage that transcended the boundaries of language, of gender, of region, and even the distinction between Protestant and Catholic. The liberal arts continued to be thought of as providing intellectual discipline, as well as teaching moral examples and civic duty.

Humanism's deep interest in rediscovering, translating, and circulating ancient Greek texts reinvigorated mathematics with new sophisticated sources. Indeed, Francesco Maurolico (1494–1575) spoke explicitly of a "renaissance of mathematics." This "renaissance" brought advanced mathematical texts – Archimedes, Pappus, Apollonius, and Diophantus – into European mathematics and also included a drive to restore parts of the text which had not survived (Rose 1975, p. 179). Such

---

[3] See Chapple (1993a, p. 7), Cesareo (1993, p. 17), Cruz (1999, p. 250), and Taton (1964).

attempts at restoration themselves became real mathematical research, like Descartes' and Fermat's reconstruction of works of Apollonius using modern algebraic methods, and, not so incidentally, developing analytic geometry. A similar example is found in Fermat's notes on Diophantus's *Arithmetica*, notes that jump-started modern number theory, including the conjecture now called Fermat's Last Theorem (Katz 2009, pp. 498–499; Rose 1975, p. 292). The mathematical Renaissance was embodied in universities, especially in Italy, and what was taught in those universities helped initiate the great achievements of mathematics and science in the seventeenth century (Grendler 2002, pp. 408–429).

In the seventeenth century, mathematics proved overwhelmingly successful in modeling the laws of the cosmos. The Newtonian idea that natural laws were the laws of God linked mathematics to Christianity. The new authority of mathematics led to its institutionalization in university education, as part of the intellectual heritage of any liberally educated man. And the success of what was billed as the new scientific method strengthened the philosophical and political ideas associated with the Enlightenment.

The eighteenth and nineteenth centuries saw an even greater role for mathematics as useful in warfare and statecraft but also as intellectual enrichment and discipline. Women as well as men participated in the latter category. The journal "Ladies' Diary," from 1704 to 1841, was dedicated to teaching women the mathematical sciences and contained problems and puzzles which were successfully solved by female readers (Schiebinger 1989, p. 41). Mathematics as intellectual enrichment and discipline is seen across the board in educational institutions as different as the universities designed to provide a gentleman's education like Oxford; Harvard and other early American colleges; Cambridge University, which since the late eighteenth century was dominated by the mathematical Tripos examination; and the German universities dedicated to pure research, together with their American followers like Johns Hopkins and the University of Chicago (Merz 1904, pp. 89–301; Rudolph 1962, pp. 244–286, 349–354). The liberal arts ideal in the colleges in the Colonial period of the United States helped inspire the founding of many small American colleges throughout the eighteenth and nineteenth centuries (Rudolph 1962, pp. 44–67).

Columbia College in 1919 pioneered requiring all freshmen to take a course called "Introduction to Contemporary Civilization in the West" based on the liberal arts. In the 1920s with the Progressive movement in America, colleges addressed anew the question of what a liberal arts college ought to be. Influential responses included Alexander Meiklejohn's "Experimental College" at the University of Wisconsin, which began with the study of Plato; the complete Great Books curriculum founded in the 1930s and still in force at St. John's College in Maryland; and the explicit classicism of Robert Maynard Hutchins and Mortimer Adler who in the 1930s began the Core Curriculum at the University of Chicago. With the advent of the Cold War between the United States and the Soviet Union, liberal arts education was promoted as developing the free and inquiring intellect in opposition to totalitarianism; this view was influentially expressed in the book *General Education in a Free Society: Report of the Harvard Committee* (1945). All these and their many followers explicitly intended to revive the ancient liberal arts tradition in twentieth-century society (Rudolph 1962).

As a result of all these trends, the ideal of general or liberal education, in opposition both to premature specialization and to vocationalism, continues to structure most university-level education in the United States today. The category "liberal arts colleges," listing hundreds of such schools, appears in almost all guidebooks to American higher education; for instance, the *U. S. News and World Report* list gives data on 266 such schools. Colleges of this type are being developed on the American model in other countries as well, including New York University in Abu Dhabi; Xing Wei College in Shanghai, China; Bard College's partner institutions in St. Petersburg, Russia, and in Berlin; Yale University in Singapore; and Smith Women's College in Malaysia. Quest University in British Columbia is Canada's first private liberal arts institution. And mathematics remains part of such liberal arts education.

As for pre-university education, teaching mathematics is almost universal. Although the prevalence of mathematical instruction may be in some part due to mathematics' place in the traditional liberal arts curriculum, many other justifications for its inclusion are given in the modern world: preparing students for the vastly increasing number of modern technical careers, helping students understand science and economics, aiding citizenship, and expanding and training the mind to take on any intellectual challenge.

Rarely, though, is teaching mathematics justified by saying that mathematics is and has always been at the heart of the disciplines we now identify as the liberal arts. Furthermore, in the past, "liberal arts" always designated an education for an elite. The study of the liberal arts in general, and mathematics as a liberal art in particular, was never extended to an entire citizenry. To educate modern citizens for a free society, though, this essay will argue that it is necessary to go beyond teaching mathematics solely as the prerequisite to something else.

Elsewhere the author has sketched the history of the central role mathematics has played in Western thought (Grabiner 1988, 2010). The reasons for that central role go far beyond simply following the pattern of traditional education. As will be shown in the next sections, that central role has been the result of two aspects of mathematics. One is that mathematics appears to provide truths, truths that can be proved. The other is that mathematical ideas work to produce knowledge of the world, in areas ranging from the arts to the study of nature. Philosophers of mathematics often call these aspects of mathematics "certainty" and "applicability." Historically, these aspects of mathematics have often been invoked as slogans by those advocating including mathematics in education. But the history goes far beyond slogans. Together, these two aspects of mathematics – certainty and applicability – explain and illuminate both how and why mathematics has been central throughout the history of the liberal arts. Demonstrating that central role throughout history justifies making mathematics a key part of liberal education in the world today. To see mathematics in this central role, we will look first at mathematics as a provider and exemplar of truth.

25.3 Mathematics, Truth, and Proof

25.3.1 The Greek Model

As in all of Western thought, one must begin with Plato and Aristotle. Plato said that the certainty of mathematics comes from the perfection of its subject matter. In the natural world, everything changes, comes into being, and passes away; the objects of mathematics, by contrast, are unchanging and eternal. Mathematics provides a model for Plato's philosophy of ideal Forms that transcend our changing experience: the idea of justice, the ideal state, and the idea of the Good. In the Western tradition, the common terms "certain" and "true" preserve Plato's belief in an unchanging transcendent reality, and Plato consistently argued for it using examples from mathematics. And, as discussed earlier, Plato decreed that the philosopher-ruler of his ideal *Republic* should study mathematics to be brought to the truth.

For Aristotle, though, the truth of mathematics comes more from its method than from its subject matter, since the results of mathematics can be demonstrated logically, proceeding from self-evident assumptions and clear definitions. Aristotle held that other subjects could also gain certainty if they could be put into the same form, the form of what he called a demonstrative science (Heath 1925, pp. 117–121; McKirahan 1992). Thus mathematics, especially Euclid's geometry, came to be seen as a model for much of scientific and philosophical reasoning. For instance, medieval theologians tried to demonstrate the existence of God from first principles. In 1675, Benedict Spinoza wrote an *Ethics Demonstrated in Geometrical Order* (Spinoza 1953), with explicitly labeled axioms and definitions, and including theorems like "God or substance consisting of infinite attributes … necessarily exists," whose proof he closes with the letters QED. Isaac Newton's great *Mathematical Principles of Natural Philosophy* of 1687 has the same definition-axiom-proof structure. Newton called his famous three laws of motion "axioms," and he labeled and proved the fundamental laws of his mechanics as theorems (Newton 1934).

The American *Declaration of Independence* is another example of an argument whose authors tried to inspire faith in its certainty by using the Euclidean form. "We hold these truths to be self-evident," the mathematically sophisticated author, Thomas Jefferson, began his argument, "that all men are created equal" (Becker 1922; Cohen 1995). Another self-evident truth in the *Declaration* is that if any government fails to secure human rights, it is the right of the people to alter or abolish it. The second section of the *Declaration* makes clear that this is a proof: it says that King George's government does not live up to the postulates, followed by the words "to *prove* this, let facts be submitted to a candid world" (Italics added). And the actual declaration of American independence is in fact the conclusion of an argument, so it begins with a "therefore": "We, *therefore* … declare, that these United Colonies are, and of right ought to be, free and independent states" (Italics added).

The same model of reasoning also pervades the law, and its mathematical antecedents are sometimes explicitly recognized. For instance, Christopher Columbus

Langdell, the pioneer of the case method in American legal education and Dean of Harvard Law School in the 1870s, was part of a long tradition that saw law as a science very much like geometry (Hoeflich 1986; Kalman 1986, p. 3; Seligman 1978). Law, according to Langdell, is governed by a consistent set of general principles. One gets these principles by looking at individual cases by induction, according to Langdell, in a manner reminiscent of Newton's *Principia.*[4] But once one has the general principles, one proceeds as in geometry. The correct legal rules are to be logically deduced from those general principles and then applied to produce the correct legal ruling in line with the facts of a particular case (LaPiana 1994, p. 3; Seligman 1978, p. 36). In the theory of law as in liberal arts like philosophy and the study of nature, the Euclidean model of reasoning has shaped conceptions of proof, truth, and certainty.

25.3.2 Symbols and Algorithms

The ability of mathematics to exemplify truth was not limited to geometry. Between the Renaissance and the eighteenth century, the paradigm governing mathematical research changed from a geometric one focused on proof to an algebraic and symbolic one. In algebra just as in Aristotle's view of demonstrative sciences like geometry, one can consider the method independently of the particular subject matter. The algebraic or algorithmic method in mathematics finds truths by manipulating symbols according to fixed rules. The algorithmic approach long preceded symbolic algebra, entering Europe in the Middle Ages.

Influential in developing the idea of "algorithm" was the twelfth-century Latin translation of a work on the Hindu-Arabic number system by the ninth-century mathematician Muḥammad ibn Mūsā al-Khwārizmī. This system is the base-10 place-value system now universally learned in school, and the new computational power it produced was enormous. Multiplication is relatively easy in a place-value system, since multiplying by 3 million is as simple as multiplying by 3. The rules for producing new truths involving these numbers, including rules not only for ordinary arithmetic but also for more intricate problems like taking square roots, were called the "method of al-Khwārizmī." Later his name became Latinized into Algorismus and then, perhaps by association with "arithmos" for number, into "Algorithmus," whence the modern term "algorithm" for any set of powerful rules that can be easily and mechanically applied. The algorithms used to calculate with the Hindu-Arabic numbers are now known to every schoolchild. Equally important, these algorithms were eventually seen as similar to the later manipulations of symbolic algebra.

---

[4] Distinguishing experimental philosophy from reasoning from arbitrary hypotheses, Newton wrote, "In this philosophy particular propositions are inferred from the phenomena, and afterwards rendered general by induction" (Newton 1934, p. 547). Once Newton had his general principles, his *Principia* could take the logical structure familiar from Euclid's *Elements*.

The Arabic word “algebra,” derived from the Arabic title of another book by al-Khwārizmī, *Kitāb al-jabr wa l-muqābala*,[5] the first Arabic-language treatise on algebra, at first designated the systematic study of the processes of solving equations, with the equations expressed in words. But the word “algebra” today first brings algebraic symbolism to mind. In the 1590s, François Viète systematically developed and exploited general symbolic notation much like that used currently (Klein 1968; Struik 1969, pp. 74–81). This now familiar invention has the power to produce abstract, general truths in mathematics. For instance, given any pair of distinct numbers, say, *7* and *9*, schoolchildren are taught that not only does $7+9=16$, so does $9+7$. There are of course infinitely many such examples. Viète’s general symbolic notation for the first time allows the writing down of the infinite number of such facts all at once:

$$B+C=C+B.$$

A century later, Isaac Newton summed up the power and generality of Viète’s innovation by calling algebra “universal arithmetic.” Newton meant that we could derive and prove general algebraic truths from the universal validity of the symbolic manipulations that obey the laws of ordinary arithmetic.

More can be learned from a less trivial example than adding two numbers. First consider the quadratic equation

$$2x^2-11x+14=0.$$

Imagine being told, “*2* and *3 ½* are the solutions.” But being given these solutions provides no information about how those answers were obtained. However, with general symbolic notation, it is clear that *every* quadratic equation has the form

$$ax^2+bx+c=0,$$

where a is any nonzero real number and b and c can be any real numbers.

Solving the *general* equation by the algebraic technique of completing the square gives the general solution, the well-known quadratic formula:

$$x=\left[-b\pm\sqrt{\left(b^2-4ac\right)}\right]/2a.$$

Unlike the numbers *2* and *3 ½* in the original example, numbers which could have been produced by many possible arithmetic operations, each term in the general solution reveals the way it was produced; for instance, the term ac was

---

[5] Khwārizmī’s title can be translated as “the book of restoring and balancing,” where the Arabic “al-jabr” or “restoring” was interpreted as adding the same thing to both sides of an equation and “al-muqabala” or “balancing” the subtraction of the same quantity from both sides of an equation (Berggren 1986, p. 7). The sense of “al-jabr” as “restoring” remains in Spanish, where, for instance, in *Don Quixote*, Part II, Chap. XV, a bonesetter is an “*algebrista*” (Merzbach and Boyer 2011, p. 207).

produced by multiplying the coefficients a and c. Thus, the general solution to the quadratic equation preserves the record of every operation performed on the coefficients to find that solution. In the original example, $a = 2$, $b = -11$, $c = 14$, so it is now apparent how the answers *2* and *3 ½* were obtained from the coefficients in the equation. More important, the process of finding the solutions by completing the square proves in general that these and only these are the solutions.

Recognizing the generality and problem-solving power of symbolic algebra, in the 1630s René Descartes and Pierre de Fermat, working independently, combined the method of geometry and proof with the method of symbolic algebra into a new subject, analytic geometry. Problems in geometry, Descartes said, could be solved by translating geometric relationships into algebraic expressions, manipulating the algebraic expressions according to the rules of algebra, and translating the results of these manipulations back into the geometric solution of the original problem. He and Fermat, using the insight that problems could be translated back and forth between algebra and geometry, solved a range of previously intractable problems, and Fermat, in his geometric work, anticipated some of the discoveries of the calculus (Boyer 1956; Mahoney 1973).

Furthermore, Descartes' success in devising a new method for solving problems that had stumped the ancient Greek geometers helped him conclude that "method" was the key to all progress. When he theorized about this in his *Discourse on Method*, though, he drew on the structure of Euclidean geometry as well as that of algebra. He argued that the method of making discoveries begins with analyzing the whole into the correct "elements" from which truths could later be deduced. "The first rule," he wrote in the *Discourse*, "was never to accept anything as true unless I recognized it to be evidently such."

The second rule "was to divide each of the difficulties which I encountered into as many parts as possible, and as might be required for an easier solution…." Then, "the third rule was to [start] … with the things which were simplest and build up gradually toward more complex knowledge" (Descartes 1637a, Part II, p. 12). A mathematical example, from Descartes' *La Géometrie* (Descartes 1637b), is building up a polynomial from a set of linear factors, making visible the truth that a polynomial equation has as many roots as the polynomial's highest degree. Descartes' rules in the *Discourse* mirror his "rules of reasoning in philosophy" and are part of a long tradition of arguing by means of analysis and synthesis (Gaukroger 1995, pp. 114, 124–126, 180). But later thinkers took Descartes himself as a starting point, considering him "the figure who stands at the beginning of modern philosophy" (Gaukroger 1995, p. vii), and his influence on subsequent philosophy, from Locke's empiricism to Sartre's existentialism, has been enormous. For the purposes of this essay, the key point is the large debt Descartes' philosophical views about method owe to his ideas about mathematics.

Later on in the seventeenth century, Gottfried Wilhelm Leibniz was so inspired by the power of algebraic notation to simultaneously make and prove mathematical discoveries that he invented an analogous notation for his new differential calculus. Leibniz's dy/dx and $\int y dx$ notation is still prized and used because of its heuristic power. In fact what Leibniz meant by choosing the term "calculus" was that he had invented a set of algorithms for operating with the differential operator *d* (Leibniz 1969). Furthermore, Leibniz envisioned an even more general symbolic language that would be able to establish the indisputable truth in all areas of human thought. Once there was such a symbolism, which Leibniz called a "universal characteristic," he predicted that if two people were to disagree, one could say to the other, "let us calculate, sir!" and the disagreement would be resolved (Leibniz 1951). These ideas of Leibniz make him a pioneer in what has become the modern philosophical discipline of symbolic logic.

Other seventeenth-century thinkers also pointed out the algorithmic and mechanical nature of thought. For instance, Thomas Hobbes wrote, "Words are wise men's counters, they do but reckon by them" (Hobbes 1939, Chap. 4, p. 143). By the eighteenth century, not only did many mathematicians think that discovery and proof should be based on abstract symbolic reasoning but prized such reasoning above intuition and geometry. For instance, in 1788 Joseph-Louis Lagrange wrote his *Analytical Mechanics* with no diagrams whatsoever. Other scientists inspired by this ideal introduced analogous heuristically powerful notations in their own fields. For instance, Antoine Lavoisier and Claude-Louis Berthollet developed a new chemical notation that Lavoisier called a "chemical algebra" (Gillispie 1960, p. 245). Anyone who has ever balanced a chemical equation has benefited from their innovation.

The success of these ideas about symbolism, both within and beyond mathematics, led the Marquis de Condorcet to write that algebra "contains within it the principles of a universal instrument, applicable to all combinations of ideas" and to go so far as to say that the general algebraic method could "make the progress of every subject embraced by human intelligence… as sure as that of mathematics" (Condorcet 1793, p. 238; pp. 278–279). He used these ideas to support his central thesis that "the progress of the mathematical and physical sciences reveals an immense horizon … a revolution in the destinies of the human race" (Condorcet 1793, p. 237). Here his view epitomizes the Enlightenment idea of progress in its clearest form. In the nineteenth century, George Boole produced the first modern system of symbolic logic and used it to analyze a wide variety of complicated arguments (Boole 1854). His system, developed further, underlies the logic used by digital computers today, including applications ranging from automated theorem-proving to translators, grammar checkers, and search engines, approaching a full embodiment of Condorcet's dream of the algebraic method embracing every subject.

25.3.3 The Method of Analysis

The second rule in Descartes' *Discourse on Method*, the idea of divide and conquer, fits beautifully with the Greek atomic theory, which had just been revived in the seventeenth century. If all matter is made up of small particles, one could analyze the properties of the whole on the basis of the properties of the parts. This idea became central to both chemistry and physics, and indeed still is. Familiarity with these ideas also permeates art and literature, in examples as different as the nineteenth-century pointillism of Georges Seurat and the conclusion of the poem "Mock on, mock on, Voltaire, Rousseau" by William Blake (1757–1827):

> The Atoms of Democritus
> And Newton's Particles of Light
> Are sands upon the Red Sea shore,
> Where Israel's tents do shine so bright.

Another line of influence of Descartes' divide-and-conquer method can be seen in economics, notably in Adam Smith's 1776 *Wealth of Nations.* Smith analyzed the competitive success of economic systems by using the concept of division of labor. He explained how the separate elements of the economy, with each one acting as efficiently as possible, combine to produce the economic system's overall prosperity. Famously, Smith said that each individual in the economy, while consciously pursuing only his individual advantage, is "led as if by an Invisible Hand to promote ends which were not part of his original intention" (Smith 1974, p. 271), the optimal outcome for the entire society.

In France after the Revolution came another application of the divide-and-conquer method, inspired directly by Smith's views. Gaspard François de Prony had the job of calculating a set of logarithmic and trigonometric tables. He undertook to do this by applying Smith's idea about the division of labor. Prony described a hierarchical divide-and-conquer system to produce the tables. First, mathematicians decide which functions to use; then, technicians reduce the job of calculating the functions to a set of simple additions and subtractions of preassigned numbers; and finally, a large number of low-level human "calculators" carry out the actual additions and subtractions.

In England, Charles Babbage took Prony's analysis of large-scale mathematical calculation and embodied it in a machine, the first digital computer ever conceived (Hyman 1982). Babbage described the basic idea in a chapter elegantly called "On the Division of Mental Labour" (Babbage 1832, Chap. XIX). Mathematicians were to decide what the machine would do and with what numbers it would do it, and then a machine could carry out the low-level task of performing the additions and subtractions. Babbage was a follower of Leibniz's views on the power of notation to make mathematical calculation mechanical. So, the first modern computer owes much both to the analytical method that Descartes promoted and to Leibniz's ideas about algorithms.

25.4 Mathematics Versus Skepticism

The fact that there is a subject, mathematics, which seems to be able to find irrefutable truth, has been philosophically powerful in other ways than those so far described. Since the existence of mathematics supports the conclusion that some sort of knowledge truly exists, the success of mathematics has long been used as a weapon against skepticism. For instance, Plato, going beyond his teacher Socrates' critical method, used mathematical examples repeatedly to show that learning and knowledge were possible. In the 1780s, Immanuel Kant used the example of Euclidean geometry to show that there could indeed be non-tautological knowledge that is independent of sense experience and thus argued that metaphysics, skeptics like David Hume to the contrary, is also possible (Kant 1950; Kant 1961). This same point – that mathematics is knowledge, so that objective truth does exist – is convincingly conveyed when Winston Smith, the protagonist in George Orwell's novel *1984*, heroically asserts, in the face of the totalitarian state's overwhelming power over the human intellect, that two and two are four.[6]

Another way that mathematics, as an example of certain knowledge, has challenged skepticism is by providing an answer to what has been called the problem of the criterion (Popkin 1979). If all sides to a controversy seem to disagree, what is the criterion by which the true answer can be recognized? Of course, if there were only one system of thought available, people might well accept it as true, a situation somewhat like the status of Roman Catholicism in the Middle Ages. But the Reformation presented alternative religious systems, the Renaissance revived the thought of pagan antiquity, and Cartesianism and the new science of the seventeenth century provided further challenges. Now finding a criterion that could identify the true system seemed urgent. But mathematics seemed to have solved this problem.

What, then, asked philosophers, was the sign of the certainty of the conclusions of mathematics? The fact that nobody disputed them. So the criterion of truth, many seventeenth- and eighteenth-century thinkers concluded, was universal agreement. Voltaire elegantly summed up this conclusion when he wrote, "There are no sects in geometry. One does not speak of a Euclidean, an Archimedean" (Voltaire 1901a, c). What every reasonable person agrees upon, that is the truth. Applying this to religion, Voltaire observed that some religions forbid eating beef, some forbid eating pork; therefore, since they disagree, they both are wrong. But, he continued, all religions agree that one should worship God and be just; that must therefore be true. Applying the same idea to ethics, Voltaire said, "There is but one morality… as there is but one geometry" (Voltaire 1901a, b).

25.5 Mathematics and Its Applications

But mathematics is more than an exemplar of truth and certainty; it also works in the world, not only the world of engineers and bankers but the world of the liberal arts as well. But why should mathematics apply to the world at all? For Plato, it is because this world is an approximation to the higher mathematical reality. For Aristotle, on the other hand, mathematical objects are abstracted from the physical world by the intellect. Later empiricists, such as John Stuart Mill, have agreed with Aristotle. However, since mathematical ideas often are applied to situations

---

[6] The point will be clearer with a fuller quotation: "With the feeling…that he was setting forth an important axiom, he wrote: *Freedom is the freedom to say that two plus two make four. If that is granted, all else follows"* (Orwell 1949, p. 81; his italics).

quite different from those in which they arose, the empiricist answer seems insufficient. In any case, Plato's answer has wielded great influence.

25.5.1 Mathematics and Nature

From the ancient Pythagoreans onward, many thinkers have looked for the mathematical reality beyond the appearances. In the sixteenth and seventeenth centuries, Copernicus, Kepler, Galileo, and Newton looked for that mathematical reality – and found it in the laws that govern the physics of motion and the behavior of bodies in the solar system. The Newtonian world-system that completed the Copernican revolution was embodied in a mathematical model, based on the laws of motion and inverse-square gravitation, and set in Platonically absolute space and time (Cohen 1980, pp. 63–67; Newton 1934, pp. 6–9). The success of Newton's physics not only strongly reinforced the view that mathematics was the right language for science but also strongly reinforced the emerging ideas of progress and of truth based on universal agreement.

These successes engendered important theological and philosophical implications. The mathematical perfection of the solar system could not have come about by chance, argued Newton. The cause of this perfection had to be an intelligent designer, God, who chose to create the universe in a pattern so well suited to humanity. The search for other examples of design and adaptation in nature inspired considerable research in natural history, especially on adaptation, and this research was an essential prerequisite to Darwin's discovery of a nontheological explanation for this adaptation: evolution by natural selection.

25.5.2 Mathematics and the Arts

Other examples of the uses of mathematics come from the arts. The mathematical theories that underlie music began with the Pythagoreans and have continued since, revived and expanded upon beginning in the Renaissance. The modern study of pitch, intensity of sound, meter, and the psychology and physiology of hearing, to say nothing of the technologies of musical reproduction, all have a sophisticated mathematical basis.[7]

The same is true of the visual arts. In the Renaissance, stimulated by the rediscovery of Euclid's geometrical work on optics, painters used geometry to give the viewer the visual sense of three dimensions. Several Renaissance artists did original work in geometry, notably Piero della Francesca (1410–1492) and Albrecht Dürer (1471–1528). Piero's *De prospectiva pingendi*, the first mathematical treatise on

---

[7] (Fauvel et al. 2003; Field 2003; Helmholtz 1954; Karp 1983; Jeans 1956; Newman 1956, pp. 2278–2309 Wardhaugh 2009; Wollenberg 2003)

perspective for painting, showed geometrically how to depict objects in three dimensions, viewed from a particular standpoint, on the picture plane. Dürer's *Underweysung der Messung* of 1525, the first geometric text written in German, included applications of geometry to constructing regular polygons and polyhedra, to architecture, and to typography, and Dürer was the first to show how to project three-dimensional curves onto two perpendicular planes. The work of these artist-mathematicians helped direct attention to many of the key ideas of what, in the seventeenth-century work of Girard Desargues and Blaise Pascal, became the new mathematical subject of projective geometry (Field 1997; Kemp 1990).

25.5.3 Optimization

An especially striking example of mathematical applicability, which links mathematics with science, philosophy, and theology, is given by the history of optimization. The use of optimal principles to explain the world goes back at least to the first century CE when Heron of Alexandria showed that the law of equal-angle reflection of light minimizes the distance the light travels. In the seventeenth century, Fermat showed that Snell's law of the refraction of light minimized what Fermat called the light's "path" (distance times resistance), which, since he assumed that velocity varies inversely with resistance, is mathematically equivalent to saying that light follows the path that minimizes its time of travel (Mahoney 1973, p. 65, pp. 382–390).

Leibniz, using his newly discovered calculus, produced algorithms for finding maxima and minima and applied them to elegantly re-derive Fermat's result (Leibniz 1969; Struik 1969, pp. 278–279). In his philosophy, Leibniz argued that the universe itself is constructed by God according to optimal principles. For Leibniz, a possible world is one consistent with the laws of logic; those possible worlds with more different beings in them are better than the others, and our world is the best of all possible worlds because it is the one in which the total of existing things is maximized (Lovejoy 1936, pp. 50, 144–146, 173).

In the eighteenth century, Colin Maclaurin, when aged sixteen, used the calculus, and some theological assumptions about eternal life, to argue that the Christian doctrine of salvation maximizes the future happiness of good men (Maclaurin 1714; Tweddle 2008). This argument applied the same methods many mathematicians used to apply the principle of least action in physics, as well as to design the most efficient windmills and waterwheels. Maclaurin's classmate at Glasgow, the philosopher Francis Hutcheson, used the same idea of mathematical optimization to demonstrate his laws of virtue. For instance, Hutcheson wrote in 1728, "That Action is best, which procures the greatest Happiness for the greatest Numbers" (Hutcheson 2004, Sect. III, p. 177). Later on, a similar approach is found in the utilitarianism of Jeremy Bentham, embodied in the famous phrase "the greatest good for the greatest number."

This line of reasoning recalls the ideas of Adam Smith, who had been a student of Hutcheson's at Glasgow. In words resembling Hutcheson's, Smith influentially wrote, “Upon equal…profits…every individual naturally inclines to employ his capital in the manner in which it is likely to afford the greatest support to domestic industry, and to give revenue and employment to the greatest number of people of his own country” (Smith 1974, Book IV, Chap. II). From Smith’s work, a set of ideas common not only to mathematics but also to philosophy and theology has entered the vocabulary of the most hardheaded of economists.

25.5.4 The Social Sciences

Just as the example of mathematical truth made finding truth elsewhere seem possible, so the examples of applying mathematics to natural science inspired those seeking to perfect other disciplines. This was especially true for the early nineteenth-century pioneers of the social sciences, Auguste Comte and Adolphe Quetelet. Both men knew their science, Comte having been influenced principally by Lagrange, Quetelet by Pierre-Simon Laplace. Lagrange’s *Analytical Mechanics* of 1788 had claimed to reduce all of mechanics to mathematics. Comte went further: if physics was built on mathematics, so was chemistry built on physics, biology on chemistry, psychology on biology, and finally his own new creation, *sociology* (a term Comte coined) would be built on psychology (Comte 1830, Chap. 11).

Comte said that science had once been theological, invoking God, then metaphysical, invoking general philosophical principles, but now science, including social science, would be based only on observed connections between things, a stage of science he called “positive,” stimulating the beginning of the philosophical stance called positivism. Comte’s philosophy, owing much to mathematical physics, influenced not only twentieth-century logical positivism but also the views on science and history held by Ludwig Feuerbach (1804–1872) and Karl Marx.

Still, Comte did not develop a quantitative social science. Here the prime mover was Quetelet, for whom the applicability of mathematics was crucial. “We can judge of the perfection to which a science has come,” he wrote in 1828, “by the ease with which it can be approached by calculation” (Quetelet 1828, p. 233). Quetelet was especially impressed by Laplace’s use of the normal curve of errors to determine planetary orbits from observations. Quetelet found empirically that not only the distribution of measurement errors but also the distribution of many human traits, including height and chest circumference, gave rise to the same normal curve. From this, he defined the statistical concept and the term, “average man” *(homme moyen)* (Porter 1986, p. 52). These ideas are essential to modern social science.

25.5.5 Freedom and Determinism

Quetelet observed also that many social statistics, such as the number of suicides in Belgium, produced roughly the same figures every year. One might think that crimes are the result of free individual choice. But the constancy of these rates over time, he argued, suggests that murder or suicide has constant social causes. Quetelet's discovery of the constancy of crime rates raised an important philosophical question: Is human behavior determined by social laws, as he seemed to think, or are we free to choose our fate?

Laplace, even though he needed probability to do physics, did not believe that the laws governing the universe were ultimately statistical. Since the true causes are not yet known, Laplace said, people believe that events in the universe depend on chance. But in fact everything is determined. To an intelligence which knew all the forces in nature and the exact situation of the beings that composed it, said Laplace, "nothing would be uncertain" (Laplace 1951, Chap. II).

Later in the nineteenth century, though, the mathematical physicist James Clerk Maxwell, in his work on the statistical mechanics of gases, argued that statistical regularities in the large reveal nothing at all about the behavior of any individual. Maxwell cared about this point because it allowed for free will. Maxwell considered such issues not just because of physics but because he had read and pondered the work of Quetelet on the application of statistical thinking to society (Porter 1986, pp. 118–119). A similar dispute about the meaning of probabilistically stated laws has arisen in modern debates over the foundations of quantum mechanics.

So, discussions of basic philosophical and theological questions like "is the universe an accident or a divine design?" for Newton and Leibniz, "is there free will or are we all programmed?" for Quetelet and Maxwell, or "are the laws of nature ultimately statistical?" for Laplace, Maxwell, Bohr, and Einstein owe much to questions about the applicability of mathematics to the world and to society.

25.6 When "Mathematics as Universal Truth" Fails

So far, although the people discussed have disagreed about philosophical matters, they have not argued about the essential truth of mathematics itself. However, universal agreement about mathematics and its relationship to the natural and social worlds did not survive the nineteenth century, and the older ideas of universal mathematical truth and the consequent universal agreement have had an interesting trajectory since then. To sketch this trajectory, one must ask what happened to the rest of thought when the very nature of mathematics and its relationship to the world seemed to change. The place to begin is with the overturning of the long-held view that there is only one geometry.

25.6.1 Questioning Euclidean Geometry

Since the time of Euclid, mathematicians had viewed his Fifth Postulate as considerably less self-evident than the others. Although Euclid's postulate is sometimes called the “Parallel Postulate,” it does not mention parallel lines at all. Instead of the more intuitive postulate “Only one parallel to a given line can be drawn through an outside point” that one finds in many high-school texts today, Euclid’s Fifth Postulate was this assumption: “That, if a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which are the angles less than the two right angles” (Euclid, *Elements* 1925, Postulate 5; Heath 1925, p. 202).

Over many years since Euclid, mathematicians thought that the postulate should not be assumed but proved. When mathematicians tried to prove it from Euclid’s other postulates by indirect proof, they deduced a variety of surprising “absurd” consequences from denying Postulate 5. Among the consequences of denying the postulate are “parallel lines are not everywhere equidistant” and “there can be more than one parallel to a given line through an outside point.” In the early nineteenth century, Carl Friedrich Gauss, Janos Bolyai, and Nikolai Ivanovich Lobachevsky each separately recognized that these consequences were not absurd at all, but rather were valid results in a different, equally consistent geometry (Gray 1989, pp. 86–90, 106–124). Gauss chose an appropriate name for the new geometry: non-Euclidean (Bonola 1955, p. 67).

Kant had said that space (by which he meant the only space he knew, Newton’s three-dimensional Euclidean space) was the form of all our perceptions of objects, a unique intuition of the mind in which we must order these perceptions (Friedman 1992; Kant 1961). But what, then, can be said about non-Euclidean space? The nineteenth-century psychologist and physicist Hermann von Helmholtz asked whether Kant might be wrong. Could we imagine ordering our perceptions in a non-Euclidean space? Yes, Helmholtz said, if we consider the world as reflected in a convex mirror (Helmholtz 1962, pp. 240–241). The reader can do this by consulting M. C. Escher’s famous drawing “Hand with Reflecting Sphere” or by using a car’s side mirror that carries an explicit warning that the space we see in it is not Euclidean. In the convex mirror, parallel lines, defined by Euclid as lines on the same surface that do not meet, are no longer seen as equidistant.

Now the philosophy of mathematics as universal truth was under attack. Euclidean and non-Euclidean geometry give the first clear-cut historical example of two mutually contradictory mathematical systems, of which at most one can actually represent the world. This suggests that mathematical axioms are not self-evident truths related to the world at all, but may be, as Helmholtz argued, empirically based. Our idea of space is gained through sight and through touch. Two-dimensional beings living on a visibly curved surface, said Helmholtz, would invent a non-Euclidean geometry. So, Kant to the contrary, our idea of space is not unique, let alone necessarily Euclidean. To a non-empiricist, our ideas of space may even be intellectually free creations.

Inspired by Helmholtz’s philosophy of geometry, the English mathematician and philosopher William Kingdon Clifford (1845–1879) discussed the matter in the broadest possible historical and philosophical context. Clifford said, “It used to be that the aim of every scientific student of every subject was to bring his knowledge of that subject into a form as perfect as that which geometry had attained." But no more. "What Copernicus was to Ptolemy," Clifford wrote, "so was Lobachevsky to Euclid" (Clifford 1956, pp. 552–553). Before Copernicus, said Clifford, people thought they knew everything about the entire universe. Now, Clifford stated, we know that we know only one small piece of the universe. The situation is similar in geometry.

Before non-Euclidean geometry, the laws of space and motion implied an infinite space and infinite time, whose properties were always the same, so we knew what is infinitely far away just as well as we knew the geometry in this room. Lobachevsky has taken this away from us, said Clifford. That space is flat and continuous is true just as far as we can explore, and no farther. Speaking statistically about our experience of space, Clifford continued, "If the property of elementary flatness exists on the average, the deviations from it being too small for us to perceive, we would have exactly the conceptions of space that we have now" (Clifford 1956, p. 566). So Clifford, using non-Euclidean geometry, drew conclusions similar to those of the philosophers and scientists who concluded that the laws of nature were ultimately statistical. In fact, Clifford used his ideas to attack the entire Newtonian philosophy of science, especially singling out Newton's idea that human beings can have a universal theory of gravitation that applies to all bodies whatsoever.

Another perspective on these questions about geometry came from the great French mathematician, physicist, and philosopher of science Henri Poincaré (1854–1912), who disagreed both with Kant and with Helmholtz. If, as Helmholtz said, geometry were an empirical science, it would not be an exact science but would be subjected to continual revision. Poincaré of course knew about non-Euclidean geometry, so he knew that we have more than one space in our minds. From this he concluded that geometrical axioms are neither synthetic a priori intuitions (as Kant had said) nor experimental facts (as Helmholtz said). Geometrical axioms, said Poincaré, are conventions. So which set of axioms should be used in geometry? Poincaré said that, as long as we avoid contradictions, "our choice among all possible conventions may be guided by experience, but our choice remains free." The axioms of geometry are really only definitions in disguise. And Poincaré concluded, "What are we to think of the question: Is Euclidean geometry true? The question has no meaning. We might as well ask if the metric system is true, and the old weights and measures are false. One geometry cannot be more true than another; it can only be more convenient" (Poincaré 1952, p. 50). This very modern conclusion might shock Plato and Newton, but makes clear how revolutionary non-Euclidean geometry was for fields outside of mathematics.

The power of the Euclidean model, of course, did not die. Some influential thinkers stood by him. For instance, the famous English economist William Stanley Jevons (1835–1882) thought that Plato was right and Helmholtz was wrong. Transcendental or necessary truth, according to Jevons, is not produced by experience; it is recognized rather than learned (Richards 1988, pp. 87–90). The great English algebraist Arthur Cayley (1821–1895) was also not convinced by Helmholtz's argument that two-dimensional beings living on an obviously curved surface would invent a geometry describing such a curved surface. Cayley said that those beings would in fact invent three-dimensional Euclidean geometry. It would be, he said, “a true system” applied to “an ideal space, not the space of their experience” (Richards 1988, p. 90). And the Dutch philosopher J. P. N. Land thought that Helmholtz’s convex-mirror experiment proved nothing, saying in 1877 that the world in the mirror requires practice to interpret in a Euclidean way, but we can learn to do it (Richards 1988, pp. 100–101).

Nevertheless, Clifford’s views seemed to fit better with the increasingly empirical nature of nineteenth-century natural science. Popularizers of natural science like the physicist John Tyndall (1820–1893) and the Darwinian paleontologist Thomas Henry Huxley (1825–1895) insisted that people can only claim to know the information received through the senses. And transcendental realities, say Tyndall and Huxley, contrary to Plato and Kant, are both unknown and unknowable (Richards 1988, pp. 104–105). For Clifford and Helmholtz, this unknowability applied to space; for the agnostic Huxley, it applied to God.

The conclusions drawn from the existence of non-Euclidean geometries had a counterpart in nineteenth-century algebra. William Rowan Hamilton devised a noncommutative algebraic system, the quaternions, a system in which the product of two elements *ab* is not necessarily equal to the product *ba*. Discoveries like this led mathematicians increasingly to view their subject as a purely formal structure. Algebra was not the general science of number, any more than geometry was the science of space. Mathematics is nothing more than, as the American algebraist Benjamin Peirce put it in 1870, “the science that draws necessary conclusions” (Peirce 1881). The world is no longer, as Plato had thought, an imperfect model of the true mathematical reality. Instead, mathematics provides a set of different intellectual models, which can, but need not, apply to the one empirical reality. The sciences now merely model reality; they no longer claim to speak directly about it. Kurt Gödel applied this view to mathematics itself, using a formal model of mathematical reasoning to prove the surprising result that the consistency of mathematics cannot be demonstrated. Now a philosopher could say that there is no certainty anywhere, not even in mathematics (Barrett 1958, p. 206).

25.6.2 Space and the Social Sciences

Yet the widespread applicability of mathematics to the world meant that the new geometrical ideas would immediately become involved in still other debates, notably in the social sciences and the arts. As the example of Helmholtz indicates, one place where geometry has interacted with social science is in the psychology of perception. Even before the birth of non-Euclidean geometry, Bishop Berkeley and Thomas Reid had pointed out that we do not really see distance; we merely infer distance from the angles that we do see. Consider, for instance, looking upward at the corner in a rectangular room where the ceiling meets the walls. This is perceived as a place where three 90° angles come together. But if one measures the individual angles as they actually appear and are projected onto the viewer's retina, each of the angles is greater than 90° and together they add up to 360°. Our visual space is not the same as the space we claim we see.

And humans do not see parallel lines well either. Helmholtz did an experiment where he asked people in a dark room to put little points of light that got progressively farther away into two lines that always maintained the same distance from each other – that is, parallel lines. But the lines these people made out of these points of light turned out to curve away from the observer. Experiments like these have led psychologists to conclude that visual space is not represented by any consistent geometry (Wagner 2006).

Social scientists have also investigated the Kantian-influenced idea that spatial categories in language are direct projections of humanity's shared innate conceptual categories. As the cultural linguist Stephen Levinson has documented, the evidence suggests otherwise (Levinson 1996; Levinson 2003). In both language and concepts, people in different cultures have other ways of ordering their perceptions than in Euclidean space. For instance, particular directions may have special connotations, and "closeness" can be cultural as well as metrical. Further, some cultures, Levinson reports, use the idea of a fixed coordinate system, having four cardinal directions and referring locations to those, as one does in saying, "the house is north of the tree." But other cultures' concepts are more like Leibniz's idea of space in which there is no absolute space, just the relations between objects, including the observer. This is what one does in saying, "the house is to the left of the tree." No coordinate system is needed. One's perceptions can also be organized by letting the intrinsic properties of an object define the spatial location, as when one says, "The house is on the mossy side of the tree." Some cultures strongly emphasize only one of these methods of ordering objects in space, while others use a variety of these methods (Levinson 1996, pp. 140–145; Levinson 2003, pp. 31–39). There is no universal agreement here.

In modern society, directions can be given by saying, "Go north for five miles, then turn east for two miles," but also by saying, "Keep going straight until you get to the traffic light, and then turn right until you reach the supermarket." The second method, the way GPS systems give directions, follows Leibniz's relational view of space. In fact, GPS navigational systems are changing people's supposedly innate and universal intuitions of space. A Maryland cabdriver who recently bought a GPS told the author, "I used to have the whole geography of greater Baltimore in my head. I don't any more. I think about each trip as, drive to such-and-such exit, then make two right terms, one left turn. And when I leave you off, to get back to the expressway I'll just reverse that – one right turn, then two left turns. I will get back, but I won't know where I've been." Kant's view of Euclidean space as the unique form of all possible perceptions common to all human minds is subject to challenge from psychology and linguistics as well as from philosophy.

25.6.3 Space, Philosophy, and Art

Using both non-Euclidean geometry and relativity, the Spanish thinker José Ortega y Gasset (1883–1955) drew revolutionary cultural and political conclusions in order to refute what he called the “dogmatisms” of absolutism, provincialism, utopianism, and rationalism (Ortega 1968; Williams 1968, pp. 148–157). All absolutisms are wrong, said Ortega, whether in geometry, physics, or philosophy; reality, he said, is relative. Provincialism incorrectly assumes that our own experience or values are universal. Like Clifford, Ortega said that Euclidean geometry was provincial, an unwarranted extrapolation of what was locally observed to the whole universe. Instead, argued Ortega, reality organizes itself to be visible from all viewpoints, and Einstein’s theory of relativity, which requires new geometries of space-time, promotes the harmonious multiplicity of all possible points of view. Thus, all cultures have valid points of view. There is a Chinese perspective, Ortega said, that is “fully as justified as the Western” (Williams 1968, p. 152).

The last two of Ortega’s dogmatisms, utopianism and rationalism, are linked and again are both wrong. Since the Greeks, Ortega said, reason has tried to build an idealized world and say, this is true, this is how it is. Before relativity theory, Hendrik Lorentz (1853–1928) had said that matter must get smaller as it goes faster; that is, said Ortega, matter yields so that the old laws of physics can continue to hold. But Einstein said instead, “Space yields. Geometry must yield, space itself must curve.” According to Ortega, Lorentz might say, “nations may perish, but we will keep our principles,” but Einstein would reply, “We must look for such principles as will preserve nations, because that is what principles are for” (Williams 1968, p. 155).

In another example of radical thinking facilitated by new views of geometry, the surrealist theorist Gaston Bachelard wrote an essay attacking both reason and logic. Bachelard advocated restoring reason to its true function, which is not to shore up the agreed-upon order; instead, as the new geometries show, reason is “a turbulent aggression” (Henderson 1983, p. 346). The Russian thinker P. D. Ouspensky not only attacked the limitations of three-dimensional space, which he identified with Euclidean geometry, but also declared, “A is both A and not-A,” and “*Everything* is both A and not-A” (Henderson 1983, p. 253), an explicit repudiation of Aristotle and of all deductive logic. More recently, the French cultural theorist Jean Baudrillard applied these ideas about geometry to refute what was left of the eighteenth-century idea of progress, writing, “In the Euclidean space of history, the fastest route from one point to another is a straight line, the one of Progress and Democracy. This, however, only pertains to the linear space of the Enlightenment. In our non-Euclidean space of the end of the twentieth century, a malevolent curvature invincibly reroutes all trajectories” (Baudrillard 1994).

Modern artists and theorists of art alike were excited by the idea of new geometries. Artists often equated non-Euclidean geometry with the fourth dimension, since both seemed to attack the conventional Euclidean norms. The revolutionary role of the new geometries in art was aided by writers both from literature and psychology. For instance, in 1884 Edwin Abbott wrote a book popularizing the fourth dimension called *Flatland* (Abbott 1953; Abbott 2010). In the country of Flatland, everybody lives on a two-dimensional plane. Abbott's two-dimensional beings are visited by a sphere, which comes from the third dimension. But the Flatlanders cannot conceive of the sphere. They interpret the sphere's intersections with the plane as merely a succession of circles. The problem the Flatlanders have in imagining the third dimension, according to Abbott, is the same as the problem that we three-dimensional creatures have in understanding the fourth dimension. The psychologist of perception Gustav Fechner said that we could think of 2-dimensional creatures as shadows of 3-dimensional figures. In the same way, then, said Fechner, our world is a 3-dimensional "shadow" of the fourth-dimensional reality (Henderson 1983, p. 18). Even Euclidean ideas like Abbott's about the fourth dimension owed a debt to non-Euclidean geometry, since non-Euclidean geometry prepared the way for conceiving alternative kinds of space.

Henri Poincaré's view, discussed earlier, about freedom of choice in geometry was also very attractive to a number of artists (Henderson 1983, p. 55). The key point for the modern artist, after all, was a new freedom from the tyranny of established laws. Thus, Tristan Tzara, the founder of the art movement called "Dada," spoke of "the precise clash of parallel lines." If this should sound like a contradiction, Tzara counseled against worry; the artist can transcend contradictions. The French critic Maurice Princet challenged artists to reverse the prejudices of Renaissance perspective (Henderson 1983, p. 68). Instead of portraying objects on a canvas as "deformed by perspective," they should be expressed "as a type." In Renaissance perspective art, a rectangular table would appear on the canvas shaped like a trapezoid. But a rectangular table should not look like a trapezoid. It should be straightened out into a true rectangle. Likewise, the oval of a glass should become a perfect circle. This describes what is done in many masterpieces of Cubist art.

In Euclidean geometry, when something is moved, it keeps its shape and size. But theorists of Cubism, like Jean Metzinger and Albert Gleizes, declared that Riemann's geometry gives painters the freedom to deform objects in space. Similar views can be found embodied in architecture. For instance, Zaha Hadid, the first woman to win the Pritzker Architecture Prize, constructs buildings that express such ideas. She wrote of her work, "The most important thing is motion, the flux of things, a non-Euclidean geometry in which nothing repeats itself, a new order of space" (Hadid 2008). In the work of artists like these, non-Euclidean geometry has reshaped both our artistic and our intellectual landscapes.

All of these theorists and artists were saying that, beyond the Euclidean world that conventional people think they inhabit, there is a higher reality, a reality that artists alone can intuit and reveal. Non-Euclidean geometry both liberated and legitimated these new approaches to art. The American mathematician Morris Kline has observed, "Non-Euclidean geometry knocked geometry off its pedestal, but also set it free to roam" (Kline 1953, p. 431). And the freedom that geometers claimed for themselves was subsequently bequeathed to many people who may have thought of themselves far from mathematics but well within the traditional liberal arts. The freedom of geometry reinforced a wealth of other social and historical forces in remaking modern culture.

25.7 Anti-Mathematics as a Historical Force

Opposition to the supposed primacy of mathematics in human thought has also influenced the liberal arts and reveals negative perceptions about mathematics that educators neglect to their peril. Some of this opposition is not hostile to all of mathematics, just to its extension beyond its legitimate sphere. For instance, an early opponent of what Ortega later called "provincialism" was, perhaps surprisingly, Isaac Newton. Men like Descartes and Leibniz seemed to Newton to be saying that self-evident assumptions alone sufficed to figure out how the universe works. Newton disagreed. According to Newton, there are many mathematical systems God could have used to set up the world. One cannot decide a priori which is correct, Newton said, but must observe and experiment to find which laws actually hold. Although mathematics is the means used to discover the laws, God set up the world by free choice, not mathematical necessity. This is how Newton justified concluding that the order we find in nature proves that God exists (Newton 1934, p. 544).

Also in the seventeenth century, Blaise Pascal, who made major contributions to mathematics and, with Fermat, was a coinventor of probability theory, contrasted the "esprit géometrique" (abstract and precise thought) with what he called the "esprit de finesse" (intuition) (Pascal 1931, *Pensée* 2), holding that each had its proper sphere but that mathematics had no business outside its own realm. "The heart has its reasons," wrote Pascal famously, "which reason does not know" (Pascal 1931, *Pensée* 277).

In the eighteenth century, Thomas Malthus, in his *Essay on Population*, accepted the Euclidean deductive model. Indeed he began his essay with two "postulata": man requires food, and the level of human sexuality remains constant (Malthus 1798, Chap. 1). His consequent analysis of the way population growth will outstrip food supply rests on mathematical models. But his goal was to discredit the predictions by Condorcet and others of continued human progress modeled on the progress of mathematics and science, as Malthus's mathematical models predict eventual misery and vice instead.

In a nineteenth-century example, the mathematical reductionism of men like Lagrange and Comte was opposed by a great mathematician, Augustin-Louis Cauchy. Cauchy wrote in 1821, "Let us assiduously cultivate the mathematical sciences, but let us not imagine that one can attack history with formulas, nor give for sanction to morality theorems of algebra or integral calculus" (Cauchy 1892, p. vii; Cauchy 2009, p. 3). More recently, computer scientist Joseph Weizenbaum attacked the modern, computer-influenced view that human beings are nothing but processors of symbolic information, arguing that the computer scientist should "teach the limitations of his tools as well as their power" (Weizenbaum 1976, p. 277).

All the examples so far granted some legitimacy to mathematical argument. But there also have been people who have no use at all for the method of analysis, the mathematization of nature, or the application of mathematical thought to human affairs. For instance, the Romantic movement in the nineteenth century championed the organic view of nature over the reductionist mechanical explanations they attributed to Descartes and Newton.[8] The Romantic view is epitomized by a stanza from William Wordsworth's poem *The Tables Turned:*

> Sweet is the lore which Nature brings;
> Our meddling intellect
> Mis-shapes the beauteous forms of things:
> We murder to dissect.

Reacting against Quetelet-style statistical thinking on behalf of the dignity of the individual, Charles Dickens in his 1854 novel *Hard Times* satirized a son who betrays his father and then defends himself by saying that in any given population a certain percentage will become traitors, so no blame should be attached. And Dickens has his hero, Stephen Blackpool, denounce the analytically based efficiency of the industrial division of labor, saying it regards workers as though they were nothing but "figures in a sum" (Dickens 1854, Book II, Chap. V).

Although the certainty of mathematics, and thus its authority, has sometimes been an ally of liberalism, as it was for Voltaire, Jefferson, and Condorcet, the Russian novelist Evgeny Zamyatin saw how mathematics could also be used as a way of establishing an unchallengeable authority, as philosophers like Plato and Hobbes had tried to use it. Zamyatin wanted no part of this. In his 1920s anti-utopian novel *We,* a source for Orwell's *1984*, Zamyatin depicted individuals reduced to being numbers and mathematical tables of organization used as instruments of social control. The results were frightening (Zamyatin 1952). And mathematics and its applications were at their worst in the design of the Nazi death camps, where the analytical method was applied to the assembly-line production of corpses.

Yet the fruits of mathematics and mathematical reasoning are embodied in the idea of progress and in the advances in science and technology which have for the first time in human history made it possible, at least in theory, for all human beings to have decent food, clothing, shelter, and some leisure. The fruits of mathematics are essential to the triumphs of the scientific understanding of nature and in the use of science to liberate humanity from superstition. And the logic taught as part of mathematics is seen also in the working out of the consequences of the still radical idea that all human beings are created equal. Of course mathematics has not caused these changes all by itself. Still, it consistently has provided a powerful metaphor, reinforced by the historical authority possessed by the subject, both to drive and to legitimize these changes.

---

[8] (Olson 2008, pp. 96–121; Richards 2002, pp. 11, 308–310). The Romantics would not admit that what epistemologists call "secondary qualities" like color, so constitutive of human experience, are mere epiphenomena reducible to "primary qualities" of matter in motion nor that greater understanding necessarily follows from mathematical description. As John Keats put it in criticizing "philosophy" (science) in his poem *Lamia* (part 2):

> Philosophy will clip an angel's wings,
> Conquer all mysteries by rule and line,…
> Unweave a rainbow.

Teachers and students need to know the ways mathematics has interacted with the full range of the liberal arts and to know both the power and the limitations of the claims of mathematics to truth and certainty and to universal applicability. Knowing these things, together with some mathematical proficiency, is needed to criticize what is wrong and develop further what is right in the liberal arts tradition and to use mathematics and its fruits to make real the idea of human progress. Teaching mathematics as a liberal art, then, is an important activity. And it is a global activity that transcends the West.

25.8 Mathematics Is Multicultural and Global

> There are others also that know something of value. – Severus Sebokht, c. 662 CE[9]

As the academic study of the liberal arts expands to include global history and anthropology, transcending the bounds of Western society, mathematics fits perfectly. Almost every society has mathematics and has mathematics that solves problems that the particular society thinks are important. Recent scholarship has shown that other cultures have sophisticated mathematical ideas and practices, though these have developed along different paths than in the West. The mathematics of other traditions than the Western can be used to gain perspective on these other societies, and anthropologists and global historians regularly use it this way. But the mathematics of other traditions also can be and is being used both to strengthen the teaching of mathematics and to humanize the subject.[10] The mathematics of other cultures can sometimes reveal the origin of modern mathematical ideas; can provide instructive examples of standard mathematical topics, advanced as well as elementary; can give teachers alternative ways of looking at familiar ideas; and can serve as a source of connection to mathematics for students of many different ethnic, religious, and national backgrounds. We shall look at each of these sources of insight in turn.

25.8.1 Roots of Modern Mathematics

Modern mathematics is not just Western in origin. Of course even the Greeks had important predecessors in Egypt and Babylonia. For instance, over a thousand years

---

[9] (Joseph 2011, p. 462). Sebokht, a Syrian bishop, was challenging the supposed universal superiority of Greek scientific thought by praising the superior methods of calculation using the base-10 place-value number system from India.

[10] There is now an extensive and reliable English-language literature on the mathematics of other cultures. See, for instance, Ascher (1998, 2002), Berggren (1986), (2007), Closs (1986), Dauben (2007), Gerdes (1999), Gillings (1972), Imhausen (2007), Katz (2000), (2007), Martzloff (1997), Plofker (2007), (2009), Robson (2007), (2008), Robson and Stedall (2009), Van Brummelen (2009), and Zaslavsky (1999).

before Pythagoras, the Babylonians were aware of the Pythagorean rule for right triangles. They also developed sophisticated mathematical models to predict the motion of sun, moon, and planets, using the base-60 fractions which survive today as we divide degrees into minutes and seconds and which the Greek astronomers adopted as well.[11]

Mathematicians in the Islamic world brought together the computational traditions of the East and the geometric and proof-based methods of the Greeks into a new approach to the exact sciences (Berggren 1986, pp. 7–8; Høyrup 1994, pp. 100–103), further developing mathematical models in astronomy including some later used by Copernicus, classifying and then systematically treating the solution of all types of quadratic equations, and geometrically solving cubics (Berggren 1986, pp. 118–123; Berggren 2007, pp. 542–546; Katz 2009, pp. 287–292). At first motivated by the problem of finding the great-circle direction of Mecca from any point on the globe, Muslims greatly advanced the spherical trigonometry they had inherited from the Greeks (Berggren 1986, pp. 182–186; Van Brummelen 2009, pp. 194–201). Beginning from Indian work on what we call the sine and cosine, mathematicians in the Islamic world defined all six of the plane trigonometric functions and developed sophisticated approximation methods to produce trigonometric tables good to five base-60 places (Katz 2009, pp. 306–310). They also further studied the logical equivalents to the parallel postulate (Berggren 1986, pp. 13–15; Katz 2009, pp. 301–303). The important influence of these achievements of Islamic mathematics for later work in Europe, via the writings of Leonardo Fibonacci of Pisa in the thirteenth century and in translations from the twelfth century to the Renaissance, has been amply documented (Katz 2009, 317–318; Van Brummelen 2009, pp. 223–227).

25.8.2 Premodern Discoveries Around the World

Societies whose influence on European mathematics has been less direct, not yet documented, or even nonexistent have also developed sophisticated mathematics, often considerably earlier than did Europeans. For instance, in India combinatorics developed as early as the third century BCE, notably to explain how many different combinations of “heavy and light” (stressed and unstressed) syllables in a line of n syllables there could be. In the tenth century, the *meruprastara* (mountain-shaped figure, known now as the Pascal triangle) was developed to display the answers (Joseph 2011, pp. 352–355; Plofker 2009, p. 57). To describe planetary positions over time, Indian mathematicians worked to solve simultaneous numerical congruences, which in turn led them to give a complete theory of solving what is now called the Pell equation, long predating

---

[11] See Katz (2009, pp. 17–18, 84–88), Robson (2007, pp. 100, 140–141, 151), and Robson (2008, pp. 109–115, 218–219).

the solutions in the eighteenth century by Euler and Lagrange (Katz 2009, pp. 246–250; Plofker 2007, pp. 423–433).

Indian plane trigonometry began by using Greek methods, but advanced the subject considerably. For example, long before Taylor series were known in the West, Indian trigonometry in the fourteenth century produced the infinite power-series expansions for sine and cosine, sometimes called the Madhava-Newton series after two of its independent discoverers (Katz 2009, pp. 257–258; Plofker 2009, pp. 236–246). Indian mathematics had both interactions with and direct influence upon mathematics in the medieval Islamic world (Plofker 2009, pp. 255–278).

In China, a classic work from before the second century BCE gave methods for solving simultaneous linear equations, using what we would call matrices or Gaussian elimination, and including an example of six equations with six unknowns (Dauben 2007, pp. 346–355; Katz 2009, pp. 209–212). In the eleventh century in China, one finds again the Pascal triangle of binomial coefficients; the coefficients were used to approximate the solutions of polynomial equations of arbitrary degree, in a way analogous to the modern method named after the nineteenth-century mathematician William Horner (Dauben 2007, pp. 329–330; Katz 2009, 213–217). In indeterminate analysis, the Chinese, like the Indians, were initially motivated by astronomical problems to solve simultaneous congruences, using a method which, after it became known in Europe in the nineteenth century, has been called the Chinese Remainder Theorem (Dauben 2007, pp. 302, 311–322; Katz 2009, pp. 222–225). Like mathematicians in India and in the Islamic world, the Chinese had a base-10 place-value system, and, like mathematicians in the Islamic world, the Chinese developed decimal fractions.

Mathematicians in the Islamic world also developed systematic combinatoric methods, including steps toward the method of proof now known as mathematical induction. Their mathematicians, as had those in India and China, developed the Pascal triangle of binomial coefficients (Berggren 1986, pp. 53–63; Katz 2009, pp. 282–296) and used it for, among other things, approximating n^{th} roots. They worked out what we now call the multiplication and division of polynomials – without the benefit of algebraic symbols – including the use of negative exponents. They were the first to recognize that decimal fractions are essentially polynomials using powers of 10 and that fractions can be represented as closely as one likes by taking sufficiently many decimal places (Berggren 1986, pp. 111–118; Katz 2009, pp. 279–282).

Combinatorics was developed also in medieval Jewish culture, where the initial purpose was to work out the number of possible Hebrew words in order to understand language and, therefore, since the Bible describes God creating the universe through speech, to understand creation. Levi ben Gershon (1288–1344) called the proof method he used for combinatorial results “rising step by step without end,” anticipating the idea of mathematical induction. Also, building on the discussions of Jewish law in the Talmud, medieval Jewish mathematicians anticipated the modern idea of expected value in discussing the problem of fair division (Katz 2009, pp. 337–338; Rabinovitch 1973, pp. 143–148, 161–164).

25.8.3 Pedagogical Insights from Around the World

Looking at alternative treatments from other cultures even of less advanced topics can add insight to the teaching of mathematics. Consider, for instance, what constitutes a proof. At least before the Jesuits brought Euclidean geometry into China in the seventeenth century, Chinese mathematicians did not use proof by contradiction, even though such reasoning is found in Chinese philosophy (Hanna and de Villiers 2012, pp. 431–440; Leslie 1964; Siu 2012, pp. 431–432). In China, mathematicians produced visually convincing proofs, including for the Pythagorean theorem (Dauben 2007, pp. 221–226, 282–288; Hanna and de Villiers 2012, pp. 431–440; Katz 2009, p. 237; Siu 2012, pp. 432–433). Chinese algebraists proved the validity of some algebraic algorithms by reducing them to other algorithmic results already known (Chemla 2012; Dauben 2007, p. 377; Hanna and de Villiers 2012, pp. 423–429). Going beyond proof methods, it is of pedagogical interest to contrast Chinese and Greek mathematical methods in a variety of contexts (Dauben 2007, pp. 375, 377; Horng 2000).

Indian mathematicians, like those of China, did not use postulates as a basis for their proofs, but like the Chinese, they systematically, though usually implicitly, assume that areas remain the same when dissected in different fashions, and provide rational justifications for a range of results, including the Pythagorean theorem (Plofker, pp. 247, 251).

Among other examples of non-Western materials that can add to the understanding of modern topics, consider how in India between the sixth and eighth centuries, long before the writings of Leonardo Fibonacci of Pisa, the Fibonacci series arose in answering a question about poetic meter.[12] The structure of the answer suggests that this series can solve a wider class of problems, as indeed later history shows that it does. And in the Islamic world, Euclidean geometric theorems about areas, used to justify the derivation of the algebraic technique of solving quadratic equations, are illustrated by the visual picture of completing the square, a picture that greatly enhances student understanding of the solution of quadratics (Berggren 1986, pp. 104–110; Joseph 2011, pp. 477–480; Katz 2009, pp. 272–276).

25.8.4 Mathematical Ideas from Many Cultures

Examples of topics now part of modern mathematics abound also in the mathematics of many of the cultures studied by modern anthropologists as well as that of other

---

[12] The question is, if long or heavy syllables are two beats and short or light syllables are one beat, what is the number of different arrangements $A(n)$ of long and short syllables for a line of n beats? For example, if there are two beats and if we use “S” for short and “L” for long, the arrangements are SS and L. If there are three beats, the arrangements are SSS, SL, and LS. If there are four beats, the arrangements are SSSS, SSL, and SLS (formed by placing an S in front of each of the arrangements for three beats), plus LSS and LL (formed by placing an L in front of each of the arrangements for two beats). Thus, $A(4)=A(3)+A(2)$. Since $A(2)=2$ and $A(3)=3$ and since the method of forming $A(n)$ from $A(n\text{-}2)$ and $A(n\text{-}1)$ must follow the same pattern, this gives the Fibonacci series (Singh 1985).

ancient societies. These examples are often unexpected and therefore interesting to mathematicians as well as to anthropologists, linguists, artists, historians, and educators. For instance, the eminent algebraist André Weil has shown how the systems of marriage laws in some Aboriginal societies in Australia can be modeled by the theory of groups, and Marcia Ascher gives a variety of examples of such marriage laws, both in Australia and among the Malekula people of Vanuatu (Ascher 1998, pp. 70–81; Weil 1949, 1969). Not only is the Malekula system's structure isomorphic to that of the dihedral group of order 6, the Malekula themselves reason using a geometric diagram to describe, explain, and answer questions about their kinship relationships (Ascher 1998, pp. 77–81). Both the Bushoong people of central Africa and the Malekula can distinguish between graphs which have what are now called Eulerian paths and those that do not. The Bushoong use such graphs for purposes ranging from embroidery to political prestige (Ascher 1998, pp. 31–37), while the Malekula use knowledge of them in stories and myth (Ascher 1998, pp. 43–62). There are now several textbooks using such culturally based graphs and designs to teach mathematics; an excellent example is Gerdes (1999).

Geometric symmetries abound in the various artistic designs used in many cultures. The beauty of these designs makes them valuable examples in teaching about the structure of groups of symmetries (Ascher 1998, pp. 155–183; Washburn and Crowe 1998). And just as in classical Chinese and Indian civilization, modern mathematical instruction in the algebra of congruences and in astronomical models can draw on calendars from a variety of cultures that have chosen to deal in different ways with the different periods of the apparent motion of the stars, sun, moon, and planets. Comparing and studying the different calendrical systems used by, for instance, the Maya in the Americas; modern inhabitants of Bali; the ancient civilizations of Egypt and Babylonia, China, and India; and Jews, Muslims, and Christians, can link mathematics and astronomy to culture and religion (Ascher 2002, pp. 39–88).

Studying different number systems and different number bases becomes alive when linked to particular cultures, especially cultures related to one's students' own backgrounds. Examples interesting to US students can include the base-20 place-value system of the Maya and the sophisticated astronomical calculations for which it was used (Ascher 2002, pp. 62–74; Closs 1986), the multiplication by adding multiples of appropriate powers of two of the multiplicand used by the ancient Egyptians (Katz 2009, pp. 4–5), the variety of number bases used by different indigenous cultures of Africa (Zaslavsky 1999), and the base-60 place-value system of the ancient Middle East that gives us "modern" minutes and seconds.

The study of the mathematics of cultures other than the Western and interest in placing such mathematics in its cultural setting and using it to teach mathematical ideas and practices, all have attracted much interest in the past few decades. This approach has come to be called "ethnomathematics," a term introduced in D'Ambrosio (1985), and has generated a rich literature. For the purposes of the present essay, this brief sketch of some of the relevant mathematical ideas and practices will have to suffice, but as the sources cited in this section make clear, there is now a wealth of excellent scholarship devoted to mathematics in different cultures and time periods, regardless of whether or not that mathematics has influenced modern mathematics. The connection of mathematics with subjects ranging from anthropology to the visual arts is vastly enriched by a multicultural perspective. Here, then, is another important link between mathematics and the liberal arts, where in this case the liberal arts range far beyond the traditional texts of the Western canon.

25.9 Teaching Mathematics as a Liberal Art in the Modern University

After soaring into space with Euclid and Newton and Lobachevsky, roaming the globe and sampling mathematical thought across time and across continents, and after transforming world views with the architects and anthropologists, the philosophers, and theologians, let us come down to earth and enter a few classrooms in the English-speaking world, where, to quote the Yeats poem again, “The children learn to cipher.” Students are using the quadratic formula to solve $2x^2-11x+14=0$. For what purpose? Why does the formula work? Who thought it up, and why? Nobody says. The formula is rarely derived even algebraically, let alone in the intuitively pleasing way with the geometric picture of completing the square. A student recently told the author that he “knows” the quadratic formula because a teacher taught his class to sing it to “Pop Goes the Weasel.” In elementary schools, the rules of arithmetic are too often presented in the manner satirized as “Ours is not to reason why; just invert and multiply” (Wilson 2003, p. 6). Such methods of instruction may have been appropriate to produce a nineteenth-century nation of shopkeepers in an age without electronic calculators, but not to develop citizens who can independently apply mathematical and statistical reasoning to the quantitative ideas so pervasive in modern society and who understand the role of mathematics in the wider world.

Students need to know why, not just how, so that they can adapt what they have learned to new situations. Teachers need to know how young people learn and to know not only the elementary mathematics that they teach but also what it leads to and how it is used. The history of mathematics could help link mathematics with the rest of the world and to the rest of the liberal arts. But using algorithms, rather than being liberating and empowering as it was to seventeenth-century mathematicians, now has become a rule-based march toward the multiple-choice test.

The present chapter will not presume to prescribe solutions to the problems of pre-university mathematics education or to explain how to overcome the political and social forces that stand in the way of improving instruction, save to emphasize “For everything there is a reason” and to encourage teachers to explain the why as well as the how.[13] At the university level, those students specializing in

---

[13] Discussions about how this can and has been done, and how it has been assessed, may be consulted in Alternatives for Rebuilding Curricula Center (2003), Ball et al. (2005), Boaler and Staples (2008), Hill et al. (2005), and Tarr et al. (2008). A cross-cultural study involving Chinese and American teachers at the elementary-school level can be found in Ma (1999).

science and mathematics will manage relatively well. Their professors will understand the mathematics, be able to answer student questions, and will point students toward real applications. Courses in the history and philosophy of mathematics can help mathematically literate students see the kinds of links described in the present paper. But what of the self-defined liberal arts student, who comes to the university definitely wanting *not* to study mathematics? This essay will conclude by addressing this question.

A common practice in many American colleges and universities is to teach all these students precalculus. This usually repeats what did not work for them in high school. Such an approach frustrates students and teachers alike, and a terminal precalculus course seems to defeat any logical purpose. Another approach is to use one of the textbooks designed to teach mathematics to liberal arts students (e.g., Burger and Starbird 2012; Jacobs 2012), or the applications-oriented book *For All Practical Purposes* (COMAP 2013) and others that resemble it. Such texts have been successful in a variety of universities, and those who find the books successful with their own students should of course use them and recommend them to colleagues.

But for those who find the story told here sufficiently compelling to try to design their own courses for liberal arts students, some principles useful for classes designed by individuals are worth considering. First, base the course on something of interest to contemporary students in which the instructor has expertise, whether it is "mathematics and art," "games and gambling," or "mathematics in many cultures."[14] After all, mathematics was considered important and interesting throughout history because people wanted to solve particular problems, some within mathematics itself, some of importance to the wider society. Teaching what instructors themselves find interesting and exciting recapitulates the history of mathematical creativity.

Second, although the mathematics chosen must be accessible to liberal arts students, it should also be important mathematics in the eyes of mathematicians. The liberal arts goals require this. Third, for students who will probably never take another mathematics course, learning mathematics should be empowering, not overwhelming. It is more important for them to be able to use the mathematics they know than to be shown more mathematics that they cannot master. A liberal arts course isn't prerequisite to anything. There is merit in going slowly enough so that 90 % of the students will get 90 % of the mathematics. This lets them, perhaps for the first time, experience mastery in mathematics; this is part of understanding what mathematics is all about. "I get it now" is a necessary prerequisite for seeing the beauty and elegance of mathematics, and also of being able to apply it to a new situation.

---

[14] Examples of books that might be suitable for such courses include Ascher (1998 and 2002), Frantz and Crannell (2011), Gerdes (1999), and Packel (1981). For details about the author's courses, see Grabiner (2011). A superb online resource for liberal arts mathematics teaching is the Mathematical Association of America's "magazine" of the history of mathematics and its uses in the classroom, *Convergence* (n.d.).

Fourth, all students have expertise. It may not be in mathematics, but they do have expertise in their major or some outside interest. A liberal arts course should allow each student to build a course project incorporating that expertise and thereby impress and teach everybody else, sharing their course projects with each other in the class. This will produce many more applications of mathematics than most professors could generate and a surprising range of fascinating mathematical topics. Just as in the case of the instructors teaching what interests them, the depth of the individual student's excitement about the topic will enhance that student's learning. And the individual student becomes the class expert on one piece of mathematics, perhaps for the first time in that student's life.

Students often identify mathematics with number and calculation alone or perhaps with elementary geometry and trigonometry. In modern times, though, because of the increasing abstraction of contemporary mathematics and because many branches of mathematics, from topology to infinite-dimensional spaces, transcend ordinary experience, a broader characterization of mathematics has developed. In the recent influential words of Lynn Steen, "No longer just the study of number and space, mathematical science has become the science of patterns, with theory built on relations among patterns and on applications derived from the fit between pattern and observation" (Steen 1988, p. 611). "Pattern" is a valuable metaphor in accounting for the applicability of mathematics, since mathematical patterns can mesh with the patterns of order of the universe. But the metaphor also underscores the beauty of mathematical ideas, linking mathematics in a different way to the rest of the liberal arts. As G. H. Hardy, perhaps the earliest to use the idea, put it, "A mathematician, like a painter or a poet, is a maker of patterns…. The mathematician's patterns, like the painter's or the poet's, must be *beautiful*; the ideas, like the colours or the words, must fit together in a harmonious way" (Hardy 1967, pp. 84–85, italics his).

Faculty members at many institutions may not have the freedom to invent new courses, but the general principles should help every teacher of mathematics for non-mathematicians. Mathematics is fun and exciting, both beautiful and useful. It makes unique claims to truth, is governed by logic and reason, and has interacted with every conceivable subject. It has been created by human beings all over the world, in the past and in the present, by men and by women.[15] To be able to follow logical arguments and to criticize them is liberating; as Jacques Barzun observed, "The ability to feel the force of an argument apart from the substance it deals with is the strongest possible weapon against prejudice" (Barzun 1945, p. 121). It is liberating to have understood the "why?" rather than just to have memorized processes, so that people can use the mathematics they know to analyze ideas and solve problems they have never encountered. Mathematics matters not just to stu-

---

[15] On women in mathematics in general, see the online biographies maintained by Agnes Scott College (2012), the sourcebook Grinstein and Campbell (1987), and the Mathematical Association of America's poster *Women of Mathematics* (MAA 2008). On important individual women in mathematics, see Arianrhod (2012), Brewer and Smith (1989), Dahan-Dalmédico (1991), Deakin (2007), Hagengruber (2012), Katz (2009, pp. 189–190, 616–617, 714–715, 787, 874, 896–898, 899), Koblitz (1983), Mazzotti (2007), Neeley (2001), Reid (1996), and Zinsser (2006).

dents but to all members of a free society. As this essay has argued, mathematics lies at the heart of the ancient and medieval liberal arts and of those fields called liberal arts today. Viewing mathematics as a liberal art shows both why mathematics is important and how it should be taught.

Acknowledgments This essay is dedicated to the memory of Herman Sinaiko (1929–2011), peerless teacher and scholar of the liberal arts. I am grateful to the anonymous referees and to the editor, for their scholarly expertise, comments, and criticisms, which have materially improved this chapter. I also thank the Pitzer family, donors of the Flora Sanborn Pitzer professorship, for their generous support of my research.

Judith V. Grabiner is the Flora Sanborn Pitzer Professor of Mathematics at Pitzer College, one of the Claremont Colleges in California. She received her B.S. in Mathematics with General Honors from the University of Chicago and her Ph.D. in the History of Science from Harvard. Her published books are *The Origins of Cauchy's Rigorous Calculus*; *The Calculus as Algebra: J.-L. Lagrange, 1736–1813*; and *A Historian Looks Back: The Calculus as Algebra and Selected Writings.* Her publications also include many articles (seven of which have won prizes from the Mathematical Association of America) in the history of mathematics, including "The Centrality of Mathematics in the History of Western Thought," "Computers and the Nature of Man: A Historian's Perspective on Controversies about Artificial Intelligence," and "Who Gave You the Epsilon? Cauchy's Contributions to Rigorous Calculus." Before coming to Pitzer she taught at UCLA, UC Santa Barbara, California State University at Dominguez Hills, and Pomona College, and she has been a visiting scholar at universities in England, Scotland, Australia, and Denmark. Grabiner taught a DVD course for the Teaching Company entitled "Mathematics, Philosophy, and the 'Real World,'" won the Mathematical Association of America's national Deborah and Franklin Tepper Haimo Award for Distinguished College or University Teaching in 2003, and is a Fellow of the American Mathematical Society.

Chapter 26
The Role of History and Philosophy in University Mathematics Education

Tinne Hoff Kjeldsen and Jessica Carter

26.1 Introduction

In this chapter we discuss the roles of the history and philosophy of mathematics in the learning of mathematics at university level. University mathematics is organised differently in different universities and countries. In some universities mathematics is separated into different programmes: masters in pure mathematics, in applied or industrial mathematics, in financial mathematics, in teacher training education, etc. In this paper we consider mathematics programmes that lead to a graduate degree in mathematics, i.e. mathematics programmes where pure mathematics plays an essential role.[1] In the context of the present handbook, the following three questions immediately come to mind: (1) Why do we need a chapter that focuses especially on mathematics? (2) Why do we need a chapter that focuses especially on university level mathematics? (3) Why combine history and philosophy?

The first question has also been addressed by Michael N. Fried in the Chap. 21. Fried pointed out that there are differences between the sciences and mathematics that justify the inclusion of this question in the present handbook of separate chapters focusing on history and philosophy of mathematics in mathematics education. Here we will mention the picture of mathematics as the epitome of timeless truths and mathematical objects as ideal, timeless entities – named by some as an

---

[1] For the roles of the history and philosophy of mathematics in liberal arts education, we refer to the previous chapter by Judith Grabiner.

absolutist philosophy of mathematics. One consequence of this picture, which is conveyed to students by traditional mathematics educations at all levels (François and Van Bendegem 2007), is that it portrays mathematics as a cumulative science of a seemingly static and infallible character of knowledge (Otte 2007, p. 243).

An essential difference between the history and philosophy of mathematics in primary and secondary mathematics education and mathematics at university level is that at university level these subjects often have their own courses within the mathematics programme: with their own learning goals, curriculum, disciplinary standards and agendas which are not restricted by a mathematics curriculum that has to be taught in the same courses as well. Hence, the history and philosophy of mathematics can play very different roles in mathematics education at the university level than at the primary and secondary level. These differences justify a separate chapter within the present handbook that focuses on the university level.

Finally, during the past few decades, research in the history and philosophy of mathematics has witnessed a trend towards a focus on mathematical practices from which historical and philosophical investigations and analyses have taken a point of departure. On the one hand this has strengthened the relationship between the professional academic disciplines of history and philosophy of mathematics, with historical investigations serving as cases for philosophical studies and vice versa philosophical ideas serving as inspiration and tools for historical analyses.[2] On the other hand, studying the history and philosophy of mathematics from the practices of mathematics brings these subjects close to mathematical research activities, to processes of knowledge production in mathematics and hence to mathematics education at university level. It therefore makes sense to look at the history and philosophy of mathematics in a common perspective in relation to the roles they (can) play in mathematics education at university level.

In the following we first briefly introduce a historiographic framework of a multiple perspective approach to the history of mathematics from its practices together with some reflections about uses of history, and we introduce the direction of research in the philosophy of mathematics that is denoted 'Philosophy of Mathematical Practice'. We then link the history and philosophy of mathematical practices to recent ideas in mathematics education in order to identify different roles history and philosophy can play in mathematics education at university level. This is followed by presentations, analyses and discussions of different examples of the inclusion of history and philosophy in university programmes in mathematics. These presentations are divided into courses in history and philosophy, since this is the main way they are organised at the universities. We shall see, however, that the history courses address philosophical questions and that the philosophy courses employ historical material. The chapter is rounded off with comments on how mathematics educations at university level can benefit from history and philosophy of mathematics.

---

[2] Our joint paper (Kjeldsen and Carter 2012) serves as an example of this mutual beneficial relationship.

26.2 History and Philosophy of Mathematics from Its Practices

The history and philosophy of mathematics are two independent professional disciplines that have followed their own trajectories. As mentioned in the introduction, during the past few decades the research in the history and philosophy of mathematics has witnessed a trend towards a focus on mathematical practices. In the following we will introduce a historiographical framework of a multiple perspective approach to history of mathematics from its practices and introduce one direction of research in philosophy of mathematics that is denoted ‘Philosophy of Mathematical Practice’. These are methodological issues in the professional disciplines of history and philosophy of mathematics. In mathematics education at university level, approaches to history can be found that are not necessarily aimed at purely historiographical goals, but are directed towards the teaching and learning of mathematics. In order to analyse such approaches, we also introduce parts of a framework for uses of the past.

26.2.1 History of Mathematics from Its Practices and Uses of the Past

Research into people’s uses of history has shown that people use history in many different contexts, for different purposes and with different approaches; see, e.g. Ashton and Kean (2009) and Jensen (2010). In this context, the Danish historian Eric Bernard Jensen conceive of history as an umbrella term for related forms of knowledge and practises people uses in their lives, and he defines history accordingly by saying that we are dealing with history ‘when a person or a group of people is interested in something from the past and uses their knowledge about it for some purpose’ (Jensen 2010, p. 39). Historians (or users of history) might have different perspectives on history depending on their aims. This is also the case for history of mathematics which is, and has been, studied and used in different contexts with different goals.[3] In his book *What is History*, Jensen (2010) provides a framework in which different uses of the past can be characterised. The framework can be used to analyse and characterise implementations of history in mathematics education. Here we will only introduce his distinction between a *pragmatic* and a *scholarly* approach to history.[4]

A historian who studies history from a utility perspective is said to have a *pragmatic* approach to history. It is an approach in which history is conceived of as ‘the master of life’, i.e. we can learn from history. In a pragmatic approach to history,

---

[3] See, e.g. Lützen and Purkert (1989) where the different historiographical views of Cantor and Zeuthen are discussed.

[4] In Kjeldsen (2012) Jensen’s terminology is outlined and used as lens through which we can identify and distinguish between different conceptions and uses of history of mathematics.

the historian will try to make history relevant in a present-day context. In Jensen's terminology, historians who focus on understanding and interpreting the past on its own terms, regardless of the present situation, is said to have a *scholarly*[5] approach to history. According to Jensen the scholarly approach has been the dominant one in academic, professional history since the mid-nineteenth century.

In the following we will present a multiple perspective approach to history of mathematics from its practices. The multiple perspective approach to history is inspired by Jensen's (2003) thinking about historiography. His underlying premise is that people produce history and are shaped by history. In order to understand social-historical processes and gain insights into the past, history is studied from perspective(s) of the historical actors. The historian pays attention to the historical actors' motivations, their projects, their intentions as well as unintended consequences of their actions. The perspective of the actors is taken into account which means that perspectives such as the actors' placement in space and time, in a certain society and/or in a particular intellectual context are considered as part of historical investigations.

If we think of mathematics as a historical and cultural product of knowledge that is produced by human intellectual activities, then a multiple perspective approach to history can be adapted to historiography of mathematics. Studying the history of mathematics then also involves searching for explanations for historical processes of change, such as, but not limited to, changes in our perception of mathematics as such, in its status and function in society, in our understanding of mathematical notions or objects and in our idea of what counts as legitimate arguments for mathematical statements.

Studying processes in the development and shaping of mathematics from mathematical practices means asking why mathematicians introduced specific concepts and definitions; why they studied the problems they did, in the way they did; and what were the driving forces behind their mathematical investigations; see, e.g. Epple (1999, Chap. 1) and Epple (2004, p. 133). One approach is to study concrete episodes of mathematical research activities focusing on the 'workplace' of the involved mathematicians in order to uncover and understand the dynamics of the knowledge production. The methodological framework of epistemic objects, techniques and configurations (Epple 2004), originally developed by the philosopher of science Hans-Jörg Rheinberger (1997), has been used recently in the historiography of mathematics; see Epple (2004, 2011) and Kjeldsen (2009). In short, epistemic objects refer to the mathematical objects about which new knowledge is searched for. Epistemic techniques refer to the methods and mathematical techniques that are used to investigate the mathematical objects in question; and epistemic configuration of mathematical research refers to the total of intellectual resources present in a specific episode. These terms are not intrinsically given, but are bound to concrete episodes of mathematical research. They are to be understood functionally, they change during the course of mathematical research and they might shift place. They are excellent tools for analysing the production of knowledge and the understanding of mathematical

---

[5] This is our translation of the Danish word 'lærd'.

entities in historical texts, because they are constructed to differentiate between how problem-generating and answer-generating elements of specific research episodes functioned and interacted. In Kjeldsen (2011a) it is suggested how this framework can be used in connection with student project work in history of mathematics for the learning of and about mathematics in university mathematics education.

In bridging the history of mathematics with mathematics education, we find a multiple perspective approach to the history of mathematics, from its practices, that is particularly relevant to mathematics education at university level. This is due to its striving for understanding the dynamics of mathematical knowledge production, the status and functions of mathematics in society and in concrete episodes from the past. This will be discussed below in the examples from our own approach of specific implementations of history in mathematics programmes at university level.

26.2.2 Philosophy of Mathematical Practice

Similar to the history of mathematics, the philosophy of mathematics poses different kinds of questions and offers ways of dealing with these. New questions may arise because of changes in the practice of mathematics, and changes in perspectives are often the outcome of perceived limitations of previous methods. At present there is a growing interest in what is denoted ‘Philosophy of Mathematical Practice’. There are many motivations for this shift in interest; some are indicated below. Since this perspective is our focus, we will describe it in more detail.

It is no easy task to define philosophy. One way to describe it is that it poses fundamental questions concerning the world and our place in it. In addition philosophy seeks to answer these questions and, equally important, find arguments for the given answers. Philosophy – unlike mathematics – is a discipline where there seems to be very little agreement about answers. This does by no means entail that ‘anything goes’. There are certain standards measured, for example, by the coherence of one’s proposal, soundness of arguments as well as quality and sensibility of assumptions. Ideally, philosophy should advance our knowledge by critically examining our ideas, assumptions and arguments. Mathematics also gives rise to philosophical queries. Traditionally, philosophers have mainly asked questions within ontology and epistemology: questions such as ‘What kind of entities are mathematical objects?’ and ‘Do they exist independently of the activities of human beings?’ and epistemological questions like ‘how do we obtain knowledge in mathematics?’ Philosophers at all times have been fascinated with the apparent necessity of mathematical truths and the fact that mathematics is applicable to the real world while its subject matter seems remote from anything real. Philosophers such as Plato, Aristotle, Descartes, Kant and Mill all found that something should be said about mathematics.[6]

---

[6] Their views on mathematics are very different. For a presentation of their positions, see Shapiro (2000). For a nontraditional description of Plato’s philosophy, in line with the perspective of mathematical practice, see McLarty (2005).

During the nineteenth century, mathematics changed drastically. From being conceived as somehow describing the real world, mathematics changed into an autonomous body of its own ideas. Gray (2008) characterises modern mathematics as being remote from the real world, having a strong 'emphasis on formal aspects of the work and maintaining a complicated – indeed anxious- rather than a naive relationship with the day-to-day world' (p. 1). For one thing, these changes led *mathematicians* to pose fundamental questions regarding the nature of mathematics and – perhaps more importantly – concerning how to obtain a secure foundation.[7] These questions led to the three foundational schools, Logicism, Intuitionism and Formalism; see, e.g. Benacerraf and Putnam (1983), Mancosu (1998), and van Heijenoort (1967). Outcomes of these programmes were the development of logic and proof theory[8] as well as a (one-sided) focus on questions pertaining to the justification of mathematics. Philosophy of mathematical practice can be seen as a reaction to the philosophers' one-sided stress on formal mathematics. Among the first to enter this lane was Lakatos (1976) who found that answers could be found by studying the practice of mathematics, writing (explicitly referring to Kant's famous line from Critique of Pure Reason A51,B75) 'Philosophy of science without history of science is empty; history of science without philosophy of science is blind' (Lakatos 1970, p. 91). Lakatos held that philosophy should also deal with questions concerning discovery or more precisely he argued that the processes of discovery and justification are intertwined. This approach to the philosophy of mathematics has gradually increased in popularity. Pioneers are Kitcher (1984), Maddy (1990), Tymoczko (1985), and later Corfield (2003). In what could be denoted as 'Philosophy of mathematical practice' today,[9] a (rough) distinction can be made between three approaches. These outlooks can be termed social, historical and epistemological. Since our approach to the philosophy of mathematics lies mainly within the epistemological strand, we describe this in more detail below.

The strand that has a sociological focus takes as a starting point the view that mathematics is a human activity (Hersh 1979) and as such can be described by sociological tools (Heinz 2000). Others are closer to mathematics education; see

---

[7] Another interesting development in mathematics around the turn of the century was the move towards structuralism. What is studied in mathematics is not the objects as such – it is the relations between objects. This is most famously described by Hilbert saying 'one must be able to say "tables, chairs, beer-mugs" each time in place of "points, lines, planes"' (Blumenthal 1935, pp. 402–403), expounded mathematically in his Foundations of Geometry (Hilbert 1899). Traces of this conception about mathematics can still be found in today's philosophies of mathematics; see Benacerraf (1965), Hellman (1996), Resnik (1999), and Shapiro (1997). More recently philosophers have argued that category theory provides a sound basis of a 'top-down' structuralist view (Awodey 1996; Landry and Marquis 2005).

[8] Since the original foundational schools failed for a variety of reasons, other ways of obtaining a foundation were looked for. It was, for example, proved by Gentzen during 1930s that if sufficiently strong methods (induction over ε_0) are used, then it is possible to prove the consistency of arithmetic. A different approach is to find a weaker system than Primitive Recursive Arithmetic where completeness and consistency are provable.

[9] See, e.g. Ferreiros and Gray (2006), Mancosu (2008), Van Kerkhove and Van Bendegem (2007), and Van Kerkhove et al. (2010).

Bloor (1994), Ernest (1998), and Restivo (1993). This outlook is also the basis of the fairly recently formed Phimsamp group.[10] It is already integrated with mathematics education, especially through the work of Ernest (see http://people.exeter.ac.uk/PErnest/ and references throughout this chapter).

The second strand has history of mathematics at its core. One such perspective notices that mathematics itself at different times has posed philosophical questions and seeks to bring out the historical circumstances for these questions. This was the case in the period during which the foundational schools were formed – and as noted above, the people asking the questions and providing answers were in fact mathematicians themselves. A nice example of this outlook is presented by J. Tappenden (2006). He shows that there are certain misconceptions regarding Frege's mathematical motivation for engaging in his project.[11] Another perspective deals with the philosophical conceptions of the mathematicians themselves and how these conceptions help form the development of mathematics.

The final strand asks traditional philosophical questions and seeks answers to these by considering mathematical practice. Mancosu (2008) presents a number of excellent papers within this strand. For us taking this approach means that both questions and means for answering these questions are taken from mathematical practice. We acknowledge that questions may arise within mathematical practice itself and that assumptions should to some extent agree with practice. This is in part a reaction to traditional philosophical approaches, where one starts with an assumption about mathematics, such as 'mathematical statements are necessarily true', and then argues that it follows that mathematical objects exist (by necessity). There are two objections to this procedure. First, mathematics itself is missing from the picture. Second, the assumption needs to be examined. It is not clear whether mathematical statements are necessary or, if so, in which sense they are necessary (Carter 2008). When taking this approach, the aim is to obtain a better understanding of the mathematics that we (as human beings) know and use. The focus of Carter is to understand better contemporary mathematics; but in principle any part of mathematics could be the object of study. Which practice – or case – to study depends (in part) on which question is posed. This approach also has as consequence that it may not make sense to talk about the 'right' picture. Instead one may talk of useful pictures, in terms of determining for a given picture what is achieved by adopting this picture. We are still concerned about the coherence of pictures of mathematics, and that sound arguments should be provided. Thus in addition to the triple of standards – sensible assumption, valid arguments and coherent theory – a fourth component is added, namely, value of theory to a practice. This outlook may not be so different from the social outlook. A major difference concerns the set of

---

[10] Philosophy of Mathematics: Sociological Aspects and Mathematical Practice.

[11] One misconception is that when Frege started worrying about the foundation of analysis, it had already been settled by the work of Weierstrass in Berlin. The fact of the matter, Tappenden argues, is that problems of *real* analysis were being solved, but Frege knew of the (revolutionary) work of Riemann from the 1850s integrating geometry and complex analysis, opening up whole new fields of study.

assumptions built in. On the social outlook, for example, it would be assumed that there exist a community of learners and teachers (Ernest 2009) and some mathematics, created by human beings, which need to be taught/learned. In addition it is a helpful assumption when teaching mathematics that communication is possible (Carter 2006). Our interest focuses on the nature of mathematical objects and development of mathematics in general and thus implicitly requires the assumption of the existence of mathematicians doing mathematics. On this perspective, the relevant practices to study are the different contexts in which mathematics is developed. It is also important to note that what we study is *how we humans acquire knowledge of mathematics*. By doing this, our intention is not to assume anything about the true ontology of mathematics.

Since we take as a starting point mathematical practice, the history of mathematics is an important ally in providing case studies. The dependency relation, however, is a two-way relation which was already pointed out by Lakatos. Even though philosophy and history 'feed on each other', our aims are different. The philosopher tries to establish whatever general can be stated by considering particular cases. But sometimes interesting things can also be said about the particular cases – see below for an example. In contrast, the historian seeks to bring out the particular in each practice. As argued in the section above, when doing this the historian needs certain (philosophical) tools or concepts. To conclude this section, we give an example of how this 'philosophy' works in practice. When addressing the question concerning the nature of mathematical objects, a way to obtain an answer is to look into the practice of introducing mathematical objects (Carter 2004). As a result of such studies,[12] Carter (2013) concludes that mathematical objects are often introduced with reference to, or even as representations of, already accepted objects. The importance of contexts both for introducing objects and reasoning with them is also pointed out. These are general categories that can again be tested against historical studies. The aim of Kjeldsen and Carter (2012) is to test these claims against a case study on the introduction of convex bodies in the work of Minkowski. We find that overall this case fits the given description. In addition we find that the cases display important differences, which also provides insight about the general development of mathematics. One such difference concerns the type of relation between the new object and its referent. The convex body is defined as a set having certain properties singled out as important when solving problems within number theory, whereas a Riemann surface is an actual representation of part of the defining expression of an Abelian function.

When teaching the philosophy of mathematics for university students, we find that it is particularly important that this teaching takes as its starting point the actual *practices* of doing mathematics. In their ordinary mathematics courses, students are exposed to one picture of mathematics. We believe they should be exposed to different pictures. We stress, though, that students should also be aware that different pictures have different assumptions and that these are, useful or not, merely *assumptions*.

26.3 History and Philosophy in Mathematics Education: Mathematical Competence, Critical Mathematics Education, Interdisciplinarity and Thinking as Communicating

In this section we link history and philosophy of mathematics with conceptions of mathematics education and learning in order to identify different roles history and philosophy can play in mathematics education at university level.

The cultural argument for mathematics in education and a need for students to develop interdisciplinary competences both provide roles for the history and philosophy of mathematics in mathematics education. Mathematical knowledge is a historical and cultural product of human intellectual activity. Its development and thoughts are tied to arts, philosophy and science. By integrating history and philosophy in mathematics education, the cultural argument for mathematics in education is emphasised. Through interdisciplinary teaching, history and philosophy can play a role in mathematics teaching and learning in developing students' interdisciplinary competences by counteracting disciplinary narrow-mindedness (Beckmann 2009).

Both of these roles for the history and philosophy of mathematics in mathematics education are embedded in the competence-based view of mathematics education as developed by Mogens Niss (2004) in the Danish KOM-project.[13] In Niss' competence-based description of mathematics education, mathematics curricula on all levels are based on mathematical competencies instead of a catalogue of subjects, notions and results. In the KOM-project, eight main competencies were identified. They are divided into two groups: (1) a group that has to do with the ability to ask and answer questions within and with mathematics (thinking, problem tackling, modelling and reasoning competencies) and (2) a group that concerns abilities and familiarities with language and tools in mathematics (representing, symbol and formalism, communicating, aids and tools competencies). Besides developing students' mathematical competencies, mathematics education should also provide students with three second-order competencies, so-called overview and judgement, regarding mathematics as a discipline. The first concerns actual applications of mathematics in other areas, the second concerns the historical development of mathematics in culture and societies, and the third concerns the nature of mathematics as a discipline. The second one explicitly requires knowledge about history of mathematics, though not as an individual discipline (the goal is not to educate competent historians of mathematics), but to develop students' overview and judgement regarding the historical development of mathematics resting on concrete examples from the history of mathematics. The third one explicitly requires knowledge related to the philosophy of mathematics. In the examples of actual implementations and incorporations of history and/or philosophy of mathematics given in the next section, we will discuss the

---

[13] The project was called Competencies and Mathematical Learning. It was initiated by the Danish National Council for Science Education in 2000. For a shortened English version of the original report, see Niss and Højgaard (2011).

roles history and philosophy of mathematics (can) play in university mathematics programmes in the framework of mathematical competence.

The three types of overview and judgement concern the character of mathematics and its functions and roles in the world. This relates to issues that have been raised and researched in the field of critical mathematics education. In his paper 'Critical mathematics education for the future', Ole Skovsmose (2004, p. 10) points towards

> an important concern in mathematics education: Mathematics must be reflected on and criticised in its variety of forms of actions.

One of the aims in critical mathematics education is to develop in students the ability to critique the uses of mathematics. This relates to the first of the second-order competencies introduced above. In the next section we give an example of how history can function in mathematics education at university level with authentic cases that have the potential to develop students' ability to critique the uses of mathematics. Since critique is at the core of philosophy, it is also developed in the philosophy courses.

The last theoretical framework from mathematics education that we want to link to the role history of mathematics can play in mathematics education, is Anna Sfard's (2008) *Theory of thinking as communicating*. In Kjeldsen (2012) it is argued that, within this theory, history of mathematics can function at the core of what it means to learn mathematics. Sfard defines thinking as 'the individualized version of interpersonal communication' (Sfard 2008, p. xvii). Her theory is also referred to as the theory of commognition where the term commognition captures the combination of communication and cognition. Mathematical thinking is a human activity and Sfard treats mathematics as a type of discourse, where discourse 'refers to the totality of communicative activities, as practiced by a given community' (Sfard 2000, p. 160). Learning mathematics means to become a participant in mathematics discourse. Discursive patterns are the results of communicative processes that are regulated by rules. Sfard distinguishes between object-level rules and meta-level rules of mathematics discourse. Object-level rules concern the content of the discourse. Meta-level rules have the discourse itself as an object. They govern 'when to do what and *how* to do it' (Sfard 2008, pp. 201–202) – they are implicitly given. To develop proper meta-level rules is essential for becoming a participant in mathematics discourse. It is an important aspect of teaching and learning mathematics to create situations where meta-discursive rules are exhibited and made into explicit objects of reflection for students. These rules are contingent. They develop and change over time and as such they can be subject to historical investigations.

This is demonstrated in Kjeldsen and Blomhøj (2012) and Kjeldsen and Petersen (forthcoming) where it is shown how historical sources, investigated and interpreted within the mathematical practice of the historical actors, can function as 'interlocutors' that are following a set of meta-level rules within the mathematical community of their times. Through such historical investigations, students can become confronted with differences in metarules between rules that governed the mathematician(s) of the past episode they are studying, their own (maybe) and the rules of their textbooks and/or their teacher. In this way, meta-level rules can be revealed and turned into objects for students' reflections. This will be illustrated by one of the examples given in the next section of some students' investigations of a concrete mathematical episode from the past. From a philosophical view, we note that Sfard's position is just *one* possible view about mathematics in line with a social outlook on mathematical practice.

Within general mathematics education, philosophy of mathematics plays different types of roles. It is generally acknowledged that the teacher's conception of mathematics forms his or her teaching; see, e.g. Hersh (1979) and Lerman (1990). Chassapis (2007) therefore argues that it is relevant to train teachers in some kind of philosophy of mathematics and also shows one way to do it. Correspondingly it is also acknowledged that students' beliefs[14] on mathematics influence their learning. Prediger (2007) convincingly shows how addressing themes from philosophy of mathematics help pupils make sense of mathematical problems. She even argues that philosophical reflections *must* play a prominent role in the learning process.

With respect to beliefs about mathematics, two major camps are usually described. The discussion between these two sides is termed the 'science wars' (Ernest 2004). In one camp are the 'absolutist' views; these are often taken to include Platonism and Formalism. Ernest (1994) describes it as the 'Euclidean paradigm of mathematics as an objective, absolute, incorrigible, and rigidly hierarchical body of knowledge' (p. 1). In the other camp are the 'fallibilist' views. The often mentioned hero of this programme is Lakatos (1976). Other fallibilist views include Ernest (1998) and Bloor (1994), i.e. views that stress that mathematics is created by human beings and mathematical knowledge is as fallible as the rest of our knowledge. As a reason for the shift from absolutist views to fallibilist views is pointed to 'Gödel's theorems' which show that 'formal axiomatic systems can never be regarded as ultimate' (Ernest 1994, p.1). Another reason (which is more in line with the outlook of this paper) is the desire for a philosophy to pay attention to mathematical practice.

The roles philosophy play can be divided into three levels: the level of the individual, mathematics and society. On the mathematical level, one could claim that pupils/students should be able to reflect on the nature of mathematical objects and knowledge. As we have seen above, it is argued that such reflections are vital for both the learning and teaching of mathematics. On the level of society, as indicated above, educators have pointed to the social and political role that mathematics education (can) play. The 'Mathematics Education and Society' (MES) conferences were started in 1998 in Nottingham, UK, in order to focus on these roles. This perspective believes that there is much more to be said in mathematics education than a narrow picture of learning accomplished by an interrelation of the mind of a learner and (the value free and objective) mathematics to be learned. For one thing, it leaves out the class room and the teacher and the social relations between these which also affect learning. On a much broader scale are questions pertaining to the role of mathematics education in a particular society, such as who is included and what determines whether you are 'in' or 'out'? In some (most?) countries

---

[14] It is generally held that students' beliefs influence their learning, for example, that affective beliefs play a major role (Burton 2004). Here we are only interested in philosophical beliefs.

knowledge of mathematics is a ‘gatekeeper’ to the inclusion of the society (see Skovmose 2004). We will not delve more on these roles, but merely state that they are important and complex. Skovsmose (2004), for example, describes how mathematics education can empower or disempower, include or exclude and discriminate, advancing what he denotes critical mathematics education. Finally, at the level of the individual, it could be the case that awareness of philosophical matters concerning mathematics could help the individual learn and – as we will discuss later – even become better mathematicians.[15]

On the actual implementation of philosophy in the teaching of mathematics, not much is written. In secondary level mathematics, Flanders, François and Van Bendegem (2010) conclude there is little room for philosophy of mathematics. Concerning philosophy of mathematics for university education, the authors ask:

1. Is there room for philosophy of mathematics at university level? We answer YES!
2. If so, what kind of philosophical approach? Should one stress the fallibility of mathematical knowledge, should one stress the social nature of mathematics or should one stress the curious mechanisms that have led to such a strong consensus among mathematicians (François and Van Bendegem 2010)? We answer neither! All pictures could be presented. The point would be to introduce the questions to which these are answers as well as tools to deal with them, so that students may form their own conclusions.

In this chapter our task is to consider implementation and possible roles for history and philosophy for university mathematics students. It seems clear that these students must be considered among the included people of the society. They already know how to learn mathematics, and hopefully even like it. The role that philosophy should play in university education is thus clearly different. However, the roles introduced above are relevant in the following ways. We will argue below that both philosophy and history of mathematics will make mathematics students better as mathematicians, not necessarily because they learn more mathematics, but since they will be able to get a wider picture of their subject. We also find that mathematics students should *be made aware of* some of the social implications of mathematics, even though they themselves may not personally be affected by them. We return to a discussion of these roles when we have presented actual examples of implementing courses in history and philosophy of mathematics.

26.4 Examples of History in University Mathematics Programmes

In this section we will present and discuss some specific implementations of history in mathematics programmes at university level. We have chosen three examples that illustrate different ways and approaches of integrating history as well as different

---

[15] It has also been argued that knowledge of philosophy can turn you into a better person. Philosophy teaches rational thinking, and in particular, ethics deals with the good and bad.

roles history plays in these programmes. The third example comes from our own approach and will be treated in more depth. The examples will be presented, analysed and compared with respect to their aims, their learning objectives, their use of sources and the significance of history. The function of history in these implementations will be analysed within the conceptions of mathematics education and learning of mathematics that were introduced above. We will point out and explain situations where we find the approach of history and philosophy of mathematics from the perspective of mathematical practices particularly relevant for mathematics education at university level.

26.4.1 Ex. 1: History of Mathematics 1: Copenhagen University

History of Mathematics 1 is a course that is offered in the mathematics programme at Copenhagen University, Denmark. It has been developed and taught by Jesper Lützen, who is a historian of mathematics. The history course is placed at the bachelor's (undergraduate) level in the mathematics programme. The students who follow the course are mathematics students, who will finish with a university degree with a master's in mathematics or a master's in another subject and a bachelor's in mathematics. The study programme in mathematics is not divided into pure, applied or teacher education programmes, but History of Mathematics 1 (or a similar course in the history of mathematics) is required for students who (later on) decide to become high school teachers in mathematics.

The course is a general history of mathematics course and its main purpose is to teach a survey of the history of mathematics from ancient times to the present. The course book is Victor Katz's (2009) *A History of Mathematics: An Introduction* which is supplemented with a booklet (Lützen and Ramskov 1999) with selected sources and exercises comprised and developed for the course. The objectives of the course are formulated in terms of what the students should be capable of doing after following the course, namely, to[16]:

1. Communicate orally as well as in written form about the history of mathematics
2. Use the history of mathematics in connection with mathematics teaching and more generally reflect on the development of mathematics
3. Place a concrete piece of mathematics in its historical context
4. Find literature (primary as well as secondary) on the history of mathematics
5. Give a historical analysis of a mathematical text from the past
6. Independently formulate and analyse historical questions within a limited field
7. Use the history of mathematics as a background for reflections about the philosophical and social status of mathematics

These objectives are reached on one hand through broad lectures on various cultures and time periods following (more or less) the outline of Katz's book

---

[16] http://sis.ku.dk/kurser/viskursus.aspx?knr=121117&sprog=2&forrige=57876

and on the other hand through a small group-organised project work on either tangent and max-min methods or methods of quadrature and curvature. The aim of the project work

> is [subjectwise] to give the student insight into the early history of the differential and integral calculus. Methodologically, the aim is to give the students a chance to work together in a group on a subject from the history of mathematics, to interpret primary sources, assess the secondary literature, chose important aspects, formulate a written report, and constructively criticize the work of another group.[17]

All objectives are formulated with respect to history (of mathematics). The overall goal is to provide students with historical knowledge about the development of mathematics and develop their historical awareness. The connections to subject matter of mathematics come about through reading of secondary literature (Katz's book), through analyses of sources and through the project work. The content matter of mathematics is subordinate to the content matter of history and historiographical issues. The overall impression is that the cultural argument lies underneath this implementation of history in the mathematics programme at Copenhagen University. The description of the objectives of the course is rounded off with the following declaration of expected outcome:

> Moreover the course will show connections between different mathematical fields that may appear unconnected in the more specialized mathematics courses. It will help students to formulate and form opinions about meta-mathematical questions and will counteract the tendency to absolutism that can result from ordinary text books. The students will see that during history there have been many different approaches to mathematics and they will meet cases where there are still different views about mathematical and meta-mathematical questions. That will ripen the student's view of mathematics.[18]

Historiographically, the ambition is to have a scholarly approach to history where historical episodes are interpreted on their own terms with an emphasis on differences between now and then. We also see indications of arguments in line with Beckmann's (2009) argument for interdisciplinary teaching as a way to counteract disciplinary narrow-mindedness and history as a method for revealing connections between mathematical fields that appear autonomous and disconnected in mathematics study programmes in universities. There is also a focus on the changing of meta-level rules. Philosophical issues are addressed in the course in connection with the historical development of mathematics, and we have here a clear interaction between history and philosophy.

26.4.2 Ex 2: Teaching with Original Historical Sources in Mathematics: New Mexico State University

The second example we have chosen comes from the developmental work that has been going on at New Mexico State University, USA, from the late 1980s spearheaded by the Professors David Pengelley and Reinhard Laubenbacher.[19] Their idea

---

[17] http://sis.ku.dk/kurser/viskursus.aspx?knr=121117&sprog=2&forrige=57876

[18] http://sis.ku.dk/kurser/viskursus.aspx?knr=121117&sprog=2&forrige=57876

[19] http://sofia.nmsu.edu/~history/; http://www.cs.nmsu.edu/historical-projects

was to teach mathematics through primary historical sources. The group has developed and taught two undergraduate mathematics courses that are based on students' study of original sources from the history of mathematics. One of the courses is a lower division course in which students are introduced to 'great problems of mathematics'.[20] According to Laubenbacher and Pengelley (1992, p. 2), the course 'serves as an "Introduction to Mathematics" drawing good students to the subject [mathematics]'. The other course is called 'Great Theorems: The Art of Mathematics', and it functions as 'a capstone course for college juniors and seniors with substantial mathematics background' (Pengelley 2002, p. 1). A book for each course has been completed based on annotated original sources (Laubenbacher and Pengelley 1999; Knoebel et al. 2007). The courses (and the books) are centred around selected problems and theorems from different mathematical subjects. Each problem/theorem (chapter) comes with an extended introduction in which the authors present a chronicle of the problem/theorem often extending over several centuries.

Laubenbacher and Pengelley have presented the ideas behind their developmental work at conferences and in articles of which most can be found on their website 'Teaching with Original Sources in Mathematics'.[21] In contrast to what was the case at Copenhagen University, their aim is not to teach history of mathematics per se. Their aim is to teach mathematics through the use of mathematical sources from the past. Their work originated out of a critique of traditional undergraduate mathematics instruction in which they found a lack of motivation for abstract concepts and an approach in modern textbooks and typical instruction that 'deprives students of the sense that mathematics is a process … [and] … fail to illustrate the way mathematicians actually think about and work on problems' (Laubenbacher et al. 1994, p. 1). They wanted to remedy this by introducing a historical perspective in which the study of original sources is firmly integrated into 'all our courses, presenting these sources to motivate the modern theories they have spawned'. They provide two arguments for this:

> First, by reading original sources students are brought as close as possible to the experience of mathematical creation. … [Second], when students read original sources, they are initiated into the way mathematics is practiced. … Mathematicians at the cutting edge of their field don't read textbooks; they read research papers. (Laubenbacher et al. 1994, p. 2)

Hence, their argument for history in mathematics teaching at university level is pedagogical. Students should learn from the masters of the past.

In Jensen's terminology, we are dealing with the use of history that is guided by the idea that we can learn from history, i.e. a pragmatic use of history. The historical sources are subordinate to the mathematics. The selection and the reading of the sources are guided not by historical questions, but with respect to how central they are for the curriculum and their utility with respect to the learning of modern mathematics. Many of the exercises presented to the problems/theorems the courses are evolving around are mathematical questions aimed at understanding the modern theories.

---

[20] http://sofia.nmsu.edu/~history/

[21] http://sofia.nmsu.edu/~history/

In the preface to their second book, they describe some of the benefits they have observed of using the past in this way as an approach to teaching mathematics. They write:

> Although teaching and learning with primary historical sources requires a commitment of study, the investment yields the rewards of a deeper understanding of the subject, an appreciation of its details, and a glimpse into the direction research has taken. (Knoebel et al. 2007, p. v)
>
> Primary sources also inject students directly into the process of mathematical research. They become active participants at the cutting edge of their own knowledge, experiencing actual research through grappling with the writings of great thinkers of the past. This creative immersion into the challenges of the past helps students better understand the problems of today. (Knoebel et al 2007, p. vi)

The main point is to learn mathematics, and history is used in the sense that the reading of the sources from the past is used as a pedagogical teaching method to teach students mathematics in an inquiry, research-like way. It can be argued that this approach to teaching has the potential to train, evoke and develop many of the eight mathematical competencies from Niss' conception of mathematics education. Historiographic and philosophical issues do not seem to play any significant role. In this respect, the courses differ fundamentally from the history of mathematics course taught at Copenhagen University. The selected sources also play very different roles in the two settings. In the booklet completed for the course in Copenhagen, the selection of the sources have been guided by historical and philosophical issues regarding the development and understanding of mathematics in the corresponding time period. The students are guided in their reading of the sources through questions that also point out how the mathematics of the past differs from our modern understanding and how the rules of the game have changed over time. In the courses developed at New Mexico State University, the selection of the sources has been guided by pedagogical principles (Barnett et al. 2011, p. 188). The sources play the role of authentic pieces of mathematics at research level for their time. They provide a context in which students can gain experiences with mathematical research processes. The students are guided in their reading of the sources through mathematical questions, and often they are asked to connect the mathematics of the source with the way it is presented in modern textbooks. The sources function as motivation for our modern theories and concepts.

Pengelley and his group have by now integrated their pedagogical approach of learning from the masters into many of the regular mathematics courses in the curriculum at New Mexico State University. This is done mostly in the form of modular projects.[22] Their goal is to allow students to learn all their mathematics in regular courses from primary sources. According to Pengelley, the 'team has now taught at least 3 of the regular dept. courses entirely from the projects we have developed, no more textbook'.[23] Some of these projects have also been implemented at Colorado State University (Barnett 2012).

[23] Personal e-mail correspondence between David Pengelley and Tinne Hoff Kjeldsen on Monday the 25. of June, 2012.

26.4.3 Ex 3: Problem-Oriented Student-Directed Project Work: The RUC Model, Roskilde University

The last example of specific implementations of history (and philosophy) in mathematics education comes from the educational practice at Roskilde University in Denmark. Historical and philosophical perspectives on mathematics are implemented through problem-oriented, student-directed and group-organised project work. We have chosen to present three such projects. One of us (Tinne Hoff Kjeldsen) was supervising professor for two of the projects and was consulted as a supervisor by the group of students who completed the third project. The project works are exemplars of our own approach.

As will be explained below, the problem-oriented, student-directed and group-organised project work (the RUC model) as it is carried out at Roskilde University creates very complex learning situations for students. Hence, each project work has potential for multifaceted learning outcomes. However, in our presentation and discussion of the three projects, we have singled out in each of them one particular aspect of (possible) roles history and/or philosophy play in the mathematics education at Roskilde University.

All study programmes at Roskilde University are based on the four overarching pedagogical principles of problem orientation, student-directed project work, interdisciplinarity and exemplarity which constitute the RUC model (Salling Olesen and Højgaard Jensen 1999, pp. 16–17). In each semester the students participate in project work of their own choice. At the beginning of the semester, the students in a particular study programme form groups of 3–8 students in accordance with their interests.[24] They formulate a problem that they want to work on throughout the semester. A problem is eligible if it fulfils the requirements for the students' semester, e.g. in the mathematics programme each student participates in three projects, fulfilling three semester requirements: a 'modelling' requirement, a 'mathematics as a discipline' requirement and a 'profession'[25] requirement.[26] The justification for the project requirements is a mixture of the cultural argument, an argument for interdisciplinarity in its own right and as a vaccination against disciplinary narrow-mindedness, and arguments similar to those of the critical mathematics education: in the project work the students come to reflect upon and criticise mathematics in some of its forms of actions. In the project work, the students develop their three second-order competencies of overview and judgement from Niss' competence description of mathematics education presented above.

---

[24] Three to eight students is the common group size, but students are allowed to perform a project on their own.

[25] Under the 'profession' requirement, the students have a choice between a modelling project, a pure mathematics project, a history and/or philosophy of mathematics project or a project on aspects of mathematics education, according to in what kind of direction, they want their future profession to move.

[26] See also Niss' (2001) narrative on his 25 years of experiences with the RUC model.

The projects where history and/or philosophy of mathematics enters are the ‘mathematics as a discipline’ projects and sometimes the profession projects. Before the students enter into the mathematics programme, they have completed a four semester interdisciplinary science programme (Blomhøj and Kjeldsen 2009). In this programme, the project requirement for the third semester is a ‘meta’ requirement, meaning that the students should work with a problem through which they will gain experiences with science as a cultural and social phenomenon. Of the three projects we discuss below, the first two are ‘mathematics as a discipline’ projects from the master’s programme whereas the third one is a ‘meta’ project performed in the 2-year interdisciplinary science programme (Kjeldsen and Blomhøj 2009). The projects are only constrained by these requirements. The problem a group of students chose to work on in a project should fulfil the requirements, and the project should meet the academic level to be expected of students who have reached the corresponding semester. There are no requirements on the content of the project work. The content is determined by the problem the students decide to work on. During the first 1–2 weeks of each semester, the students form groups based on their interests. Suggestions for problems will be raised, discussed and qualified in discussions between students and the professors who are going to be assigned as supervisors for the semester.

When the groups are formed, they will write an application to the board of study seeking approval of their problem and their project. They will also indicate which professor(s) they would like to have as a supervisor. The supervisor will follow the group throughout the entire semester. Normally, the group will meet with the supervisor once or twice a week for 1–2 h. The agenda of the meetings often comes from the students. They decide what they want to discuss, what they need help with and how they want to ‘use’ their supervisor. The supervisor makes sure that the academic standards are met and will let the students know if they are on a false track. In the RUC model, the project work can be thought of as student research projects. In each semester every student is part of a research team of fellow students, who perform a research project guided by the problem they chose to work on and by a supervising professor.

In the following we will present and discuss three specific student projects from the RUC model. As should be clear by now, the RUC project work creates a very complex studying and learning environment for the students. However, in the following we will focus, as mentioned above, on only one aspect of learning outcome for each project and leave the rest aside.

Project 1

Generalisations in the Theory of Integration: An Investigation of the Lebesgue Integral, the Radon Integral and the Perron Integral

This project was performed by two students. The students documented their work in a written report of 75 pages.[27] It originated out of a curiosity about different

---

[27] The students’ project report can be downloaded at the following address: http://milne.ruc.dk/ImfufaTekster/pdf/403.pdf.

types of integrals. In the students' first analysis course, there was a footnote in the textbook that pointed out that there exists functions that are not Riemann integrable and that there are other types of integrals that can handle more functions than the Riemann integral, e.g. the Lebesgue integral. The two students wanted to investigate what these other types of integration can do. They immediately found out that the Lebesgue integral is just one of many different integrals. There is also the Denjoy, the Perron, the Henstock, the Radon, the Stieltjes and the Burkill integral, to mention just a few. The students noticed that they were often presented in the literature as generalisations of either the Riemann or the Lebesgue integral. These observations generated a bunch of questions (we are quoting from the students' project report): 'What do these integrals do? Why have so many types of integrals been developed? Why is it always the Lebesgue integral we hear about? What is meant by generalization in this respect? In what sense are the various integrals generalizations of former definitions of integrals? Are the generalizations of the same character?' (Timmermann and Uhre 2001, p. 1).[28]

In the end the students' project work was guided by the following problem:

> What were Lebesgue, Perron and Radon motivated by in their pursuit of their generalizations of the integral?
>
> What are the character and scope of the generalizations by Lebesgue, Perron and Radon, and what are the differences between them? (Timmermann and Uhre 2001, p. 3)

The students performed a historical study to answer the first part of their problem formulation. In Jensen's terminology, they had a scholarly approach to history. They studied a concrete episode from the history of mathematics from the perspective of the historical actors' motivation to extend and generalise the concept of the integral. The students read a selected variety of sources – Journal articles and books by Denjoy, Henstock, Lebesgue, Perron and Radon – with focus on the work of the last three mathematicians. For example, with respect to Lebesgue, the students read his note *Sur une généralisation de l'intégrale définie* which was published in *Comptes Rendus de l'Académie des Sciences de Paris* in 1901 and his thesis *Intégrale, Longueur, Aire* from 1902. They interpreted his motivation for the generalisation of the integral concept, as they explained in their report, 'detached from the context in which it is part of today and detached from our knowledge of the later significance of the concept' (Timmermann and Uhre 2001, p. 4).

As in the courses at New Mexico, the students studied the masters by reading research literature from a past episode in the history of mathematics, but in contrast to the courses at New Mexico, they were not guided by mathematical questions, but by historical questions. However, these questions were answered with reference to analyses of the mathematical content, theorems, definitions, proofs and techniques of the sources. In this way, the students gained first-hand experiences with processes and initiations of research in pure mathematics. With regard to mathematical competencies, an analysis of the students' work shows that six of the eight competencies

were invoked and trained during this project work, but the main purpose of their project was to develop their second-order competency of overview and judgement regarding the historical development of mathematics.

Project 2

Fourier and the Concept of a Function: The Transition from Euler's to Dirichlet's Concept of a Function

This project was designed and completed by four master students.[29] Their project work was guided by the following interest and curiosity:

> We wish to investigate the significance of Fourier for the development of the concept of a function. (Godiksen et al. 2003, p. 2)

The students analysed relevant sources from the works of Euler, Fourier and Dirichlet with respect to changes in as well as discussions about the concept of a function and the proper way to argue with functions. The relevance of the reading of sources from these three mathematicians was explained in the following way in the students' project report:

> The strength of focusing on these three mathematicians is, that it has given us the opportunity to study their original works (sometimes in translations) in depth, which have given us a more direct impression of their thoughts than secondary literature could have given us. (Godiksen et al. 2003, pp. 2–3)

We are again dealing with an ambition of employing a scholarly approach to history. The students wanted to interpret the past on its own terms. In their project report, they compared the works in the sources by Euler, Fourier and Dirichlet with each other and with our modern approach. They used the sources as 'interlocutors' emphasising the central ideas and the differences. With respect to Euler's concept of a function, the students' wrote in their report:

> The main elements of Euler's conception of a function could easily be explained very shortly, but that would not contribute to any deep understanding of the concept. In order to obtain this, one has to *look* at how Euler worked with functions. (Godiksen et al. 2003, p. 17; italic in the original)

In order to understand Euler's conception of a function, the students point out that it is necessary to study Euler's mathematical practice – how *he* worked on and used functions. The students gave the following interpretation of Euler's conception of a function:

> The definition of a function [Euler's definition] does not contain any specific information about its domain and image. This is because in Euler's theory, variable quantities are ascribed a property that render specifications of such sets superfluous. …
>
> … Euler conceived a variable as an arbitrary element, quite like our conception, but no constraints are allowed. The variable should be able to take all values … (it is universal). (Godiksen et al. 2003, p. 18)

---

[29] The students' project report can be downloaded at the following address: http://milne.ruc.dk/ImfufaTekster/pdf/416.pdf.

Euler's analysis is global in nature – variables were universal, they were not limited in scope, and hence, Euler's functions had the property of analytic continuation. The students identified two meta-level rules of Euler's mathematical discourse: the generality of the variable and the general validity of analysis – two rules that were revealed and made into objects of the students' reflection through this historical project work, as can be seen from the following discussion in the students' report, where they wrote:

> This property which […] has been named the criteria of the *generality of the variable* clearly reflects the earlier mentioned paradigm of *the general validity of analysis*.
>
> […]
>
> Even though the use of the methods of analysis often created weird results the methods were used frequently in Euler's concept of a function. The reason why there weren't that many contradictions and paradoxes was that almost all Euler functions, which consists of analytical expressions, *have* all the above mentioned properties [they were nice], except maybe in isolated points. … Hence, there was no natural driving force that led to a clarification of the concepts of continuity, differentiability, and integration, since these properties so to speak were built into the concept of a function. (Godiksen et al. 2003, p. 22; italic in the original)

As pointed out by the students:

> Euler … was of the opinion that the analysis had to be developed such that it was able to describe all situations that occur in nature. (Godiksen et al. 2003, p. 23)

And in their treatment of Fourier's work, they continued:

> Fourier expresses clearly that mathematics is a tool for describing nature and mathematics had to be governed by nature. (Godiksen et al. 2003, p. 53)

The idea that mathematics has to be governed by nature is a third meta-level rule of past mathematical discourse that became exposed for the students and became an explicit object of reflection for them.

The students wrote a report of 88 pages explaining, analysing and interpreting the mathematics and the ideas about mathematics in the sources in order to answer their problem formulation. Again, it can be argued that six of the eight main mathematical competencies were invoked and trained during the project work together with the second-order competencies of history and philosophy. Here we have focused only on how this project work in history of mathematics functioned as a learning and teaching situation for students to experience meta-level rules in mathematics discourse and gain experiences with how these change over time (for further details, see Kjeldsen and Blomhøj (2012)). Within Sfard's theory of thinking as communicating, this project work is an example of how history of mathematics can function at the core of what it means to learn mathematics, as explained above.

Project 3

Rashevsky's Pride and Prejudice

The two projects discussed above relate to the two second-order competencies of history and the nature of mathematics. The project presented here on Nicolas Rashevsky's model for cell division from the 1930s relates to the third second-order competency of gaining knowledge about and experiences with actual applications of mathematics in other areas. In this case, it is the application of mathematics as a practice in other sciences. The project was conducted by four students. They read a paper by the physicist Nicolas Rashevsky (1934), where he discussed what he called *physico-mathematical aspects of cellular multiplication and development*. He presented the paper at a Cold Spring Harbor symposium on quantitative biology (see Keller (2002), and Abraham (2004)). His talk was followed by a discussion where the biologists in the audience were very critical of Rashevsky's approach in explaining cell division. Rashevsky's talk and the discussion were published from the proceedings of the meeting.

The students were curious about the hostile attitude of the biologists. They formulated the following problem that guided their project work:

> Why was Rashevsky unable to get through to the biologists of his time with his ideas? Was it because the biologists could not accept Rashevsky's scientific method? If so, was this then caused by a fundamental difference in biologists and physicists conception of biology and were/are controversies about the scientific method then a manifestation of this difference? (Andersen et al. 2003, p. 2)

The students studied the status of biology and of mathematics and physics in biology in the 1930s to understand the scientific culture of biologists and their conception of the significance of physics and mathematics in biology at the time. In reading Rashevsky's paper, the students became aware that he held a reductionist view of science. The students studied philosophy of biology and physics in order to understand whether the differences in opinion between the biologists and Rashevsky could be explained by differences in philosophical standpoints about science. Rashevsky's strategy was to take a general phenomenon that occurs in all cells and investigate its mathematical consequences. He chose cell metabolism. If, as he wrote in the paper, the process of division is found among such consequences, then cell division can be explained logically and mathematically as a direct consequence of the forces arising from cell metabolism.

In order to understand the critique raised by the biologists, the students had to read and understand Rashevsky's paper. It can be argued that in this process all eight mathematical competencies were invoked and trained. Regarding the second-order competency of gaining knowledge about actual applications of mathematics in other areas, the students experienced that the validity of arguments depends on the scientific context. For further details, see Kjeldsen (2010) and Kjeldsen and Blomhøj (2009). The students' historical and philosophical investigations in the project work contributed to critical mathematics education in the sense of Skovsmose, since the students came to reflect upon and criticise a form of action of mathematics, the action of mathematics in the production of knowledge in other scientific areas. For further details, see Kjeldsen and Blomhøj (2013).

The upper level undergraduate courses at Copenhagen University and New Mexico State University and the RUC model of project work at Roskilde University all address students who educationally wise are similar. However, the arguments, aims and objectives of the three different approaches of integrating history into the mathematics study programmes are, as we have seen, quite different. The project work in a sense combines the two approaches from Copenhagen and New Mexico. The problem, the students work on in the RUC model, is a so-called metaproblem. It is a problem *about* mathematics, historical and sometimes also philosophical, but the students' domain of inquiry is the mathematics of the past. In order to answer their problem formulation, the students work as historians (and philosophers) with historical (philosophical) problems. To get answers, they dig into the sources, studying and interpreting the mathematics – though not from a modern perspective, as is the case in the New Mexico approach, but from the historical actors' perspective within their mathematical practice.

26.5 Examples of Philosophy in University Mathematics Programmes

26.5.1 Philosophy of Science in University Education in Denmark: Aims

In 2000 the Danish Government and the Association of Vice-chancellors of Danish Universities decided to reintroduce a philosophy course for all university students.[30] This new course is called 'Fagets videnskabsteori' which translates to 'philosophy of science of the subject of study'. The overall aim of this course is to qualify students' specialisation in their subject by allowing them to see it from a broader and more general perspective. Ten specific points were listed as requirements; see http://www.nbi.dk/~natphil/FVT/i_Alment.html. We mention in particular 3 and 4 that address the particular implementation of these courses, requiring (i) that the courses should be research based and (ii) that the curriculum should 'take interesting questions from the field of study and combine them with questions of a more general kind'.

The overall aim was to address the question of how knowledge is tackled in a knowledge society. A university graduate should not only know narrowly his/her own subject but should also obtain competencies within values and perspectives and be able to reflect. These aims are elaborated on by Professor Hans Fink, who was one of the researchers involved in the discussions prior to the Bill (Fink 2001). He states that the overall aim is to produce better students and to prepare them for the job market. He says:

> We thought that a course that allows the students to reflect on their subject's distinctive philosophical character, seen in a wider, general, philosophical, and historical context,[31] would be well-founded, if it could forestall the risk that the students' professional absorption

---

[30] Until 1971 it was compulsory for all university students in Denmark to take an introductory philosophy course, so-called filosofikum. This course was mainly handled by philosophers.

[31] In addition 'videnskabsteori' is mentioned. It is best translated as 'theory of science' and is usually thought of more broadly than philosophy of science, including social science, history of science and ethics.

> leads to narrow-mindedness that makes them less fit to engage with the interdisciplinary connections that they will later have to deal with. A course like this will also counter the often criticised schoolification of the universities by encouraging the students to systematic reflection about what a university, science and research actually are. … Finally, the course could fulfil a large need of society, if it could ensure that everyone with a university degree is given the opportunity to make clear the social and ethical responsibility of both science and the individual researcher.

It is thus clear that the aims of this course are broad. One major requirement, however, is that all these reflections take as a starting point the actual subject. The course – in mathematics – should therefore:

1. Include philosophical reflections relevant to the subject in question, i.e. mathematics.
2. Place the subject in a wider context, e.g. discuss mathematics' distinctiveness in relation to other subjects.
3. Discuss the role of mathematics, research and universities in society.
4. Discuss ethical questions relevant to the subject.

Overall the stress is on the students' abilities to *reflect* and *critically examine ideas*. These are philosophical competencies, so the core of the course is a philosophical one. This means in particular that the course should not dictate any one perspective as the right perspective, but should aim at giving the students tools to handle these competencies. In what follows we present examples of how this course is implemented.

26.5.2 Implementation of Philosophy of Science Course in Aarhus University and University of Southern Denmark

In what follows we give concrete examples of how this course is handled at the Universities of Aarhus (AU) and Southern Denmark (USD). The overall structure of both courses is the same. Both courses' credit is 5 ECTS. They include common lectures, presentations by students, discussions and group projects, and they address the above-mentioned points. Many of the included topics are the same. But there are differences in how these are presented. We present Aarhus first, since the Centre for Science Studies at Aarhus University has devoted much time to develop a 'philosophy' on how to handle courses on the philosophy of natural science. In a recent paper Kragh Sørensen writes:

> We have adopted a teaching philosophy of using historical and contemporary case studies to anchor broader philosophical discussions in the particular subject discipline under consideration. Thus, the courses are tailored to the interests of the students of the particular programme whilst aiming for broader and important philosophical themes as well as addressing the specific mandated requirements to integrate philosophy, some introductory ethics, and some institutional history. These are multiple and diverse purposes which cannot be met except by compromise. (Kragh Sørensen 2012, p. 1)

The course starts by addressing the question ‘what is mathematics?’ and includes topics like the application of mathematics, discussing the question concerning ‘The Unreasonable Effectiveness of Mathematics in the Natural Sciences’ (Wigner 1960) and issues concerning modelling, the role of proofs and the foundation of mathematics and the role of mathematics and university in society, including mathematics and gender and ethical issues. To give a better sense of how this philosophy works in practice, we present two examples in more detail. One concerns the role of proof in mathematics, the other, the (unreasonable effectiveness of the) applications of mathematics.

Example 1

When dealing with the role of proofs, the course takes as a starting point a general held belief, presumably also among the students. A proof is taken to be[32]:

- Axiomatic deductive, obtained from accepted assumptions
- Employing logical steps in a specified logical system
- (In principal) fully formalised (or possible to formalise)

For homework the students are asked to consider the following questions:

- What is the difference between foundation and practice?
- What is the difference between formal and rigorous proofs?
- What is the foundation, and how certain is it?
- Can proofs prove or can they (at most) convince?

The aim of the treatment of this topic is to ‘enable discussions about proofs that go beyond the idea that proofs merely guarantee truth’. In addition, the teacher ‘wishes to emphasise the role of proofs as tools of communication in a mathematical discourse’ (personal communication).

The first case study to challenge the standard conception of proof is Perelman’s proof of the Poincaré assumption. This case shows, among other things, that the mathematical community may disagree on whether a presented proof is actually a proof. It also illustrates different motives for pursuing a mathematical career – fame, glory and money – or the pleasure of obtaining insight. Later the course considers the role of proof in more detail. In order to discuss this theme, for example, Wiles’ proof of Fermat’s last theorem is presented. This case challenges the standard conception of proof. For one thing, the proof is too long and too complicated for the average mathematician to follow it through. This leads to a discussion about how one trusts a given proof and which criteria should hold for a ‘good proof’. The discussion brings in many examples from current mathematical practice. The phenomena of experimental mathematics (and use of computers in mathematical proofs in general) are treated in order to discuss, for example, the notion that mathematical proofs and knowledge are a priori.

---

[32] The following is taken – and translated – from slides used in the course.

Example 2

Questions pertaining to the conception and role of a proof could be taken to be internal to mathematics. In contrast are questions concerning the relation between mathematics and reality. One question that has puzzled philosophers and scientists concerns 'The Unreasonable Effectiveness of Mathematics in the Natural Sciences' (Wigner 1960). It is clear that mathematics is applied to the real world. Since the modern development of mathematics, however, it has been a challenge to explain actually why and how mathematics can be applied. The answers – and the degree of mystery involved – depend on which view of mathematics is taken. Wigner presents a view of mathematics, where concepts are developed with no connections to considerations of the world but in order to develop beautiful and interesting theorems. On this view, it is clearly a mystery that mathematics can say anything about the physical world. Several solutions to this problem have been offered; see, for example, Grattan-Guinness (2008). The course in Aarhus introduces this question and indicates how proponents of different views would account for the applicability (Platonism, Formalism, Kant, Empiricism). In addition, some case studies are introduced in order to qualify the discussion. One example illustrates interrelation between development of mathematics and – in this case – chemistry. It tells part of the story on the development of crystallography. In this theory crystals are modelled as certain lattices with symmetry properties (translation and rotation). According to the main theorem of crystallography, crystals can only have certain types of symmetries. In 1984, however, a crystal was found contradicting this result. This led to the notion of a quasicrystal and an ongoing search for a mathematical theory describing these.

The course also stresses the point made by several mathematicians (Hilbert 1902; Poulsen 2001, and Toft 2001) that mathematics solves *problems*. Problems can be either internal mathematical problems or external problems.

An important part of this topic is 'to point out and discuss the difference between a mathematical model and the part of reality that it is supposed to be a model of. In this lies also the task to point out the choices (perhaps even theory-laden) made when formulating the model, and the relations one could (wrongly) think there is between a model and reality. This leads to the possibility of discussing predictions made from mathematics and mathematical explanations in natural science' (personal communication with Kragh Sørensen). Mathematical models are widely used in today's society and for many different purposes. In some uses, models are tools to solve problems. As such, they can be very simple or extremely complicated giving rise to a whole range of problems.[33] Mathematical models are also used in arguments. When used in this way, it is important to be aware of the fact that a model can at most tell something about the actual data or assumptions put into the model. If the model is complex, meaning that the resulting mathematical problem cannot be solved by exact methods, it may not even give certain results about these. Even so, mathematical models are

---

[33] The topic of the role of models in society is also dealt with at USD, and the following description is mainly based on the treatment there.

often used in, for example, political debates, where the certainty of mathematics (faultily) is attributed to the model (see Kjeldsen 2011b). When teaching this topic, the students are shown traditional steps of a modelling process and are asked to think these through for various examples. In addition they find examples of models used in society, discussing which roles they play and – if possible – which assumptions have been made when formulating the model.

Overall, the philosophy of allowing examples to generate the philosophical discussion seems to work. In order to generate and qualify the discussion, however, certain philosophical theories and notions need to be explained as the course moves along. It is also the case that certain convictions the students (may) hold need to be explicitly stated before they are discussed as was the case in the first example, where the standard conception of proof is discussed. This is not surprising, since we are dealing with mathematics students, not philosophers. It takes training to think philosophically, i.e. to be able to pose the relevant questions or to pose questions at all and to learn to use tools to handle these questions.

26.5.3 Example from University of Southern Denmark

In contrast, the course in Odense takes as a starting point certain *philosophical questions* and tries to answer these based on actual examples of mathematics. When entering the mathematics programme at USD, a student will take courses within natural science during the first year – together with all students who wish to study natural science. The philosophy behind this is to strengthen the interdisciplinarity of subjects within natural science. This philosophy carries through to the course in the philosophy of science, where there is a common core and the lectures are held for all students. The course also consists of a subject-based part so that, for example, mathematics students have a number of classes that addresses issues particularly relevant for mathematics. In the common part, it is possible to address general themes such as the distinctiveness of natural science and mathematics, ethics and the role of research and university in society. We also treat ‘standard’ schools in philosophy of science, such as inductivism, Popper’s critical rationalism and Kuhn’s paradigms and revolutions. The point here is not so much to discuss these from a philosophical point of view, rather it is to see which questions they raise and how they propose to answer them. The main idea is to consider these questions and answers in the light of their subject. As a supplement, the students are presented a number of case studies, illustrating and challenging conceptions of science. These examples range from the overthrow of the Phlogiston theory to discussions concerning Creationism and Intelligent Design and the status of research in particle physics.

In Danish, the word for science is ‘videnskab’. It includes ‘viden’ which means knowledge and infers that it is a practice that yields knowledge. Students are given the philosophical definition of knowledge as ‘justified true belief’ and are encouraged throughout the course to reflect on whether the methods used in their discipline do in fact yield knowledge in this sense. It is also stressed many times during the course that it poses questions and provides *possible* answers and their job is to reflect on these answers, finding their own.

Example 3

The final example concerns the question about the nature of mathematical objects. In the lecture, the students are introduced to the realism-antirealism debate in the philosophy of science. One point is that even in natural science – that supposedly should concern the real world – there are questions to ponder about. For a first example, take the phlogiston theory that during part of the eighteenth century was held to explain processes of combustion. This theory was overthrown by Lavoisier's theory stating that oxygen is the fundamental matter at play in such processes. The question is whether our theories today could suffer the same fate or our current scientific theories are better? If they answer yes to this last question, the challenge is to argue just *how* these theories are better and even explain what a 'better' theory means. Most scientists' intuitions will tell them that there is progress in the development of scientific theories. The challenge is to explain in which sense. A more recent example concerns the theory of dark matter and energy. So far we (the scientists) only have circumstantial evidence that these types of 'objects' exist. Scientists have never seen (it cannot be observed, since it does not radiate electromagnetic force) or isolated samples of dark matter. Even so, they are convinced it exists (see Sannino 2009). This raises the challenge to formulate rational criteria to determine whether something exists. Within philosophy of mathematics is the dispute on whether mathematical objects exist independently of human beings, in case one is a realist – or Platonist – or whether they do not, in which case one is an antirealist. The way this question is tackled is to present the students with:

- A number of different versions of realist and antirealist positions. Pointing out that there are many possibilities for being of each kind.[34]
- Equally important, the motivation for and arguments typically given in favour both of realism and antirealism. Realists would, for example, argue that mathematical propositions are true, and then it follows from a correspondence theory of truth that mathematical objects exist. An influential argument which dates back to Frege but is usually credited to Quine is the indispensability argument (Colyvan 2001; Shapiro 2000). It combines the fact that mathematics is indispensable to natural science with a confirmational holism[35] and an ontological commitment to entities of any accepted theory. Anti-realists in turn argue (with Benacerraf 1973) that the existence of abstract mathematical objects outside of space and time makes it a mystery of how we obtain knowledge in mathematics.

---

[34] Maddy's (1990) set theoretic realism and Shapiro's (2000) ante rem structuralism are examples of what is presented. In addition we discuss Field's (1980) fictionalism and the empiricism of Mill.

[35] A scientific theory is confirmed as a whole. If mathematics is part of a confirmed scientific theory, then the included mathematics is also confirmed.

> A popular strand of anti-realism is fictionalism, denying that mathematical statements are true (else realism follows) rather they are a certain kind of fictitious statements.

Based on these positions, arguments and motivations, the students are asked to determine for themselves which kind of position they find most convincing. When doing this they are, of course, asked to take into account their own experience with mathematics. Taking any one position also requires producing arguments for this position and in some cases countering the arguments of the other side. As an example, one could question the statement that mathematical sentences are true in the same sense as ordinary sentences or that mathematical theories are confirmed alongside scientific theories.

In addition we have responsibility to show students the many sides of mathematics that they do not encounter in their traditional lectures. They are most often taught from textbooks.[36] These are re-presentations of the mathematical theories, definitions, theorems and proofs as presented in research articles, presented in a form that intends making it accessible for the student. In this form, however, the original presentation and motivation is often lost. What else is missing is the, often long, process leading to the results in question.

26.5.4 Are the Aims Fulfilled?

The examples given mainly address aim number 1, i.e. introducing students to philosophical questions to their subject. We hope to have conveyed in the above presentation that we aim at the following:

1. Making the students aware of some of the philosophical questions underpinning their subject.
2. Providing them with tools to tackle these questions, by teaching them a certain terminology, positions and ways of thinking distinct to philosophy.
3. An emphasis on the fact that they are mathematicians, so that their expertise when dealing with such questions lies in the ability to critically examine mathematical assumptions and point to misconceptions about mathematics.
4. It is also our task to show our students a variety of examples enabling them to fulfil 3.

These aims are in part achieved. In general, however, we find that students are not particularly motivated to take the courses in philosophy of science. It is our impression, though, that most students appreciate the course more after finding out what it is actually about. As we were about to write this chapter, the second author of the present chapter asked students from her last class about their thoughts

---

[36] In Aarhus and Copenhagen, it is very common for teachers to write their own textbook material.

concerning the relevance of such a course. One student complains that he/she does not find it relevant now, but still concludes that it might later lead to some reflections. Among the positive responses, a student found the course relevant, because it teaches them to think differently. Answers like this are particularly welcome!

We recall the three types of second-order competencies. The first competency addresses applications of mathematics whereas the other two concerned the historical development of mathematics as well as its nature. It is clear that the courses in philosophy of mathematics described above intend to provide students with competencies in order to deal with both the problems concerning various applications of mathematics as well as fundamental questions regarding mathematics. More specifically, we find that one major role (on the mathematical level) these courses play is to present *a wider picture of mathematics* than is usually given in regular mathematics courses. Students are shown that mathematics is more than 'definition-theorem-proof' – a picture objected to by the Fields medallist Thurston (1994). The intention is to get them behind the scenes of doing mathematics. A related role is to enable and convince mathematics students to become ambassadors of mathematics. For one thing, they, if no one else, should be able to say something about what mathematics is, its distinctiveness and importance (mathematics is actually used everywhere in our society), and that mathematics need not be frightening.

Students ought to also be aware of some of the ethical problems concerning application of mathematics – or applications in general – and have some tools to handle these.

Finally, the course may even help them on a personal level in their mathematical studies. Philosophy as well as mathematics seeks *arguments*. Training to argue within philosophy strengthens ability to argue correctly in mathematical reasoning.

26.6 Conclusion

Comparing the identified roles of the courses in history and philosophy of mathematics, we find that they (to a large extent) coincide. On the mathematical level, one motivation for both history and philosophy is to provide students with a wider picture of mathematics, in particular to include meta- mathematical considerations 'preventing the absolutist tendency of mathematics textbooks'. On a social, or cultural, level is the motivation of interdisciplinarity counteracting disciplinary narrow-mindedness (Beckmann 2009; Fink 2001). In addition is a responsibility to show the political and social roles of mathematics, which can be done by both history and philosophy. On a personal level it is argued that including historical and philosophical perspectives make the students better mathematicians. We have even seen that both perspectives can be used to strengthen their abilities in mathematics. Philosophy of mathematics does this, for example, by teaching them to argue.

Although history and philosophy are quite different (history analyses and interprets sources and searches for explanations for historical processes of change – philosophy poses questions, critically examines ideas and provides arguments), they do interact in fundamental ways. In the history courses, most notably in the group projects, the motivations for doing the historical studies were in some cases philosophical. For example, the question concerning different types of generality, posed by the first group, is a philosophical question. Similarly, the aims of the philosophy courses could not be fulfilled without a handful of good (historical) cases to show to the students.

One remaining challenge is to convince students that courses like these are important for their mathematical training. It is also an open question whether the students actually benefit and use tools obtained from these courses in their professional careers.

Tinne Hoff Kjeldsen is Associate Professor at IMFUFA, Department of Science, Systems and Models at Roskilde University, Denmark. Kjeldsen has a master's degree in mathematics from Copenhagen University and a Ph.D. degree in history of mathematics from IMFUFA, Roskilde University, from 1999. Her historical research has helped to identify, define and clarify forces of internal mathematical and external sociological nature that have driven developments of pure and applied mathematics in the twentieth century. In particular, she has focused on the history of the moment problem, game theory, the development of the theory of linear and nonlinear programming in the post-war USA and the emergence and development of the theory of linear inequality systems. She is currently working on the history of the modern theory of convexity; see, e.g. 'Egg-forms and Measure Bodies: Different Mathematical Practices in the Early History of the Development of the Modern Theory of Convexity'. (*Science in Context*, 2009). Her research in didactics of mathematics focuses on roles of modelling and history for the teaching and learning of mathematics; see, e.g. 'Beyond Motivation - History as a method for the learning of meta-discursive rules in mathematics' (*Educational Studies in Mathematics*, 2012). She has been an invited lecturer at numerous international conferences in Europe, North and South America and Asia. Her research is published in books and major journals of history, philosophy and didactics of mathematics and science.

Jessica Carter is Associate Professor at the Department of Mathematics and Computer Science at University of Southern Denmark, Odense. Carter obtained her Ph.D. degree in 2002, financed by the Centre for Educational Development in University Science, based at the University of Southern Denmark. Before obtaining the position in Odense, she worked 2 years at the Danish University of Education in Copenhagen. Her main research interests are within the philosophy of mathematical practice. Her current work concerns the role of representations in mathematical reasoning. The recent paper, 'Diagrams and Proofs in Analysis' (International Studies in the Phil. Sci., 2010), shows roles that visual representations play in mathematics. Another interest is the topic of mathematical understanding. Carter is one of 9 founders of the Association for the Philosophy of Mathematical Practice (see http://institucional.us.es/apmp/) and is also the secretary of this association.

Chapter 27
On the Use of Primary Sources in the Teaching and Learning of Mathematics

Uffe Thomas Jankvist

27.1 Introduction

Why would one go to the extent of using a, possibly very old and maybe even somewhat inaccessible, primary original source[1] in the teaching and learning of mathematics, when so many contemporary textbooks are ready-made and pedagogically prepared for dealing with the same mathematical topics using modern-day language, coherent notation, etc.?

The above question is the overall one to be addressed in this chapter. The question is, of course, not a new one. It is a question which has already been addressed on several occasions and by various researchers of mathematics, the history of mathematics, and of course mathematics education, notably in the ICMI[2] Study on *History in Mathematics Education* (Fauvel and van Maanen 2000), where Jahnke, Arcavi, Barbin, Bekken, Furinghetti, El Idrissi, Silva da Silva, and Weeks, in the chapter on *The use of original sources in the mathematics classroom,* state:

> Among the various possible activities by which historical aspects might be integrated into the teaching of mathematics, the study of an original source is the most demanding and the most time consuming. In many cases a source requires a detailed and deep understanding of the time when it was written and of the general context of ideas; language becomes important in ways which are completely new compared with usual practices of mathematics teaching. Thus, reading a source is an especially ambitious enterprise, but […] rewarding and substantially deepening the mathematical understanding. (Jahnke et al. 2000, p. 291)

---

[1] Throughout the chapter the phrases "primary original sources," "primary sources," and "original sources" are used interchangeably but always to mean the same.

[2] ICMI is *International Commission on Mathematical Instruction*.

U.T. Jankvist (✉)
Aarhus University, Campus Emdrup, Denmark
e-mail: utj@dpu.dk

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_27,

This chapter addresses some of the reasons usually given for resorting to primary original sources in the teaching and learning of mathematics as well as exemplifies some of the approaches to doing so. At the end of the chapter, the use of original sources as a potential way of dealing with certain problems and issues in mathematics education in general is discussed, i.e., problems not only related to the teaching and learning of mathematics itself. Some illustrative examples on the use of original sources, and (empirical) didactic findings in relation to such, will be given later in the chapter. But before we get to that point, a bit of background information seems in order.

27.2 The Background and Academic Forums of Using Primary Original Sources

As mentioned, the discussion of using primary original sources in the teaching and learning of mathematics is not a new one. Historically speaking, it was the French, whom with the Commission Inter-IREM[3] first dealt with the use of original sources in a more productive manner and developed a wide range of related activities (see, e.g., Jahnke et al. 2000).[4] In the English-speaking part of the world, the HIMED movement[5] in England, initiated by John Fauvel, made several contributions, and so did the IHMT[6] initiative in the USA, one result being the massive collective work *Historical Modules for the Teaching and Learning of Mathematics,* edited by Katz and Michalowicz (2004). Traditionally, the discussion of using original sources is one which is embedded in the larger discussion of generally using history of mathematics in mathematics education (cf. Chap. 21 by Michael Fried). For that reason, much of the literature on using original sources is to be found within the literature on using history.[7] Still to this date, the most comprehensive volume available on the topic is the aforementioned ICMI Study (Fauvel and van Maanen 2000), which provides an account of the literature available up until the year 2000 as well as extensive examples on the use of history and original sources. The purpose of this chapter is therefore not to repeat what has already been done and said in the ICMI

---

[3] IREM is *Institut de Recherche sur l'Ensignement des Mathématiques*. Inter-IREM here refers to the particular Inter-IREM Commission on history and epistemology of mathematics under the coordination and leadership of Evelyne Barbin.

[4] Of course, smaller-scale initiatives had been taken in other places. As an example, the pioneering work of Abraham Arcavi from Israel is mentioned, beginning with his Ph.D. (Arcavi 1985) and the subsequent extensive publications in several journals.

[5] HIMED is *History in Mathematics Education*.

[6] IHMT stands for *Institute in the History of Mathematics and its use in Teaching*.

[7] A few examples of collections published before year 2000 including discussions of the use of original sources are Calinger (1996), Katz (2000), Laubenbacher and Pengelley (1999), and Swetz et al. (1995).

Study and its chapter on original sources,[8] but instead to provide a slightly different perspective on the use of original sources and refer to some of the more recent developments on this topic.

As a brief overview of literature in general on the use of original sources after the year 2000, the following account is offered: In 2002, a conference was held in Kristiansand as a tribute to John Fauvel who passed away one year earlier and also as a celebration of the bicentennial year of the birth of Niels Henrik Abel – *the Abel-Fauvel Conference* – the proceedings of which was published in the book *Study the Masters,* edited by Bekken and Mosvold (2003). Besides offering various contributions related to the history of mathematics, this book also offers some papers on the use of original sources in the classroom.[9] The Abel-Fauvel Conference was a Nordic preconference to ICME[10] 10 and the HPM[11] satellite conference of 2004. In the proceedings of HPM2004, which were edited by Furinghetti et al. (2007), there are also some contributions of interest, not least the report from a panel discussion coordinated by Barbin on original sources in the classroom. The HPM2004 was a joint meeting with the ESU4,[12] since their quadrennial and triennial conferences coincided in 2004. The proceedings from ESU5 edited by Barbin et al. (2008) also offer various input on the debate of original sources and do so in relation to various educational levels and teacher training.[13] The same goes for the proceedings from ESU6, edited by Barbin et al. (2011), from which special attention should be given to the plenary talk by Glaubitz (2011), which empirically compares some of the approaches for using original sources to be discussed later in this chapter. In fact, this plenary is the first entry in an entire section devoted to the use of original sources in the classroom and their educational effects.[14] At ICME there is a Topic Study Group (TSG) on *The role of history of mathematics in mathematics education*. Another recent initiative in relation to history, and therefore also original

---

[8] It should be mentioned that Chap. 9 in the ICMI Study is not the only one which addresses elements of using original sources, so do also Chap. 5 (in particular Sect. 5.3 in this), Chap. 7 (e.g., Sect. 7.3 which addresses matters of the genetic approach), and Chap. 8 in which many of the outlined examples rely on original sources.

[9] For example, those of Furinghetti and Somaglia, Horng, Pengelley, and Siegmund-Schultze.

[10] ICME stands for *International Congress on Mathematical Education*, the quadrennial world congress of ICMI, which took place in Copenhagen in 2004, and since in Monterrey, Mexico, in 2008 and in Seoul in 2012.

[11] HPM stands for ICMI-affiliated *International Study Group on the Relations between the History and Pedagogy of Mathematics,* which has its quadrennial international meeting at the time of ICME but also has yearly local meetings as, for example, those of the *HPM Americas*. The HPM satellite conference was in Uppsala in 2004 and since then in Mexico City in 2008 and in Daejeon in 2012.

[12] ESU stands for *European Summer University on History and Epistemology in Mathematics Education*, which is an initiative of the French IREM. ESU5 was in Prague in 2007; ESU6 is Vienna in 2010; and ESU7 is planned for Barcelona in 2014 and will now be held every fourth year so that it no longer coincides with HPM satellite meetings.

[13] Some examples are the contributions by Bastos and Veloso, Fried and Bernard, Glaubitz, Guichard, Katz, Poulos, Thomaidis and Tzanakis, and Weeks.

[14] Other contributions related to the use of original sources also occur outside this section of course, e.g., those by Kjeldsen, Rosas and Pardo, and others.

sources, is the working group on *History in Mathematics Education* at CERME.[15] The volume recently published in MAA Notes on *Recent developments on introducing a historical dimension in mathematics education*, edited by Katz and Tzanakis (2011), includes papers originally presented at the ICME11 TSG on history, HPM2008, and CERME6.[16] *From Calculus to Computers: Using the Last 200 Years of Mathematics History in the Classroom*, edited by Shell-Gellasch and Jardine (2005),[17] is yet a book which was published in the MAA Notes after the ICMI Study from 2000. Another stand-alone publication which is clearly of relevance for the use of original sources in the teaching and learning of mathematics is the collection of projects relying on primary historical sources by Knoebel et al. (2007). In 2007 a special issue of *Educational Studies in Mathematics* entitled "The history of mathematics in mathematics education: theory and practice" was edited by Furinghetti, Radford, and Katz. This issue includes several articles relevant for the topic of using original sources.[18]

In relation to the use of original sources, the Oberwolfach meeting organized by Furinghetti et al. (2006) must also be mentioned. One of the outcomes of this meeting was the formulation of a set of questions to guide future research on the use of original sources:

1. What are the possible epistemological/theoretical basis and frameworks for research and development towards the integration of original sources into the teaching and learning of mathematics?
2. What are the characteristics of viable models for implementing the integration of original sources in the teaching and learning of mathematics?
3. What is the actual impact of these models on students' and teachers' learning and understanding of mathematics, and on teachers' teaching practices?
4. How can historical research and practice inspire, impact, support or supply explanatory frameworks and working tools for research on learning and teaching mathematics?
5. How can research and practice in mathematics education inspire, support and broaden the research in the history of mathematics in general, and on original sources in particular? (Furinghetti et al. 2006, p. 1287)

As the last thing, the recent conference in Paris in honor of Michèle Artigue – *Colloque Artigue 2012* – is mentioned, where a workshop on epistemology – *Atelier 5: epistémologie et didactique* – was organized by de Hosson, Chorlay, and

---

[15] CERME is *Congress of European Research in Mathematics Education*, which is held every second year in between HPMs and ESUs. The WG on history was at CERME6 in Lyon, 2009; CERME7 in Rzeszów, 2011; and CERME8 in Antalya, 2013.

[16] The most important chapters in this volume in relation to original sources are those by Barbin (Chap. 2), Kjeldsen (Chap. 15), and Pengelley and colleagues (Chaps. 1 and 17); but other chapters are clearly also relevant.

[17] Examples of contributions discussing the use of original sources in this collection are Atzema and White, D'Antonio, Pengelley, and Rogers.

[18] In particular the articles by Arcavi and Isoda (2007), Barbin (2007), Katz (2007), and Thomaidis and Tzanakis (2007)

Jankvist. The first session of this workshop was devoted to young researchers accounting for the epistemological (and historical) dimension in their doctoral theses.[19] Often, it is the case that French doctoral students begin their doctoral work with an epistemological/historical account of the mathematical concepts which their thesis addresses, and in this work the study of original sources play an essential part, for example, in identifying epistemological obstacles (e.g., Bachelard 1938; Brousseau 1997). To end this section where it began, namely, with the French Inter-IREM Commission on history and epistemology of mathematics, Evelyne Barbin, who was invited to speak in the second session of this workshop, pointed out that in the IREM context around 1994 epistemology also functioned as a "weapon" against the widespread view of mathematics as a language, since epistemology puts emphasis on mathematics as an activity.[20]

It is now time to introduce some general constructs developed in the setting of history in mathematics education – constructs, which will prove themselves useful in our further discussion of primary original sources.

27.3 A Distinction Between In-Issues and Meta-issues of Mathematics

In the context of using history – and thus also original sources – in mathematics education, we may distinguish between the inner issues of mathematics and the metaperspective issues (Jankvist 2009a). When history is used as a *tool* for teaching and learning of mathematics,[21] the primary focus is on the inner issues – or *in-issues* – of mathematics such as mathematical ideas, concepts, theories, methods, algorithms, and ways of argumentation and proof. When history is used more in terms of a *goal*,[22] the focus is on the metaperspective issues – or *meta-issues* – of mathematics as a scientific discipline, regarding it as a goal to show the students something about how mathematics has come into being, its historical development, human and cultural aspects of this development, its interplay

---

[19] The presenters were Thomas Barrier, Patricia Crépin, Mathias Front, Eric Laguerre, and Caroline Poisard. Furthermore, posters on the role of epistemology and history, also in relation to original sources, were presented.

[20] Currently, *Science & Education* is preparing a special issue on "History and Philosophy of Mathematics in Mathematics Education," guest edited by Victor J. Katz, Uffe Thomas Jankvist, Michael N. Fried, and Stuart Rowlands. This issue will include new articles discussing the use of primary original sources in mathematics education.

[21] The history-as-a-tool arguments may be subcategorized into being concerned with history as a motivational and/or affective tool, history as a cognitive tool (e.g., the idea of epistemological obstacles), and the role of history in what may be referred to as the evolutionary arguments (the recapitulation argument or historical parallelism) (Jankvist 2009a).

[22] Note that this is not the same as teaching the history of mathematics *per se*.

with society through applications, or issues of epistemology, ontology, etc.[23] For example, learning about the number sets (N, Z, Q, R, C), their interrelations, their cardinalities, etc., is considered to be a study of in-issues. On the other hand, learning about the historical development of the different kinds of numbers, the difficulties regarding the acceptance of the irrational numbers, the negative numbers, or the complex numbers concerns aspects of the meta-issues of mathematics.

Because the distinction between in-issues and meta-issues applies not only to the use of history in mathematics education but also to the use of philosophy and actual applications of mathematics (Jankvist 2013), it will be relevant for the use of original sources in any of these contexts as well. As further examples of various meta-issues to be addressed from the point of view of history, application, and philosophy of mathematics in mathematics education, we may consider:

> How does mathematics evolve over time? What forces and mechanisms can be present in the evolution? Do society and cultural circumstances play a part in this evolution? If so, how? And does mathematics then depend on culture and society, place and time? Is old mathematics also obsolete mathematics? (Niss 2001a, p. 10, my translation from Danish)

> Who, outside mathematics itself, actually uses it for anything? What for? Why? How? By what means? On what conditions? With what consequences? What is required to be able to use it? Etc. (Niss and Højgaard 2011, p. 74)

> What is characteristic of mathematical problem formulation, thought, and methods? What types of results are produced and what are they used for? What science-philosophical status does its concepts and results have? How is mathematics constructed? What is its connection to other disciplines? In what ways does it distinguish itself scientifically from other disciplines? Etc. (Niss and Højgaard 2011, pp. 75–76)

The distinction between in-issues and meta-issues bears some resemblance to that of Davis and Hersh (1981), who talk about the "inner issues" and the "outer issues" of mathematics, or that of Niss (2001b), who talks about "knowledge of mathematics from the inside" and "knowledge of mathematics from the outside."

Even though a use of history (or application or philosophy) as a tool is concerned with students' learning of mathematical in-issues, this is of course not to say that meta-issues cannot act as a means (tool), for example, by motivating students, to reach an end (goal) of learning specific in-issues. In a similar manner, when concerned with history (or application or philosophy) as a goal, it is clear that certain meta-issues cannot be understood without comprehension of some mathematical in-issues (see Jankvist 2011 for examples). The distinction between in-issues and meta-issues is merely a useful way to talk about the primary foci of including history (or application or philosophy) and thus also of resorting to primary original sources when doing so.

---

[23] For a further discussion of history as a tool and history as a goal, see also Tzanakis and Thomaidis (2012).

27.4 Various Reasons for Using Primary Original Sources

In this section we take a look at some of the reasons usually given for using original sources in the teaching and learning of mathematics, relying on the distinction between in-issues and meta-issues. To illustrate how this notion may be applied to uncover some of the underlying motives for resorting to original sources, let us have a look at the following list of reasons provided by Pengelley, one of the pioneers of using original sources at US undergraduate level:

> [1] … motivation and deep connection along time, [2] understanding essence, origin, and discovery, [3] mathematics as humanistic endeavor; [4] practice moving from verbal to modern mathematical descriptions; [5] reflections on present day status and paradigms; [6] participating in the process of doing mathematics through experiment, conjecture, proof, generalization, publication and discussion; [7] more profound technical comprehension from initial simplicity; [8] also dépaysement (disorientation, cognitive dissonance, multiple points of view); [9] and a question-based curriculum that knows where it came from and where it might be going. Questions before answers, not answers before questions that have not been asked. (Pengelley 2011, p. 3, numbering not in original)

Clearly, reason 9 refers to the commonly seen structure of modern mathematics textbooks, where definitions and theorems are usually presented first, and then, motivation and application follow afterwards. As the reader will know, the historical development of mathematical theories, concepts, etc. often is the exact opposite; one is motivated by a problem or an application, the solution of which leads to theorems, proofs, and in the end definitions.

Pengelley's other eight reasons for using primary original sources may be ordered according to their focus being either on the in-issues or the meta-issues of mathematics. Reason 3 about "mathematics as a humanistic endeavor" and the part of reason 2 which reads "understanding origin and discovery" are mainly concerned with the meta-issues. Reasons 4, 6, and 7 on "practice moving from verbal to modern mathematical descriptions" and "participating in the process of doing mathematics…" and "more profound technical comprehension…" concern in-issues in one way or another. Of course, these reasons or arguments are subject to interpretation. This is the case for the part of reason 2 which reads "understanding essence"; does this refer to in-issue mathematical essence of a given concept or topic or does it, for example, refer to the meta-issue applicational essence of the concept in an extra-mathematical context? And similarly, does reason 5 about "reflections on present day status and paradigms" refer to, for example, inner mathematical concerns of unsolved problems, unproven conjectures, etc. or to aspects of a more metaperspective nature regarding, for example, the science-philosophical status of a given concept or changes in the notion of mathematical proof? In order to find out, one would have to scrutinize the concrete use of an original source in a specific educational setting. Something similar goes for reason number 8 on *dépaysement*.

In fact, the idea of *dépaysement* is one which was originally suggested by Barbin (1997) and later translated and rephrased in Jahnke et al. (2000), as one of three general ideas for describing the special effects of using original sources:

- *Replacement* (in the original French wording, *vicariante*), which refers to the replacement of the usual with something different, for example, by allowing mathematics to be seen as more than just a corpus of knowledge and techniques.
- *Reorientation* (a translation of *dépaysement*), which challenges one's perception by making the familiar unfamiliar, eventually causing a reorientation of the reader's views and thus a deepening of the mathematical understanding – also sources remind students that mathematical constructs have come into being at one point in time (and space) and that this did not happen by itself.
- *Cultural understanding* (*culturel*), which allows us to place the development of mathematics in a scientific, technological, or societal context of a given time and place and in the history of ideas and society.

As we shall see in the given examples of the following sections, the idea of *dépaysement* is indeed a central one regarding the benefits of using original sources. As the reader may already have noticed, there is some variation in the interpretations of Jahnke et al. (2000) and Pengelley (2011). While Jahnke et al. talk about a *re*orientation and making the familiar unfamiliar, Pengelley refers to a *dis*orientation and mentions cognitive dissonance and multiple points of views. One reason for this variation may be that the idea of *dépaysement* involves a *process*. The first element is of course that of putting the student on unfamiliar ground, which is done by exposing him or her to an original source. This can indeed involve making the familiar unfamiliar. An example of this might be that of the notion of limits in real analysis: A student, who is used to the modern-day common notion, relying on Weierstrass' ε-δ-approach, may find that this becomes very unfamiliar, when seeing the earlier ideas of infinitesimals as discussed by, for example, Leibniz in his version of calculus. According to Furinghetti, Jahnke, and van Maanen:

> There are many experiences which show that students are motivated to reflect about the limit approach to calculus when they study Leibniz' way of dealing with infinitely small quantities. Also the teacher may gain insight by concentrating on the unfamiliar. It is often difficult enough to cope with unexpected solutions by students; however, studying sources enables to the teacher and students to keep an open mind. (Furinghetti et al. 2006, p. 1286)

Indeed, such a study may cause a cognitive dissonance, because the student is suddenly exposed to two different mathematical discourses. Sfard (2008) refers to such a situation as a *commognitive conflict*[24] – a situation where different discursants are acting according to different *meta-discursive rules* (not to be confused with the previously introduced meta-issues of mathematics) of mathematical discourse, which are historically given rules about proper communicative actions shaping the mathematical discourse, rules governing when to do what and how to do

---

[24] The word commognitive relates to *commognition*, which is a contraction of *communication* and *cognition*, and which means to stress the fact that communication and cognition are different intrapersonal and interpersonal manifestations of the same phenomenon (Sfard 2008).

it, and which are implicitly present in discursive actions of the mathematists.[25] Surely, such experience of cognitive dissonance, or an encounter with a commognitive conflict, may cause disorientation on the students' behalf, which should be seen as a good thing, since disorientation often is a precursor for reorientation. And of course, such reorientation may involve the development of multiple points of view on a mathematical topic, as, for example, that of the notion of limit in real analysis.

The example of the notion of limit above may of course hold in it the dimension of replacement also, since the student's idea is replaced by a different one.[26] As for cultural understanding, however, more would be needed in order to develop a student's perception of it in relation to the notion of limits.[27] For example, one might focus on the relevance of extra-mathematical phenomena for the development of limits, applicational uses, or the scientific importance of the notion. Thus, while both replacement and *dépaysement* seem to hold in them a natural focus on mathematical in-issues, cultural understanding appears to focus more specifically on the meta-issues. However, in a setting of using original sources, a true understanding of the involved meta-issues may often not be reached if the involved mathematical in-issues are not understood to some degree. For instance, if one wishes to make sense of why it was Weierstrass' ε-δ-approach that eventually became the standardized one in real analysis and not the rival one of infinitesimals (except in non-standard analysis), one will need to understand the two different notions. Another way of phrasing this is to say that the meta-issue context is rooted or *anchored* in the in-issue context (Jankvist 2011). Of course, the converse may also be true that the in-issues of an original source can be rooted in the meta-issue context surrounding it.

The various reasons discussed above do, of course, *not* make up a complete list of every possible reason one might think of in relation to the use of original sources in the teaching and learning of mathematics. Still, it illustrates that the reasons for doing so are not only multiple but also multifaceted. And the analysis of the discussed reasons illustrates that they may be viewed as focusing mainly on aspects of meta-issues or of in-issues. Regarding the in-issues, we shall later see that these may also be discussed in terms of the use of original sources contributing to the development of students' mathematical competencies. Furthermore, by relating to the three general ideas of Barbin (replacement, *dépaysement*, cultural

---

[25] A *mathematist* is a participant in mathematical discourse including students, teachers, and mathematicians (Sfard 2008).

[26] Furinghetti et al. (2006) give the example of Newton's letter to Leibniz of 1676 in which he describes how as a young man of 22 years; he arrives at the general binomial formula (a cornerstone in his fluxional calculus) as an example of possible replacement, since it is a unique document for a process of mathematical innovation progressing by bold generalizations and analogies.

[27] In relation to cultural understanding, Furinghetti et al. (2006, p. 1286) mention Heron's textbook (first century A.D.) on land surveying called *The Dioptra*. Reading parts of this, they say, "connects the topic of similarity to the context of ancient surveying techniques and shows the astonishingly high achievements of ancient engineers in this and other areas. Such sources may as well provoke students to engage in practical activities (simulations, measurements, theatre), which otherwise would not come to their mind or to the mind of their teacher."

understanding), we are able to conduct a more detailed analysis of the various reasons – or purposes – of using original sources, by placing a given use within one of the three general ideas, and then try to sort out how much focus must be (or was) put on in-issues and meta-issues, respectively.

But before we get to some illustrative examples of actual uses of original sources with students, we should look at some of the approaches to using original sources.

27.5 Various Approaches to Using Primary Original Sources

In this section, we shall have a look at some of the approaches usually discussed in the literature for using original sources in the teaching and learning of mathematics. Surely a different selection could have been made, but the one below offers both longtime well-known and more recently developed approaches, the latter of which also relates to later examples. It is important to mention that there may be overlaps between the approaches given and that some of them may resemble "philosophies" about the inclusion of original sources (or history), while others may be seen more as methodologies, methods, or models, e.g., for addressing practical issues associated with using original sources or for reaching specific goals by using such sources. Nevertheless, since all usually are referred to as *approaches* in the literature, the same is done here, although the reader shall be notified which approaches are more heavy on philosophy and which on methodology, based on the given descriptions.

Before we get to the descriptions, a certain notion from historiography must be introduced, namely, that of *Whig* history. This notion is due to the British historian Herbert Butterfield who defined it as a way of "measuring" the past in terms of the present (Butterfield 1931/1951). A well-known example hereof is that of the Bourbaki approach to the history of mathematics, in particular with Jean Dieudonné and André Weil. In a discussion related to why and how history of mathematics should be conducted, Weil, for instance, claimed that

> … it is impossible for us to analyze properly the contents of Book V and VII of Euclid's without the concept of group and even that of groups with operators, since the ratios of magnitudes are treated as a multiplicative group operating on the additive group of the magnitudes themselves. (Weil 1978, p. 232)

The problem partly consists in that one comes to follow a path from the present back to the past, where the only things which are considered are those which lead to something deemed significant today, whereas "from the perspective of the past, and that is the *historical* perspective, it is a zigzag path of a wanderer who does not know where exactly he is going" (Fried 2001, p. 396, italics in original). Thus, if we, in the context of introducing a historical dimension in mathematics education, wish to be honest to history, i.e., adopt a genuine historical perspective, we may be much better off resorting to primary original sources, since these are open to the reader's own interpretation – an interpretation which in its outset is not Whig. Also, the notion of Whig history may be used as a sort of measure of various approaches for using original sources; in the sense that while several in-issues might very well be brought forth in a Whig approach to history, the reaching of meta-issues often requires in its outset a non-Whig approach.

27.5.1 The Genetic Approach

One of the oldest approaches to including history through a use of original sources is the so-called genetic approach, which was strongly advocated by the German mathematician Felix Klein (Schubring 2011), for example, in his *Elementarmathematik vom höheren Standpunkte aus*,[28] where he argued for a genetic method of teaching wherever possible (Klein 1908). A more theoretically reflected conception of the genetic approach was formulated by another German mathematician, Otto Toeplitz. According to Burn (1999, p. 8), "the question which Toeplitz was addressing was the question of how to remain rigorous in one's mathematical exposition and teaching structure while at the same time unpacking a deductive presentation far enough to let a learner meet the ideas in a developmental sequence and not just a logical sequence." Worth noting is that Toeplitz distinguished between a *direct* genetic method and an *indirect* genetic method:

> [A]ll these requisites […] must at some time have been objects of a thrilling investigation, an agitating act, in fact at the time when they were created. If one were to go back to the roots of the concepts the dust of times […] would fall from them and they would again appear to us as living creatures. And from then on there would have been offered a double road into practice: Either one could directly present the students with the discovery in all of its drama and in this way let the problems, the questions, and the facts rise in front of their eyes – and this I shall call the *direct genetic method* – or one could by oneself learn such an historical analysis, what the actual meaning and the real core in every concept is, and from there be able to draw conclusions for the teaching of this concept which as such is no longer related to history – the *indirect genetic method*. (Toeplitz 1927, pp. 92–93, my translation from German)

In relation to the use of original sources, it is of course the direct genetic approach which is of interest. Tzanakis (2000) describes the genetic method as one in which there is no uniquely specified way of presentation in the sense of an algorithm; rather, it is a general attitude towards the presentation of a scientific subject. In that way, the motivation behind introducing new concepts, theories, or key ideas of proofs is based on their genesis and evolution. Toeplitz points out that nothing is further from his thoughts than giving a lecture on history. Instead, he wants to "…pick from history only the basics of those things that have stood the test of time and make use of them" (Toeplitz 1927, p. 95). Thus, the genetic method is not one concerned with getting messages related to meta-issues across to the students, but instead it is using history as a tool – and therefore also original sources – to teach and have the students learn mathematical in-issues.

---

[28] Usually translated to: *Elementary Mathematics from an Advanced Standpoint.*

However, as pointed out by Glaubitz (2011), Toeplitz' approach implicitly assumes that there is a "great ascending line" in history to follow, which there often is not, in which case "important stages" will have to be identified instead. Although it may be possible to identify such important stages – or key points or crucial steps, which acted as a catalyst for further progress in the historical development[29] – as in any situation where an interpretation is made of what is historically important and what is not, Whiggishness may be lurking, since such interpretation is often made from a contemporary point of view. Of course, when using primary original sources in the teaching and learning, this ought to be less likely to happen.

27.5.2 The Hermeneutic Approach

Somewhat in contrast to the genetic approach is the so-called hermeneutic approach,[30] as proposed by Hans Niels Jahnke (also in Jahnke et al. 2000) – an approach which concerns itself with meta-issues as well as in-issues of mathematics. Glaubitz describes the difference between the hermeneutic and the genetic approach as follows:

> … the big difference to the genetic approach is, that the students are not expected to trace a history of thoughts that leads them from past roots to the standards of today. Essentially that is, because the students should be very familiar with a topic before they even touch a historical text that deals with it. In the hermeneutic approach, students are asked to examine a source in close detail and explore its various contexts of historical, religious, scientific etc. nature. In hermeneutics this is called: to move within hermeneutic circles – and these are circles of ever new understanding. (Glaubitz 2011, p. 357)

Jahnke relates the idea about hermeneutic circles to original sources in the following manner:

> The process of interpreting an original mathematical source may be described by a twofold circle […] where in the primary circle a scientist (or a group of scientists) is acting and in a secondary circle the modern reader tries to understand what is going on. (Jahnke 2000, p. 298)

Following Schubring (2005), the key idea is to approach the intended meaning of the original source, this being in the primary circle, and for the modern-day reader to perform hermeneutical reconstructions of how concepts (and other mathematical in-issues) developed. It is worth noticing that being this alert of the shifting within circles makes the reader's interpretation much less prone to becoming Whig.

Due to the fact that within the hermeneutic approach, students need a prerequisite knowledge of the topic, Glaubitz explains that the approach is often applied

---

[29] See in particular Sect. 7.3 of Fauvel and van Maanen (2000) and Tzanakis and Thomaidis (2000).

[30] The hermeneutic approach is sometimes also referred to as the historico-hermeneutic approach.

only to subject matters with which the students are already familiar. He further describes the hermeneutic approach as essentially consisting of three steps:

> Usually the structure is as follows: First, the students have a quite conventional introduction to the topic. No history is involved until the second step, in which the students read a historical source. In this source, the same topic is covered, but in a way, that is historically distant, different in its representation, used in strange contexts and so forth. This is the step where the students' epistemic curiosity is – hopefully – aroused. In the third and final step students are required to explore the source in even greater detail, perform a horizon merger and reflect upon questions that occur to them. (Glaubitz 2011, p. 358)

The term "horizon merger" refers to a student's development of deeper awareness by wondering and reflecting about what she/he never thought about before (Gadamer 1990). Thus, in relation to the previously discussed reasons for including primary original sources, we notice the presence of the arguments of replacement and *dépaysement* in the hermeneutic approach.

27.5.3 Multiple-Perspective Approach

Recently, Kjeldsen has been arguing strongly for what she refers to as a *multiple-perspective approach* to history, including also the use of primary original sources in the teaching and learning of mathematics (e.g., Kjeldsen 2009a, b and 2011a, b, c; Kjeldsen and Blomhøj 2012; Jankvist and Kjeldsen 2011). Contrary to the hermeneutic approach, students do not necessarily need to possess prerequisite knowledge of the modern interpretation of the topic they are about to study through original sources. One similarity between the two, though, is that they both approach original sources from a somewhat micro-historical point of view – or *views* – since Kjeldsen by multiple perspectives is referring to the analysis and consideration of the practice of mathematical activities at a given time and place from several points of observation or contexts:

> The perspectives can be of different kinds and the mathematics can be considered from different angles, such as various sub-disciplines of mathematics, techniques of proofs, applications, "nature of mathematics" positions, other scientific disciplines, sociological institutions, personal networks, genders, religious beliefs and so on. This approach to history raises the question of which perspectives to choose, since, of course, not every perspective that one can think of is necessarily interesting (or accessible) regarding a particular historical analysis. A way to handle this difficulty when using history in mathematics education is to adopt a problem-oriented approach, that is, to have clearly formulated historical research questions and then to focus on perspectives and to choose historical episodes that explicitly address and relate to the issues one wants students to reflect upon. (Kjeldsen and Blomhøj 2012, p. 332)

Examples of such problem-oriented "research questions" to focus on while reading and studying primary original sources could be

> … why mathematicians asked the questions they did; why they treated the problems they dealt with in the way they did; what kinds of proofs or arguments they gave, and how these were perceived and received within the mathematical community(ies); why they introduced

> certain mathematical objects, definitions, areas of research etc.; and how all of the above influenced further developments in mathematics as well as changes in perceptions of mathematics. (Jankvist and Kjeldsen 2011, p. 836)

One historical framework which is particularly interesting in relation to the multiple-perspective approach is that of *epistemic objects and epistemic techniques*, originally developed by Rheinberger (1997) for the study of experimental sciences but adapted by Epple (2004) to the historiography of mathematics. Epistemic objects refer to the mathematical object(s) under investigation by the mathematician(s) in a given time and space. Epistemic techniques refer to the methods and tools that were used to study the object(s), either well-established techniques or techniques which have to be developed in the process of studying the object(s). Together, the epistemic objects and techniques constitute what Epple calls the *epistemic configuration*. This is where the (groups of) mathematicians (pure or applied), within a given space and time, perform their work – their "intellectual working place" or "mathematical workshop." It is important to notice the dynamical process inherent in the notions of epistemic objects and techniques, meaning that what in one historical setting functioned as objects might be turned into techniques later or in another setting (e.g., Epple 2004; Kjeldsen 2009b). Besides making up a non-Whig approach to the historiography of mathematics, the multiple-perspective approach is also extremely suitable for focusing on both mathematical in-issues and meta-issues when using primary original sources in mathematics education, e.g., in Epple's framework, by considering the epistemic objects and techniques themselves and then considering (cultural or societal) aspects surrounding the epistemic configuration, respectively. (The notion of objects and techniques shall be illustrated in the section on examples.)

27.5.4 Comparative Readings of Original Sources and Other (Kinds of) Texts

Whereas the three approaches discussed above are more general approaches – or "philosophies" – to the use and studying of original sources in mathematics education, the following ones are more specific in nature and more methodological. The first one concerns comparisons of different kinds of texts, which Jahnke et al. (2000) discuss in terms of the benefits of comparing original sources with secondary sources, for example, books on the history of mathematics. In contrast to merely relying on such secondary sources, the study of primary original sources helps to:

(a) Clarify and extend what is found in secondary material,
(b) Uncover what is not usually found there,
(c) Discern general trends in the history of a topic (secondary sources are usually all-topic chronological accounts, and some topics are very briefly treated or omitted altogether), and
(d) Put in perspective some of the interpretations, value judgments or even misrepresentations found in the literature. (Jahnke et al. 2000, p. 293)

As may be derived from the points above, a *comparative reading* of primary original sources with secondary literature may be quite rewarding for students (and teachers as well).

Comparison of an original source with a (modern) textbook's presentation of the topic in the original source may also be a sensible task to undertake. In relation to the previously mentioned *dépaysement*, Barnett, et al. (2011) state that it may

> Engender cognitive dissonance (dépaysement) when comparing a historical source with a modern textbook approach, which to resolve requires an understanding of both the underlying concepts and use of present-day notation. (Barnett et al. 2011, p. 188)

A more compelling reason for resorting to primary original sources over textbooks – and some secondary literature, depending on its nature – is the one pointed to by Fried (2001), namely, that textbooks by definition are *closed to interpretation*, since they merely set out to present already accepted knowledge. Primary original sources, on the other hand, which convey their own order of inquiry, are open to the reader's own reflections in a very different sense, through the author's original language of discovery and invention.

A comparative reading of primary sources with other primary sources may enhance the effect of these in relation to the originally intended purposes of resorting to primary original sources. If, for example, the intention was one of the meta-issues regarding the development of mathematics (and science), a comparison of two original sources addressing the same problem, and possibly developing the same or similar theoretical constructs, could lead to a discussion of *multiple discoveries* (e.g., Merton 1973). One example of that is the well-known one of Newton's and Liebniz' simultaneous, but very different, developments of the infinitesimal calculus. Another example of comparing different original sources might be when comparing various translations of the same source to observe how cultural aspects have influenced such translations. An example of this may be found in Siu (2011), who discusses the translation of the first European text in mathematics (Euclid's *Elements*) into Chinese, by comparing the different ways of mathematical thinking, the different style of presentation, and the different views of mathematics in the East and in the West.

27.5.5 Guided Readings of Primary Historical Sources

The second of the methodological approaches is the so-called *guided readings* of original sources developed by David Pengelley, Janet Barnett, Jerry Lodder, and colleagues (see, e.g., Barnett et al. 2011; Knoebel et al. 2007; Laubenbacher and Pengelley 1999).[31] This method offers a sensible way of dealing with the occasional inaccessibility of primary original sources. The idea is to supply or "interrupt" the students' reading of an original source by explanatory comments and illustrative tasks along the way. The group surrounding Pengelley, Barnett, Lodder, and colleagues

---

[31] See also http://www.cs.nmsu.edu/historical-projects/papers.html (Retrieved on February 1, 2012).

has developed numerous teaching modules (or projects), ready for implementation in class (undergraduate level or high school). And one of the beautiful things about their work is that they have an "open-source" policy, providing teachers and other researchers with free access to the LaTeX code of their modules, and invite them to adapt it for their own use and to share their experiences.[32] (Examples of sources which have been subject to such guided readings will be given in the following section.)

27.5.6 Essay Assignments Related to Readings of Original Sources

While the approach of guided readings originally was developed to make the mathematical in-issues of the original source more accessible and understandable to the students, the third methodological approach to be discussed here, that of *essay assignments*, was developed from the point of view of bringing out meta-issues. In a study I carried out in 2007 (and which is reported in Jankvist 2009b, 2010, 2011), focus was on creating a setting where upper secondary school students could come to discuss and reflect upon historical, philosophical, and/or applicational meta-issues of the mathematics they had studied through the use of excerpts from original sources. This was realized by having groups of students write essays (a couple of pages long) answering a series of questions on meta-issues as part of their mathematics class. For example, in a historical teaching module on the development of public-key cryptography (Diffie, Helman, and Merkle; Rivest, Shamir, and Adleman) and the underlying number of theoretical constructs (e.g., stemming to Sun Zi; Fermat, and Euler), students were asked to discuss these researchers' motivations for engaging into their studies of topics from the point of view of *inner driving forces* in the discipline of mathematics and *outer driving forces*, i.e., influence on the development of mathematics from the outside due to societal needs (Jankvist 2011). Thus, this study also adopted the multiple-perspective approach to history of mathematics (for further discussion in relation to this particular historical case, see Jankvist and Kjeldsen 2011). Also, within the setting of the multiple-perspective approach, I have used a design combining the idea of guided readings of primary original sources and the use of essay assignments (Jankvist 2013), which will be illustrated in the following section.

27.6 Illustrative Examples of Didactic Design and Findings from Using Primary Original Sources

To illustrate actual uses of original sources in the teaching and learning of mathematics, a small selection of more recent examples from the literature will be described and discussed. These examples have been chosen to illustrate some of the

---

different uses in terms of purposes and approaches (cf. previous sections), whereas not much emphasis has been put on choosing examples from many different national settings, since interested readers may already find a cohort of such examples displayed in the ICMI Study (Fauvel and van Maanen 2000).[33] Also, since the ICMI Study offers a long list of examples regarding uses of original sources to support understanding of various important mathematical concepts from the perspective of students as well as teachers, the following examples were not chosen with this in mind. Instead, focus has been on the illustration of didactic designs and didactic findings related to the use of original sources in the teaching and learning of mathematics. However, some effort has been made to illustrate the use of original sources at different educational levels: primary, secondary, and tertiary level. Furthermore, an important element in some of the chosen examples is the adherence to a theoretical framework from mathematics education research – an aspect to be discussed in the final section of this chapter.

27.6.1 An Interdisciplinary Reading of Bartolus of Saxoferrato in Dutch Grammar School

On several occasions, van Maanen has described his use of the history of mathematics through primary original sources in upper secondary classrooms (examples are van Maanen 1991, 1997). In a paper appearing in the collection edited by Swetz et al. (1995), van Maanen continues his descriptions based on personal experiences with three historical cases: seventeenth-century instruments for drawing conic sections, improper integrals, and one on the division of alluvial deposits in medieval times. The latter, which shall be discussed in more detail, is different from the other two in that it describes a project in three first-year classes of the Dutch grammar school, pupils about age 11, and because it was an interdisciplinary project with Latin.

In a medieval setting of a case of three landowners, who all had land on the bank of a river, fighting over an alluvial deposit bordering their land, the students were to investigate the problem by means of a method proposed by the Italian professor Bartolus of Saxoferrato in 1355 (the example with the landowners was the one used by Bartolus himself). The ideas of the project, as described by van Maanen, were to demonstrate the importance of mathematics in society, which relates to Barbin's idea of cultural understanding (meta-issues); to let pupils "invent" a number of constructions by ruler and compass, thus emphasizing the importance of understanding mathematical in-issues; to have them apply these "inventions" in order to solve the legal problem of the medieval example, which illustrates the applicational dimension of mathematics as a discipline; and to have them read excerpts from Bartolus' treatise in the original Latin language, illustrating "that it is impossible to interpret the sources of Western culture without knowledge of classical languages" (van Maanen 1995, p. 79), clearly, yet another meta-issue and as such, one which would

---

[33] Of course a factor in choosing these exact examples is my own familiarity with them, which enables me to perform a deeper analysis of the underlying motives for resorting to original sources.

be very difficult to illustrate without resorting to original sources. Van Maanen's evaluation of the implementations of the project is

> Making contact with Bartolus was only possible via deciphering and translating, but that was simply an extra attraction to most of the pupils. They learned to work with point-sets in plane geometry, and simultaneously their knowledge of general history increased. Last but not least, they were greatly stimulated to learn Latin. (van Maanen 1995, p. 80)

27.6.2 The Early History of Error-Correcting Codes: Working with Excerpts in Upper Secondary School

The next example is a teaching module for Danish upper secondary school (described in Jankvist 2009b; 2010). The module deals with the early history of error-correcting codes, and as part of it, the students were to read excerpts from original sources by Shannon, Hamming, and Golay. The historical background is that based on Shannon's display of Hamming's so-called (7,4) error-correcting code[34] in 1948, Golay was able to make the generalization of this into the entire family of Hamming codes in 1949 and discover a few additional codes himself. Due to the wish of the Bell Laboratories, wanting to patent Hamming's codes, his own publication was delayed until 1950 (which later caused a quarrel regarding who was in fact the originator of the codes). Having read excerpts from these sources (in translation), the students were to do an essay assignment, identifying and discussing epistemic objects and epistemic techniques in Hamming's development of the (7,4) code, the object being the code itself and the techniques the notion of metric and elements of linear algebra. One of the objectives of this essay assignment was for the students to make a distinction between the already available techniques, i.e., the well-established mathematics that Hamming was using and the techniques that he himself had to create in the process. One group of students who did rather well in making this distinction answered:

> Hamming uses generalized concept of distance; elements of linear algebra; geometrical models; and unity n-dimensional squares.
> A metric which is called a distance $D(x, y)$ is the definition of Hamming distance.
> Since x and y must be different ($x \neq y$), we can find how similar the two codes are, because we talk about a more generalized concept of distance.
> Linear algebra is concerned with the study of addition and proportionality, and it is the concept of linearity that binds the concepts of addition and proportionality together.
> We use geometrical figures to understand the n-dimensions, since these exceed what can be understood physically, i.e. 1st, 2nd, and 3rd dimension.
> n-dimensional cube is the same as the metric space. (Group 5, translated from Danish. Quoted from Jankvist and Kjeldsen 2011, p. 853)

---

[34] In this binary code, all code words consist of seven bits, four of these being information bits, hence the name (7,4)-code.

Of course, not all groups were able to distinguish in an equally clear manner the already available techniques from those constructed by Hamming in the process and therefore might list Hamming's own constructs as being already available (for an example, see Jankvist and Kjeldsen 2011). A long discussion of the mathematical in-issues mentioned in the quote above shall not be given, but despite that, it should still be clear that without an understanding of these in-issues on the students' behalf, it is not possible for them to enter into the meta-issue micro-historical discussion of Hamming's error-correcting codes coming into being. This multiple-perspective approach to mathematics through its use of essay assignments thus illustrates mathematical understanding as a prerequisite condition for deeper cultural understanding. Or to phrase it differently, an understanding of the meta-issues is *anchored* in an understanding of the in-issues (Jankvist 2011).

27.6.3 Project Work on Bernoulli's Solution of the Catenary at University Graduate Level

In the setting of students' problem-oriented project work at Roskilde University (Denmark), Kjeldsen (2011a, b) has discussed the learning outcome of five graduate students enrolled in the mathematics program while doing a project based on readings of three original sources from the 1690s: the solutions to the brachistochrone problem[35] by Jakob Bernoulli and Johann Bernoulli, respectively, and Johann Bernoulli's solution to the catenary problem[36] (see also Jankvist and Kjeldsen 2011; Kjeldsen and Blomhøj 2009, 2012). More precisely, Kjeldsen has addressed the learning outcome from two different mathematics educational perspectives: the development of students' mathematical competencies (Niss and Højgaard 2011) and students' learning of meta-discursive rules in mathematics (Sfard 2008).

The framework of students' *mathematical competencies,* as described by Niss and Højgaard (2011), lists eight mathematical competencies: mathematical thinking competency, problem-solving competency, modeling competency, reasoning competency, representation competency, symbols and formalisms competency, communication competency, and aids and tools competency. A mathematical competency is defined as "having knowledge of, understanding, doing, using and having an opinion about mathematics and mathematical activity in a variety of contexts where mathematics plays or can play a role," or in other words a kind of "well-informed readiness to act appropriately in situations involving a certain type of mathematical

---

[35] The *brachistochrone problem* (from Greek *brachistos* meaning shortest and *chronos* meaning time) is to find the curve by which a particle under influence of gravity will travel the fastest from a given point A to a given point B. The curve is the so-called cycloid, and the solution to the problem was found not only by the Bernoullis but also by both Newton and Leibniz around the same time (another example of multiple discoveries).

[36] The *catenary problem* consists in describing the curve formed by a flexible chain hanging freely between two points.

challenge" (Niss and Højgaard 2011, p. 49). In relation to the students' reading of Johann Bernoulli's original text on the catenary problem, the students' development of four of these eight competencies took place in the following way:

> The students' *problem solving* skills were trained extensively in their work with Bernoulli's text on the catenary. As emphasized above, the students had to fill in all the 'gaps' in Bernoulli's presentation in the course of which the students derived several intermediate results themselves. [...] Parts of the students' *mathematical modeling* competency were developed through their struggle to understand Bernoulli's mathematization of the physical description of the catenary, and to justify his five assumptions from statics. [...] Their *mathematical reasoning* competency was developed, in particular through their struggle to clarify the apparent lack of rigor in Bernoulli's way of arguing compared with modern standards. Bernoulli's way of argumentation is not in accordance with what is considered 'proper' or rigorous mathematical reasoning today. [...] The students' ability to distinguish between and utilize different *representations* of e.g. mathematical objects was especially challenged in [...] their study of Bernoulli's construction of the solution to the differential equation of the catenary. Here they experienced a representation of a solution that is quite different from the analytical representation they usually see in modern textbooks. (Jankvist and Kjeldsen 2011, pp. 843–844)

As evident from the quote, the development of these competencies is tightly connected to the studying of the original source, some even a direct consequence thereof. (For a discussion of the students' development of the four remaining competencies due to this project work, see Kjeldsen 2011a.) From the point of view of using history as a tool for teaching and learning mathematical in-issues, students' competency development provide a different – and possibly more natural – means for evaluating the use of original sources than just assessing students' conceptual understanding.[37]

In relation to the previous discussion of *dépaysement*, the definitions of Sfard's (2008) notions of *meta-discursive rules* of mathematical discourse and *commognitive conflict* have already been given (please refer to these if needed). In the context of the same students' reading of Bernoulli's solution of the catenary, Kjeldsen and Blomhøj explain that the learning of meta-discursive rules

> ... is difficult, and as pointed out by Sfard, because of the contingency of meta-level rules, it is not likely that learners by themselves will begin a meta-level change. Such a change is most likely to happen when (or if) the learner experiences another (new) discourse that is governed by meta-rules other than those the learner so far has been regulated by. An experience like that constitutes what Sfard (2008, p. 256) calls a commognitive conflict, which she defines as "a situation in which different discursants are acting according to different metarules." (Kjeldsen and Blomhøj 2012, p. 330)

Such commognitive conflicts may of course also arise when students compare discourses of different discussants, for example, when comparing different original sources as mentioned earlier. However, the occurrence of commognitive conflicts is to a large extent dependent on and conditioned by a non-Whig approach to history, because

---

[37] Niss and Højgaard (2011) give three dimensions for assessing a person's mastery and development of a competency: degree of coverage, radius of action, and technical level.

> If one's reading and interpretation of historical sources are constrained by the way mathematics is perceived and conceptualised in the present, the historical text cannot play the role of an "interlocutor" that can be used to create commognitive conflicts [. . .] when students "communicate" with the text, since differences in the way of communicating in the past and in the present will have been "washed away" by the whig interpretation. (Kjeldsen and Blomhøj 2012, p. 331)

Thus, original sources, or alternatively secondary sources which are very close to the original, come to play an almost indispensible role in this setting of developing students' understanding of meta-discursive rules through a use of history of mathematics.

As an addendum, the role of the original source as an *interlocutor* is also discussed by Jahnke et al. (2000, p. 296), who say that "a source can be a trigger for establishing a dialogue with the ideas expressed" and it "then becomes an interlocutor to be interpreted, to be questioned, to be answered and to be argued with." Jahnke et al. state that the role of a source as an interlocutor in particular applies to issues such as the nature of mathematical objects and the essence of mathematical activity, that is to say matters related to the meta-issues of mathematics. But as seen from the example of Kjeldsen and Blomhøj (2012), original sources as interlocutors may play an equally important role in relation to mathematical in-issues. However, a word of caution should be provided, because until recently history of mathematics has primarily been carried out by professional mathematicians in the Whig tradition (cf. the quote by Weil above). Unfortunately, this also has consequences for translations of sources and consequently for their roles as interlocutors. Schubring (2008), for example, points out that contrary to their claim of being accurate, some translations of well-known historical classics exist that have distorted the original sources.

27.6.4 Projects on Boolean Algebra and Electric Circuit Design at Undergraduate Level

The next example is situated in the context of teaching US undergraduate students with projects based on guided readings of original sources (cf. earlier). Janet Barnett has developed several such projects (see Barnett et al. 2011), and in the following we shall look at two of them.

In the first one, she deals with the origin of Boolean algebra by guiding students through carefully chosen parts of Boole's 1854 treatise on the "*Laws of Thought"* (Barnett 2011a). Boole introduces a new algebra by explaining the use of "signs" to represent "classes" and by defining a system of symbols (+,–,×, 0, 1) to represent operations on these signs and finally deducing the basic laws that the operations must follow. While so doing, Boole continuously compares his new algebra to standard arithmetical algebra,[38] one of the main differences being that in Boole's algebra

---

[38] One might talk about a built-in replacement and *dépaysement* in Barbin's sense in Boole's own presentation of his algebra.

we have that $xx=x$ (or $x^2=x$), because if, for example, x stands for "good," then saying "good, good men" is the same as saying "good men." Knowing that this can only be so if x is either 0 or 1, Boole draws the consequence by conceiving an algebra where symbols x, y, z, etc. admit indifferently of the values 0 and 1, and of these values alone, and carries on to deduce a series of laws. Barnett's (2012, p. 344) ultimate goal of this project is to have the students "develop an understanding of the modern paradigm of elementary set theory as a specific example of a Boolean algebra," and for that reason she has students study original sources of both Venn and Peirce next, as part of the project.

In the other project of Barnett's which is mentioned here, she has students read part of Shannon's famous 1938 article on design of electric circuits by means of simplification through Boolean algebra (Barnett 2011b). Using a set of postulates from Boolean algebra ($0 \cdot 0=0$; $1+1=1$; $1+0=0+1=1$; $0 \cdot 1=1 \cdot 0=0$; $0+0=0$; and $1 \cdot 1=1$) and interpreting these in terms of circuits ($0 \cdot 0=0$ meaning that a closed circuit in parallel with a closed circuit is a closed circuit and $1+1=1$ meaning that an open circuit in series with an open circuit is an open circuit), Shannon is able to deduce a number of theorems which could be used to simplify electric circuits.

From studying these two projects by Barnett, it is clear that focus is on the in-issues as she guides the reader through the original texts and eventually leads him or her up to a, in the first project, modern account of the algebra of logic, set theory, and Boolean algebra of today and in the second project to relating Shannon's original representation of connections in series and in parallel to that of today as well as introducing truth tables in the guiding tasks. Regarding the first project, Barnett says that it

> … provides an opportunity for students to witness how the process of developing and refining a mathematical system plays out, the ways in which mathematicians make and explain their choices along the way, and how standards of rigor in these regards have changed over time. (Barnett 2012, p. 344)

However, the in-issue focus must also be seen as a natural consequence of the educational setting for which the projects are designed – undergraduate students following courses relying on such projects will eventually have to follow several traditionally taught courses relying on modern-day textbooks, for which they need to know modern-style notation and standards for proof. Nevertheless, the approach of guided reading still leaves the excerpts from the original sources completely untouched, potentially enabling students to make their own interpretations along the way.

27.6.5 HAPh Modules and the Development of Upper Secondary Students' Overview and Judgment

The final example concerns students' reading of some of the same original sources as those used by Barnett but in the setting of Danish upper secondary school. The motivation for this use of original sources was twofold: to design teaching modules focusing on meta-issues of history, applications, and philosophy of mathematics in unison (Jankvist 2013) and to measure the effect of such modules on the students' development of what Niss and Højgaard (2011) term "overview and judgment" (Jankvist 2012a). The notion of overview and judgment stands in contrast to the previously mentioned one of mathematical competency, in that these do not concern "readiness to act" but instead are "'active insights' into the nature and role of mathematics in the world" which "enable the person mastering them to have a set of views allowing him or her *overview and judgement of the relations between mathematics and in conditions and chances in nature, society and culture*" (Niss and Højgaard 2011, p. 73, italics in original). Niss and Højgaard deal with three types of overview and judgment, which have already been exemplified in the quotes given when introducing the notion of in-issues and meta-issues earlier:

- The historical evolution of mathematics, both internally and from a social point of view
- The actual application of mathematics within other subjects and practice areas
- The nature of mathematics as a subject

The design encompassing all three of these dimensions – referred to as *H*istory, *A*pplication, and *Ph*ilosophy (*HAPh)* – was based on an observation that the inclusion of these dimensions share an overlap in the so-called whys and hows, i.e., that similar reasons are provided for their inclusion and that similar approaches can be used (see Jankvist 2013). Further, it was argued that the use of original sources, one for each dimension, through a guided reading and a use of essay assignments was a suitable way of evoking the desired meta-issues.

In one such HAPh module, Boole's original text on the *Laws of Thought* made up the historical dimension and Shannon's 1938 article on electric circuit design the applicational dimension (cf. the previous illustrative example). The original source for the philosophical dimension was a paper by Hamming from 1980 in which he discusses *The unreasonable effectiveness of mathematics*[39] from the viewpoint of engineering (and computer science), asking why it may be that so comparatively simple mathematics suffices to predict so much, this question making up the "unreasonable" aspect. After discussing what mathematics is, Hamming provides some tentative explanations of why mathematics is in fact so effective (see Jankvist 2013). Based on their readings of these three original sources, students were to do essay assignments discussing if the idea of Boolean algebra and its later use in describing electric circuits may be seen as an example of the unreasonable effectiveness of mathematics and if so then why (for students answers and reflections, see Jankvist 2012b, 2013). In another HAPh module, the same class of students had previously worked with the beginning of graph theory (Euler), its later use in solving the shortest path problem (Dijkstra), and the role of mathematical problems (Hilbert).[40]

---

[39] This paper was a comment to a paper by the physicist Wigner from 1960, who addressed *The unreasonable effectiveness of mathematics in the natural sciences*.

[40] For a description of this HAPh module, see Jankvist (2012a, 2013). See also Barnett (2009) for a project on graph theory.

Now, in order to actually try and measure any effect these HAPh modules may have had on the development of a class of upper secondary students' overview and judgment, one must of course have ways of both *accessing* and *assessing* such. The means for accessing the students' overview and judgment were a combination of questionnaires, asking questions related to each of the three types of overview and judgment (see Jankvist 2012a) and follow-up interviews before, during, and after the implementation of the HAPh modules.[41] As for assessment, it is argued in Jankvist (2012a) that it makes sense to address the development of overview and judgment as a combination of students' actual *knowledge* and their *reflected images of mathematics as a* (*scientific*) *discipline*, where the latter may be measured in terms of:

- The growth in *consistency* between students' related beliefs/views
- The extent to which a student seeks to *justify* his or her beliefs and views
- The amount of provided *exemplifications* in support of the beliefs and views a student holds, i.e., the beliefs appear to be held more evidentially

The mentioning of beliefs here of course refers to the vast amount of literature on students' beliefs (e.g., Leder et al. 2002). While *beliefs* are usually taken to be something rather persistent, meaning that they are not likely to develop and change over a short-time period,[42] *views,* on the other hand, may be taken to be something less persistent but with the potential to develop into beliefs at a later point in time (Jankvist 2009b, forthcoming). Thus, development in, and changes of, students' beliefs *and* views, in unison the reflected images, provides an insight into their overview and judgment. However, it is important to stress again that overview and judgment does not equal beliefs and views, since it also consists of the actual *knowledge* which the students possess in relation to both mathematical in-issues and meta-issues.

One question or topic which has proven itself particularly helpful in uncovering students' overview and judgment is that of mathematics being discovered or invented (e.g., Hersh 1997). To illustrate this, an excerpt from an interview with the upper secondary student Larry from when he had been through both HAPh modules is offered;

Interviewer	And you say about Boolean algebra that you believe it to be invented? […]
Larry	Yes, we define [it] ourselves. It's… We take a way of thinking and turn it into mathematics; this means this and that means that… Well, it might be that the way of thinking was already there, but we invent a way of writing it within mathematics. I'm not sure I can phrase it any better.
Interviewer	Okay. In question 26 you say that Boolean algebra, classes, etc. are human constructions, which of course is connected to what you just said. But do you believe mathematics in general to be something we invent, or are there also things in mathematics which we discover?

(continued)

---

[41] In some instances it was also possible to perform methodological triangulation with other data sources such as students' hand-ins, student group essay assignments, and video recordings as exemplified in Jankvist (2009b).

[42] Evidential (or evidence-based) beliefs are, however, more likely to change than non-evidentially held beliefs (Green 1971).

(continued)

Larry	Well… There can be connections in mathematics which we discover. For example the equation with Euler's number in the power of π times i minus or plus 1 equals 0 [$e^{i\pi}+1=0$]. These are some interrelations which we have not made ourselves. It is a lot of independent things which we have found and which then fits together and reveals a beautiful connection. […] I think it is a good example of something which we just discover. As far as I know these [π, e, and i] were not that associated. But that they fit together in this way, it kind of shows… that there must be a… that no matter what, we did something right.
Interviewer	Yes?
Larry	So regarding invention or discovery in mathematics, I think… I think that some things are invented and some discovered. I will risk claiming that.
Interviewer	Alright. Can you give some examples?
Larry	Well… for example our way… in graph theory, to translate bridges into numbers and the way of writing it all up [the Königsberg bridge problem]. That is something we've made. While things as… what is a good example? Things as π is something we discovered. […]
Interviewer	Okay. Is it possible to say if one precedes the other? Does discovery precede invention or does invention precede discovery?
Larry	In most cases it must… well, not necessarily… With π, for instance, I guess that discovery was before invention, because… If we say that we invented, that we set a circle to 360°. But when we calculate π […] then we don't use the 360°, as far as I recall. […] It is different within different areas of mathematics, but with π I think we discovered that there was a connection first, and then we built on that. But it's quite related; when we choose something we quickly arrive at some further discoveries.

(Interview with Larry, November 16th, 2011, translated from Danish. Quoted from Jankvist 2012a, pp. 859–860)

The excerpt illustrates well how Larry is able to both justify and exemplify his beliefs/views regarding invention and discovery. In terms of *development* of overview and judgment, Larry had started off a year and a half earlier, before the HAPh modules, to believe mathematics to be mainly an invention. In between the modules, he shifted to believing in mainly discovery. But above we see him adopting a more reflected stance, arguing that mathematics can be both.[43] To illustrate discovery, he first mentions Euler's identity ($e^{i\pi}+1=0$) as something that he finds unlikely to have been invented (Euler's identity was not part of the HAPh modules). Later he carries on to elaborate on the number π in relation to discovery, and we get an example of the interplay of beliefs/views and knowledge, when he refers to his actual knowledge of our convention of 360° in a circle being unrelated to the appearance of the number π. As examples of mathematics which is invented, he refers to the cases of the HAPh modules: first, Boole's introduction of his new algebra and later Euler's approach to dealing with the Königsberg bridge problem. Such exemplification helps Larry to hold his beliefs and views more evidentially,

---

[43] Although the dimension of consistency is not very present in the displayed interview excerpt above, a growth in consistency was present in general in the case of Larry (Jankvist 2012a).

which also assists him in justifying them as well as the development and changes in them.[44] Thus, in this respect the primary original sources play the role of *evidence* which, together with the knowledge students have acquired from studying them, comes to form the basis for developing their overview and judgment (For further discussion, see Jankvist 2012a).

27.7 Discussing the Past, Present, and Future of Using Primary Original Sources

Having now looked at the background, the various reasons and approaches for using primary original sources, and the selected illustrative examples of didactic findings, it is time to recapitulate and look at possible directions which the use of original sources may take in the future, i.e., other reasons than those already discussed. A handful of such different perspectives on the use of original sources shall be pointed to.

27.7.1 Expanding the Emphasis

As indicated, the main emphasis of the use of original sources has, until recently, been on the teaching and learning of mathematical in-issues, both in terms of students' understanding or sensemaking of mathematical concepts and notions as well as in terms of motivating these; it is clear that the experience of seeing how a certain mathematical construct was motivated historically can provide students with a deeper understanding of why this construct came to look the exact way it did.[45] What should be added is that original sources may offer *a truer mode of presentation* when compared to that of textbooks, which usually go as follows: definition(s), theorem(s), proof(s), and application(s). In reality, the historical development of a mathematical topic is close to being the reverse – as mentioned when discussing Pengelley's (2011) reason 9 earlier. With original sources' often built-in relation between theory and practice, definitions of concepts, theorems, etc. are motivated. They do not appear out of nowhere. This means that the study of original sources may have as an outcome that students become more willing to accept abstract mathematical constructs, since these come to appear as natural consequences of the mathematical investigations presented in the source.

With the ICMI Study of 2000, it became clear that *more empirical research was needed* on introducing a historical dimension into the teaching and learning of

---

[44] In the case of non-evidentially held beliefs, justification might very well take place without exemplification (see Jankvist 2009b, 2012a).

[45] Take, for example, the concepts of function, limit, continuity, and not least uniform convergence (see, e.g., Katz 1998 or the appendix on uniform convergence in Lakatos 1976).

mathematics, including the use of original sources to do so.[46] One recent example is the study by Glaubitz (2011), in which he compared different approaches to the teaching of quadratic equations and the quadratic formula and found that pupils who had been taught with original sources through the hermeneutic approach scored higher in standard tests than a control group who had been taught with a conventional approach. Also, as illustrated with the previously provided examples, some of the empirical work which eventually followed has contributed in broadening the scope of using original sources. With the studies of Kjeldsen, for instance, focus is not only on students' understanding of mathematical in-issues but also on their development of mathematical competencies as a result of studying and working with primary original sources (Kjeldsen 2011a; Jankvist and Kjeldsen 2011). Further, the examples illustrated how original sources (and excerpts of such) may play a role in teaching students something about the meta-issues of mathematics as a scientific discipline; how to do this in such a manner that the students' discussions of these meta-issues are anchored in their understanding of the related mathematical in-issues (Jankvist 2011); and how teaching modules involving readings of original sources related to history, application, and philosophy in unison may assist in developing students' overview and judgment (Jankvist 2012a).[47]

27.7.2 The Role of Theoretical Constructs from Mathematics Education Research

Another important aspect, which the chosen examples illustrate, is the relationship between empirical studies on resorting to original sources and *the use of theoretical frameworks and constructs from mathematics education research*. The discussion and "measuring" of original sources' effect on students' development of mathematical competencies and overview and judgment as defined by Niss and Højgaard (2011) are examples of this (including the discussion of students' beliefs in relation to overview and judgment). And another example is the use of Sfard's (2008) theory of commognition to illustrate the (almost indispensable) role of original sources as different discussants in students' learning of meta-discursive rules (Kjeldsen and Blomhøj 2012). But it is not only the case that the use of mathematics education research frameworks may inform the use of original sources and history of mathematics in general, in the teaching and learning of mathematics; it is also the case that the history of mathematics and the use of original sources may inform mathematics education frameworks. An example of this may be found in the study by Clark (2012), who, in a setting of teacher education, has used excerpts from an original

---

[46] Since then a handful of PhD theses to some degree addressing empirical aspects of using original sources (or excerpts of such) have appeared: Clark (2006), Glaubitz (2010), Gulik-Gulikers (2005), Jankvist (2009b), and Ta'ani (2011).

[47] For a much more detailed account of the empirical studies available in the field of history in mathematics education, see Jankvist (2012c).

source by al-Khwariszmi, presenting his methods for solving quadratic equations. Based on her findings, Clark argues that history of mathematics (including the study of original sources) is part of the "something else" in the framework of mathematical knowledge for teaching (MKT) (Ball et al. 2008), since it informs teachers in their instructional practice. Taking into consideration the obvious benefits of discussing the use of history and original sources in teacher training within the framework of teachers' development of mathematical knowledge for teaching, there is thus a dual relationship between the MKT framework and the use of history and original sources in teacher training, which deserves to be investigated further (Jankvist et al. 2012).

27.7.3 Interdisciplinarity and Original Sources

The example of van Maanen's activity of students' reading Bartolus of Saxoferrato also indicates an important role for primary original sources, namely, that of providing a natural environment for *interdisciplinary teaching and learning*. Over the past decades, interdisciplinarity in both research and education has become a frequently debated topic. However, it shall be my claim that from an educational perspective, interdisciplinarity often presents a didactic dilemma: On the one hand, students are told that interdisciplinary work is extremely important (for various different reasons); on the other hand, the students are often only shown somewhat artificial and situational constructed examples, which make the dimension of interdisciplinarity appear pasted on. But because original sources deal with reality – even if it is a historical one – any given interdisciplinary elements within them are likely to illustrate much better to students the importance of interdisciplinarity in research and society. The example by Kjeldsen and colleagues of students' reading of Bernoulli's work on the catenary is actually also an example of interdisciplinarity between mathematics and physics, since the students had to struggle with "Bernouli's mathematization of the physical description of the catenary" – in fact, the students' purpose of studying these sources was to investigate physics' influence on the development of differential equations (see Kjeldsen and Blomhøj 2012). In short, original sources bring authenticity to the dimension of interdisciplinarity in teaching and learning.

27.7.4 Recruitment, Transition, and Retention: A Triple Aspect of a Potential Role for Original Sources

Just as the role of original sources as a means for authentic interdisciplinarity is as relevant for mathematics as it is for the natural sciences (and engineering), so are the following three possible future roles, on which is speculated. The first of these is the role of original sources in relation to the *recruitment problem.* As we know, in the Western world, we have been experiencing problems with recruiting students for the mathematical sciences. Very often, upper secondary school students do not have an accurate idea of what mathematics is all about, when practiced as a scientific discipline at the tertiary levels, e.g., by pure and applied mathematicians at universities. Students' answers to the question of what professional mathematicians do typically range from having no clue at all to believing that they perform some kind of "clean-up job" consisting in finding "errors" in already existing formulas and proofs, more efficient ways of calculating already known quantities, etc. (Jankvist 2009b, forthcoming). Often such views have to do with the students' impression of mathematics as something a priori given, static and rigid – a belief not unrelated to textbooks' usual presentation of mathematical topics of course; only very few students seem to believe it possible that mathematicians can come up with actual *new* mathematics. Therefore, the students know neither what they accept to study nor what they reject to study, if they choose to engage with mathematics. Studying primary original sources can enlighten the students in this respect.[48]

The second role of original sources is related to the *transition problem* between educational levels. From the design and implementation of the HAPh modules as discussed above (Jankvist 2013) and the projects by Barnett using the same original sources, we can make the observation that choosing original sources presenting novel mathematical ideas can assist in making otherwise complicated mathematical topics more accessible to students. One of the reasons for this is that when stepping into uncharted territory, researchers may be more careful in explaining what they are doing and why, as well as why they are approaching a problem in a certain manner. Boole's text on the *Laws of Thought* is one such original source and Euler's text on the Königsberg bridge problem is certainly another. Thus, my point here is that the use of primary original sources may be seen as a way of dealing with the transition problem between, for example, upper secondary level and undergraduate university level. Because, on the one hand, when upper secondary students are presented with such material, they encounter actual research papers from mathematics and/or science, texts, in which the motivation for this piece of research and/or the application of it is sometimes discussed, and even though this happens in a historical setting, it illustrates the nature of research in academic communities in general. And, on the other hand, if such carefully chosen primary sources presenting novel ideas are used in introductory courses at undergraduate level, they may ease the students into the academic way of thinking and thereby make the transition to university level less "harsh."[49]

The third possible role of original sources which is mentioned has to do with the problem of retaining the students once they have already been recruited and

---

[48] In fact, student interview data from the HAPh module study support this claim; students expressed that due to their work with the two HAPh modules and hence their reading of the six original texts, they were able either to select or deselect a future engagement with mathematics and mathematical sciences on a more enlightened basis (Jankvist, preprint).

[49] This was also discussed in Jankvist's presentation "The use of original sources and its possible relation to the transition problem" at Colloque Artigue 2012 in Paris.

undergone transition, i.e., the *retention problem*.[50] The authenticity of the sources is also a key element in relation to this problem, as it was for the problem of interdisciplinarity. Because original sources offer a variety of real-life, that is, non-artificial, applications of various mathematical in-issues, such sources can provide *meaning* for the students in their learning. Although not taken from university level, the following quote from an interview with one of the students in the HAPh modules study illustrates this:

> For me, I personally think that I get much more interested, when I see it all, than if I'm only told that now we are studying vectors and we must learn how to dot these vectors and then we must be able to calculate a length, right. That's all very good, but what am I to use it for? Whereas, when you know about the background, the development up till today, that I think was exciting. Because when we began with the first text [Boole's text], it was kind of like, yeah, that's alright, he can figure out this thing here, and this equals that, I can follow that, and 'white sheep' and so… That was good for starters. Then more is built on top, and all of a sudden we see: Why, it's a [electric] circuit we are doing! You could begin to relate it to your own reality; that is, something you knew already. So, the thing about starting from scratch […] and suddenly seeing it form a whole, what it was used for today – and be able to relate it to something, something you knew about – that I think was way cooler. (Interview with Nikita, November 3rd, 2011, translated from Danish. Quoted from Jankvist 2012b, pp. 139–140)

Recently, Pengelley (2012) and Barnett (2012) have designed entire courses in elementary number theory and abstract algebra, respectively, around the use of original sources only – courses thought possibly to play a role also in terms of retention. But nevertheless, what may be still be needed from an empirical point of view is more quantitative data on the effect and efficacy of using primary original sources, data which can underpin and support the many positive qualitative statements, as, for example, that of Nikita above, which are present in the relatively larger number of qualitative empirical studies available in the field.

27.7.5 Additional and Concluding Remarks

In the present chapter, not much effort has been taken to distinguish between using original sources at the various educational levels, except from choosing the illustrative examples to more or less cover the possible spectra. When actually choosing which sources to use in a given situation, the educational level is of course essential, because as Jahnke et al. (2000) point out:

> Incorporating primary sources is not good or bad in itself. We need to establish the aims, including the target population, the kind of source that might be suitable and the didactical methodology necessary to support its incorporation. (Jahnke et al. 2000, p. 293)

---

[50] This role of original sources was suggested by David Pengelley, who discussed it during the panel "Empirical research on history in mathematics education: current and future challenges for our field" at HPM2012 in Deajeon.

Also, not much emphasis has been put on the use of original sources in teacher education, except when referring to the study of Clark (2012). However, based on what has been said and discussed, it is possible to provide some comments to at least four of the five questions for future research on the use of original sources formulated by Furinghetti et al. (2006) (cf. Sect. 27.2). Regarding question 1, it seems clear to me that if a use of primary original sources is to gain any real impact in the field of mathematics education, then the evaluation of such uses must build and rely on theoretical constructs and frameworks from mathematics education research. Some examples of such potentially relevant frameworks have been put forth in this chapter (e.g., Ball et al. 2008; Niss and Højgaard 2011; Sfard 2008), but clearly it is possible to find many more that applies in one way or another. As for question 2, it appears that some kind of guidance of the students is a characteristic of many viable approaches for using original sources, whether this is in the form of guided readings, familiarizing the students with the mathematical in-issues before reading a source, as done in the hermeneutic approach, or structuring students' discussions of meta-issues through a use of essay assignments. In terms of question 4, we have seen that a historical research stance, such as the multiple-perspective approach as described by Kjeldsen, indeed can support the use of original sources in the teaching and learning of mathematics. As one of the working tools of this approach, we saw that the notion of epistemic objects and techniques can assist in anchoring students' discussions of meta-issues in the related in-issues (e.g., Jankvist 2009b). Also, the notion of Whig history helped in qualifying our discussion of the various approaches to using original sources. Although question 5 makes up an interesting question, I am not aware of any examples of mathematics education having supported or broadened research in the field of history of mathematics. What is more common is that people in mathematics education, who have taught using original sources, may eventually be drawn towards doing some research in the history of mathematics. Regarding question 3 on the actual impact of the various viable approaches to students' learning and understanding of mathematics, the account given above illustrates that this is not simply a matter of getting students to learn and understand mathematical in-issues or motivate them to do so. Even though this may be the overall end goal, there are other crops to be harvested from using primary original sources, for example, the development of students' mathematical competencies and the development of their overview and judgment. And as mentioned, the development of mathematical competencies may be a much more natural way of assessing the efficiency and efficacy of using history and original sources in mathematics education (Jankvist and Kjeldsen 2011). As for potential crops to be harvested in the future field of using primary original sources, the aforementioned educational problems of interdisciplinarity, recruitment, transition, and retention make up interesting and promising research areas. Already, these problems have the attention of educational researchers, curriculum designers, and policy makers, so if positive empirical results (quantitative and qualitative) could be produced in support of these roles of primary original sources, then surely this would assist in the use of original sources gaining impact in mathematics education in general – and science education too, since these four problems are not restricted to mathematics education alone.

Uffe Thomas Jankvist is associate professor of mathematics education at Aarhus University, Dept. of Education, Emdrup, Denmark. He holds a M.Sc. in mathematics and computer science as well as a Ph.D. in mathematics education from Roskilde University and a postdoc from the University of Southern Denmark. His research interests include the use of history of mathematics, applications of mathematics, and philosophy of mathematics in mathematics education, both from a theoretical and an empirical point of view, including also students' beliefs about and images of mathematics as a (scientific) discipline. Uffe Thomas Jankvist has published in a variety of journals, e.g. *The Mathematical Intelligencer*, *Journal for Research in Mathematics Education*, *Educational Studies in Mathematics*, *Science & Education*, *For the Learning of Mathematics*, *Mathematical Thinking and Learning*, *Historia Mathematica*, *BSHM Bulletin*, and *ReLIME*. Besides being the Danish editor of *NOMAD – Nordic Studies in Mathematics Education* – he is currently involved in a new initiative to design and implement an educational program for in-service high school mathematics teachers to become 'math counselors', whose purpose shall be to provide special aid to high school students with learning difficulties in mathematics.

Chapter 28
Nature of Science in the Science Curriculum: Origin, Development, Implications and Shifting Emphases

Derek Hodson

28.1 Introduction

Before proceeding to the substance of this chapter, it is important to clarify what I mean by *nature of science* (NOS) and note the ways in which I use the term differently from some others. A number of authors seek to restrict its use to the characteristics of scientific knowledge (i.e. to epistemological considerations) and to exclude consideration of the nature of scientific inquiry.[1] This might strike some as an odd decision, given that much of our scientific knowledge and, therefore, consideration of its status, validity and reliability is intimately bound up with the design, conduct and reporting of scientific investigations. Moreover, teaching activities focused on NOS often include empirical investigations and/or critical scrutiny of existing data. Thus, as Ryder (2009) points out, the conduct of scientific inquiry and epistemological considerations are related conceptually, procedurally and pedagogically. Lederman (2006) has acknowledged that 'the phrase 'nature of science' has caused the confusion and the phrase 'nature of scientific knowledge' might be more accurate. The conflation of NOS and scientific inquiry has plagued research on NOS from the beginning' (p. 2). In other words, it would be less confusing to readers if authors used the term 'nature of scientific knowledge (NOSK)' when referring to strictly and/or solely epistemological matters. In common with

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_28,

several other recent publications,[2] the definition of NOS deployed in this chapter encompasses the characteristics of scientific inquiry; the role and status of the scientific knowledge it generates; the modelling that attends the construction of scientific theories; the social and intellectual circumstances of their development; how scientists work as a social group; the linguistic conventions for reporting, scrutinizing and validating knowledge claims; and the ways in which science impacts and is impacted by the social context in which it is located.

Given this much broader definition of NOS, it is quickly apparent that arguments for including NOS in the science curriculum have a long and chequered history. The long-standing tradition of concern for 'the public understanding of science' in the United Kingdom, encompassing much of what I refer to as NOS, dates back to the early years of the nineteenth century. As Jenkins (1990) notes, science was vigorously promoted through the activities of the numerous Mechanics' Institutes and Literary and Philosophical Societies and further supported by public lectures, scientific demonstrations and 'a remarkable variety of books, journals, tracts, pamphlets and magazines, many of which would be categorized today as 'teach yourself publications" (p. 43). Perhaps the earliest proposal for an NOS-oriented curriculum at the school level was Henry Armstrong's heuristic approach,[3] published in 1898, although it is important to note that Armstrong's interest in NOS was mainly pedagogical and motivational; the real purpose was to acquire and develop scientific knowledge. In contrast, John Dewey (1916) argued that familiarity with scientific method was substantially more important than acquisition of scientific knowledge, particularly for those who do not intend to study science at an advanced level. Similarly, Frederick Westaway (1929), an influential HM Inspector of Schools in the United Kingdom in the 1920s, made a strong case for a curriculum focus on NOS:

> Now that science enters so widely and so intimately into every department of life, especially in all questions relating to health and well-being, it is important that the community should have a general knowledge of its *scope and aims*. (p. 9, emphasis added)

Some years later, similar rhetoric formed the basis of Joseph Schwab's (1962) advocacy of a shift of emphasis for school science education in the United States away from the learning of scientific knowledge (the products of science) towards an understanding of the processes of scientific inquiry and the structure of scientific knowledge – a line of argument that eventually led to a string of innovative curriculum projects (PSSC, BSCS, CHEM Study, CBA, ECSP, etc.). NOS-oriented developments in the United Kingdom during the 1960s included the Nuffield Science Projects (with their emphasis on 'being a scientist for the day' and 'developing a proper attitude to theory') and the Schools Council Integrated Science Project (SCISP). However, as a direct consequence of their reliance on an impractical pedagogy

of discovery learning and the naïve inductivist model of science underpinning it, these somewhat elitist courses failed to deliver on their rhetoric and promise. Those of us who were required to adopt the pedagogy of discovery learning during its heyday in the 1960s will vividly recall the frustrations of not being allowed to provide students with any guidance or suggest alternative lines of approach when investigating phenomena and events.[4] Subsequently attention shifted towards the so-called process approaches to science education, exemplified by *Warwick Process Science* (Screen 1986, 1988), *Science in Process* (ILEA 1987) and *Active Science* (Coles et al. 1988), which envisaged scientific inquiry as the application of a generalized, all-purpose algorithmic method. A similar shift occurred in Australia, with the publication of the *Australian Science Education Project* (ASEP 1974), and in the United States, with initiatives such as *Science-A Process Approach* (AAAS 1967) being developed on the basis of Robert Gagné's (1963) claim to have identified thirteen basic skills of scientific inquiry.

After a period of decline, interest in NOS underwent a remarkable revival in the decade and a half between 1977 and 1992, with the publication of a number of opinion pieces and commissioned reports,[5] the establishment of the International History, Philosophy and Science Teaching Group (1987) and the first of the now biennial IHPST conferences in Tallahassee in 1987 – developments that led, through the prodigious efforts of Michael Matthews, to the foundation in 1992 of *Science & Education*, the first journal devoted primarily to NOS issues in education. Of particular significance during this period was the incorporation of NOS as a key component in the National Curriculum for England and Wales, established in 1989 following the Education Reform Act of 1988. Another landmark was the publication of Matthews' book *Science Teaching: The Role of History and Philosophy of Science* (Matthews 1994).

Although there has been continuing controversy about what the NOS component of the curriculum should comprise and how it should be implemented (Donnelly 2001), the overall curricular importance of NOS understanding per se is no longer in dispute. Indeed, it has been subsumed within the wider discussion of scientific literacy,

---

[4] For example, early on in the original *Nuffield Physics* course, students are provided with a lever, a fulcrum and some weights (uniform square metal plates) and are invited to 'explore' and to 'find out what you can'. No particular problem is stated; no procedure is recommended. It is assumed that the Law of Moments will simply emerge from undirected, open-ended exploration. Nothing could be further from the truth. First, the system does not balance in the way the students expect because the pivot is below the centre of gravity. If the weights are suspended *below* the pivot, as in a set of scales, the beam will balance. However, there is little chance that children will discover this for themselves. Second, children tend to spread the weights irregularly along the entire length of the beam. The complexity of this arrangement obscures the simple relationship that is sought. Consequently, teachers begin to proffer advice on how to make the problem simpler and to issue instructions about the best way to proceed. Similar things happen whenever children are presented with this kind of open-ended situation. See Hodson (1996) for an extended discussion of these issues.

[5] See, for example, Cawthron and Rowell (1978), Hodson (1985, 1986, 1988a, b, 1990, 1991), Matthews (1991, 1992), Nadeau and Désautels (1984)) and Royal Society (1985).

a term that first appeared in the US educational literature about 50 years ago in papers by Paul Hurd (1958) and Richard McCurdy (1958) and in the Rockefeller Brothers Fund (1958) report *The Pursuit of Excellence*, and is now regarded as a key feature of most science curricula.

Despite the term scientific literacy being enthusiastically adopted by many science educators as a useful slogan or rallying call (see Roberts 1983, 2007), there was little in the way of precise or agreed meaning until Pella et al. (1966) suggested that it comprises an understanding of the basic concepts of science, the nature of science, the ethics that control scientists in their work, the interrelationships of science and society, the interrelationships of science and the humanities and the differences between science and technology. Almost a quarter century later, the authors of *Science for All Americans* (AAAS 1989) drew upon very similar categories to define a scientifically literate person as ‘one who is aware that science, mathematics, and technology are interdependent human enterprises with strengths and limitations; understands key concepts and principles of science; is familiar with the natural world and recognizes both its diversity and unity; and uses scientific knowledge and scientific ways of thinking for individual and social purposes’ (p. 4). It is significant that these perspectives are now an integral part of the US *National Science Education Standards* (National Research Council 1996) and a central plank of the framework for the *Programme for International Student Assessment* (PISA) studies (OECD 1999, 2006, www.pisa.oecd.org). Detailed review of the literature focused on defining notions of scientific literacy is outside the scope of this chapter,[6] save to note that elements of the history of science, philosophy of science and sociology of science that constitute a satisfactory understanding of the nature of science (NOS) have now become firmly established as a major component of scientific literacy and an important learning objective of science curricula in many countries.[7] Indeed, the promotion of NOS in official curriculum documents has become so prominent that Dagher and BouJaoude (2005) have stated: ‘improving students’ and teachers’ understanding of the nature of science has shifted from a *desirable* goal to being a *central* one for achieving scientific literacy’ (p. 378, emphasis added). It follows that all arguments for scientific literacy become arguments for NOS.

---

[6] Extensive discussion of the history and evolving definition of scientific literacy can be found in Bybee (1997a, b); Choi et al. (2011), De Boer (2001), Dillon (2009), Feinstein (2011), Gräber and Bolte (1997), Hodson (2008, 2011), Hurd (1998), Laugksch (2000), Lehrer and Schauble (2006), Lemke (2004), Linder et al. (2012), McEneaney (2003), Miller (2000), Norris and Phillips (2003), Norris et al. (2013), Oliver et al. (2001), Roberts (2007), Roth and Calabrese Barton (2004), and Ryder (2001). Teachers’ understanding of scientific literacy is explored by Smith et al. (2012).

[7] For example, AAAS (1993), Council of Ministers of Education (1997), Department of Education (RSA) (2002), Goodrum et al. (2000), Millar and Osborne (1998), National Research Council (1996), Organization for Economic Cooperation and Development (1999, 2003), Osborne and Dillon (2008), and UNESCO (1993).

28.2 Arguments for NOS/Scientific Literacy in the School Science Curriculum

Reviewing what they describe as an extensive and diverse literature, Thomas and Durant (1987) identify three major categories of argument for promoting scientific literacy (and, therefore, aspects of NOS understanding): (i) benefits to science, (ii) benefits to individuals and (iii) benefits to society as a whole. Driver and colleagues (1996) contend that in addition to its intrinsic value, NOS understanding enhances learning of science content, generates interest in science and develops students' ability to make informed decisions on socioscientific issues based on careful consideration of evidence, while Erduran and colleagues (2007) argue that NOS knowledge (and the wider HPS understanding subsumed in the notion of scientific literacy) is of immense value to teachers, making them more reflective and more resourceful.

Benefits to science are seen largely in terms of increased numbers of recruits to science-based professions (including medicine and engineering), greater support for scientific, technological and medical research and more realistic public expectations of science. A related argument is that confidence and trust in scientists depend on citizens having some general understanding of what scientists do and how they do it – in particular, about what they choose to investigate, the methods they employ, how they validate their research findings and theoretical conclusions and where, how and to whom they disseminate their work.

Arguments that scientific literacy brings benefits to *individuals* come in a variety of forms. First, it is commonly argued that scientifically literate individuals will have access to a wide range of employment opportunities and are well positioned to respond positively and competently to the introduction of new technologies in the workplace. Second, it is widely assumed that those who are scientifically literate are better able to cope with the demands of everyday life in an increasingly technology-dominated society, better positioned to evaluate and respond appropriately to the scientific evidence and arguments (sometimes authentic and relevant, sometimes biased, distorted, fallacious or irrelevant) used by advertizing agencies and deployed by politicians and better equipped to make important decisions that affect their health, security and economic well-being.

Arguments that enhanced scientific literacy brings benefits to *society as a whole* include the familiar and increasingly pervasive economic argument and the claim that it promotes democracy and responsible citizenship. The first argument sees scientific literacy as a form of human capital that builds, sustains and develops the economic well-being of a nation. Put simply, continued economic development brought about by enhanced competitiveness in international markets (regarded as incontrovertibly a 'good thing') depends on science-based research and development, technological innovation and a steady supply of scientists, engineers and technicians. The case for scientific literacy as a means of enhancing democracy and responsible citizenship is just as strongly made as the economic argument, though by a very different assembly of stakeholders and interest groups. In the words of Chen and Novick (1984), enhanced scientific literacy (and its attendant components of NOS understanding) is a means 'to avert the situation where social values, individual involvement, responsibility, community participation and the very heart of democratic decision making will be dominated and practiced by a small elite' (p. 425).

This line of argument maintains that democracy is strengthened when *all* citizens are equipped to confront and evaluate socioscientific issues (SSI) knowledgeably and rationally, as well as emotionally, and are enabled to make informed decisions on matters of personal and public concern. Those who are scientifically illiterate are in many ways disempowered and excluded from active civic participation. For these reasons, Tate (2001) declares that access to high-quality science education, with its increasing emphasis on NOS, is a civil rights issue. Of course, as both Levinson (2010) and Tytler (2007) remind us, the notion of science education for citizenship raises a whole raft of questions about the kind of citizen and the kind of society we have in mind and about what constitutes *informed* and *responsible* citizenship – matters well outside the scope of this chapter.

A number of writers have claimed, somewhat extravagantly, that appreciation of the ethical standards and code of responsible behaviour that the scientific community seeks to impose on practitioners will lead to more ethical behaviour in the wider community – that is, the pursuit of scientific truth regardless of personal interests, ambitions and prejudice (part of the traditional image of the objective and dispassionate scientist) makes science a powerful carrier of moral values and ethical principles: 'Science is in many respects the systematic application of some highly regarded human values – integrity, diligence, fairness, curiosity, openness to new ideas, skepticism, and imagination' (AAAS 1989, p. 201). Shortland (1988) summarizes this rationale as follows: 'the internal norms or values of science are so far above those of everyday life that their transfer into a wider culture would signal a major advance in human civilization' (p. 310). The authors of *Science for All Americans* (AAAS 1989) present a similar argument: 'Science is in many respects the systematic application of some highly regarded human values – integrity, diligence, fairness, curiosity, openness to new ideas, skepticism, and imagination' (p. 201). Studying science, scientists and scientific practice will, they argue, help to instill these values in students. In other words, scientific literacy doesn't just result in more skilled and more knowledgeable people, it results in *wiser* people, that is, people well-equipped to make morally and ethically superior decisions. Whether contemporary scientific practice does impose and instill these values is discussed later in the chapter.

28.3 Establishing NOS Priorities

Once the lens of NOS became focused on the school science curriculum, it was quickly apparent that whatever confused and confusing views of science are held by students are compounded by conventional science education. There are particularly powerful messages about science embedded in all teaching and learning activities, especially laboratory activities. These messages too often convey distorted or over-simplified views of the nature of scientific investigations, especially with respect to the role of theory. These 'folk theories' of science, as Windschitl (2004) calls them, are also held by teachers (as a consequence of their own science education) and have substantial influence on their day-to-day curriculum decision-making, thus reinforcing similar messages embedded in school science textbooks and other curriculum materials.

As part of a major survey of Canadian science education conducted by the Science Council of Canada, Nadeau and Désautels (1984) identified what they called five mythical values stances suffusing science education:

- *Naïve realism* – science gives access to truth about the universe.
- *Blissful empiricism* – science is the meticulous, orderly and exhaustive gathering of data.
- *Credulous experimentation* – experiments can conclusively verify hypotheses.
- *Excessive rationalism* – science proceeds solely by logic and rational appraisal.
- *Blind idealism* – scientists are completely disinterested, objective beings.

The cumulative message is that science has an all-purpose, straightforward and reliable method of ascertaining the truth about the universe, with the certainty of scientific knowledge being located in objective observation, extensive data collection and experimental verification. Moreover, scientists are rational, logical, open-minded and intellectually honest people who are required, by their commitment to the scientific enterprise, to adopt a disinterested, value-free and analytical stance. In Cawthron and Rowell's (1978) words, the scientist is regarded by the science curriculum as 'a depersonalized and idealized seeker after truth, painstakingly pushing back the curtains which obscure objective reality, and abstracting order from the flux, an order which is directly revealable to him through a distinctive scientific method' (p. 32). While much has changed in the intervening years, many school science curricula and school textbooks continue to project these images.[8] For example, Loving (1997) laments that all too often

> (a) science is taught totally ignoring what it took to get to the explanations we are learning – often with lectures, reading text, and memorizing for a test. In other words, it is taught free of history, free of philosophy, and in its final form. (b) Science is taught as having one method that all scientists follow step-by-step. (c) Science is taught as if explanations are the truth – with little equivocation. (d) Laboratory experiences are designed as recipes with one right answer. Finally, (e) scientists are portrayed as somehow free from human foibles, humor, or any interests other than their work. (p. 443)

At about the same time, Hodson (1998) identified ten common myths and falsehoods promoted, sometimes explicitly and sometimes implicitly, by the science curriculum: observation provides direct and reliable access to secure knowledge;

---

[8] Abd-El-Khalick (2001), Abd-El-Khalick et al. (2008), Clough (2006), Cross (1995), Knain (2001), Kosso (2009), Lakin and Wellington (1994), McComas (1998), van Eijck and Roth (2008) and Vesterinen et al. (2011).

science always starts with observation; science always proceeds by induction; science comprises discrete, generic processes; experiments are decisive; scientific inquiry is a simple algorithmic procedure; science is a value-free activity; science is an exclusively Western, post-Renaissance activity; the so-called scientific attitudes are essential to the effective practice of science; and all scientists possess these attitudes. A broadly similar list of falsehoods was generated by McComas (1998) from his critical reading of science textbooks: hypotheses become theories that in turn become laws; scientific laws and other such ideas are absolute; a hypothesis is an educated guess; a general and universal scientific method exists; evidence accumulated carefully will result in sure knowledge; science and its methods provide absolute proof; science is procedural more than creative; science and its methods can answer all questions; scientists are particularly objective; experiments are the principal route to scientific knowledge; scientific conclusions are reviewed for accuracy; acceptance of new scientific knowledge is straightforward; science models represent reality; science and technology are identical; and science is a solitary pursuit. In quite startling contrast, Siegel (1991) states that

> Contemporary research… has revealed a more accurate picture of the scientist as one who is driven by prior convictions and commitments; who is guided by group loyalties and sometimes petty personal squabbles; who is frequently quite unable to recognize evidence for what it is; and whose personal career motivations give the lie to the idea that the scientist yearns only or even mainly for the truth. (p. 45)

Two questions spring to mind. First, is this a more authentic portrayal of scientific practice? Second, is it an appropriate view for the school science curriculum? Sweeping away an old and (for some) discredited view is one thing; finding an acceptable set of alternatives is somewhat different. Finding a list appropriate for the school curriculum is even more difficult. Many science educators will share Israel Scheffler's alarm at some of the alternatives that have been advanced:

> The extreme alternative that threatens is the view that theory is not controlled by data, but that data are manufactured by theory; that rival hypotheses cannot be rationally evaluated, there being no neutral court of observational appeal nor any shared stock of meanings; that scientific change is a product not of evidential appraisal and logical judgment, but of intuition, persuasion and conversion; that reality does not constrain the thought of the scientist but is rather itself a projection of that thought. (Scheffler 1967, p. v)

Longbottom and Butler (1999) express similar concerns when they state that 'if we go along with those who deny that modern science provides a privileged view of the world… we fall into an abyss where skeptical postmodernists, who have lost faith in reason, dismiss all knowledge claims as equally arbitrary and assume the universe to be unreliable in its behavior and incapable of being understood' (p. 482). Stanley and Brickhouse (1995) regard such remarks as examples of what Bernstein (1983) called 'Cartesian anxiety': the fear that if we do not retain our belief in the traditional objective foundations of scientific method we have no rational basis for making any knowledge claims. In short, fear that belief in scientific *progress* will be replaced by scientific *change* consequent upon power struggles among competing groups, with 'victory' always going to the better resourced. Fear that scientific knowledge is no longer to be regarded as the product of a rigorous method or set of methods; instead, it is merely the way a particular influential group of scientists happens to think and can persuade, cajole or coerce others into accepting.

In building a school science curriculum, are we faced with a stark choice between the traditional and the postmodern? Are we required to choose between the image of a scientist as a cool, detached seeker-after-truth patiently collecting data from which conclusions will eventually be drawn, when all the evidence is in hand, and that of 'an agile opportunist who will switch research tactics, and perhaps even her entire agenda, as the situation requires' (Fuller 1992, p. 401). Which view is the more authentic? Equally important, what should we tell students? What is in their interests? Some years ago, Stephen Brush (1974) posed the question: 'should the history of science should be rated X?' The question is just as pertinent to the philosophy of science and the sociology of science. Should we expose students to the anarchistic epistemology of Paul Feyerabend? Should we lift the lid off the Pandora's Box that is the sociology of science? Would students be harmed by too early an exposure to these views? When we seek to question (and possibly reject) the certainties of the traditional view of science, are we left with no firm guidance, no standards and no shared meaning? Does recognition of the sociocultural baggage of science entail regarding science as just one cultural artefact among many others, with no particular claim on our allegiance? Is any kind of compromise possible between these extremes and among this diversity? Can we retain what is still good and useful about the old view of science (such as conceptual clarity and stringent testing) while embracing what is good and useful in the new (such as sensitivity to sociocultural dynamics and awareness of the possibility of error, bias, fraud and the misuse of science)? Can the curriculum achieve a balance that is acceptable to most stakeholders? In short, what particular items from all the argument and counter argument would constitute an educationally appropriate and teachable selection? Later discussion touches on the age appropriateness of a number of NOS items, while attention at this point focuses on whether there is any nature of science understanding that can be taken for granted and regarded as no longer in dispute. Is there any consensus among scholars about an acceptable alternative to the traditional view that will allay the fears expressed by Scheffler and others?

Responses to a 20-item Likert-type questionnaire on '15 tenets of NOS' led Alters (1997a, b) to conclude that *there is no consensus* – at least, not among the 210 philosophers of science he surveyed. In the words of Laudan and colleagues (1986),

> The fact of the matter is that we have no well-confirmed general picture of how science works, no theory of science worthy of general assent. We did once have a well developed and historically influential philosophical position, that of positivism or logical empiricism, which has by now been effectively refuted. We have a number of recent theories of science which, while stimulating much interest, have hardly been tested at all. And we have specific hypotheses about various cognitive aspects of science, which are widely discussed but wholly undecided. If any extant position does provide a viable understanding of how science operates, we are far from being able to identify which it is. (p. 142)

Interestingly, despite this categorical denial of any consensus, it seems that the authors of several important science curriculum reform documents (AAAS (1989, 1993) and NRC (1996), among others) seem to be in fairly substantial agreement on the elements of NOS that should be included in the school science curriculum (McComas and Olson 1998):

- Scientific knowledge is tentative.
- Science relies on empirical evidence.
- Observation is theory laden.
- There is no universal scientific method.
- Laws and theories serve different roles in science.
- Scientists require replicability and truthful reporting.
- Science is an attempt to explain natural phenomena.
- Scientists are creative.
- Science is part of social tradition.
- Science has played an important role in technology.
- Scientific ideas have been affected by their social and historical milieu.
- Changes in science occur gradually.
- Science has global implications.
- New knowledge must be reported clearly and openly.

In an effort to shed further light on this matter, Osborne and colleagues (2003) conducted a Delphi study to ascertain the extent of agreement among 23 participants drawn from the 'expert community' on what ideas about science should be taught in school science. The participants included five scientists, five persons categorized as historians, philosophers and/or sociologists of science, five science educators, four science teachers and four science communicators. Although there was some variation among individuals, there was broad agreement on nine major themes: scientific method and critical testing, scientific creativity, historical development of scientific knowledge, science and questioning, diversity of scientific thinking, analysis and interpretation of data, science and certainty, hypothesis and prediction, and cooperation and collaboration. A comparison of these themes with those distilled from the science education standards documents in McComas and Olson's (1998) study reveals many similarities. A broadly similar but shorter list that has gained considerable currency among science educators can be found in Lederman and colleagues (2002): scientific knowledge is tentative, empirically based, subjective (in the sense of being theory dependent and impacted by the scientists' experiences and values), socioculturally embedded and, in part, the product of human imagination and creativity.

28.4 Some Problems with the Consensus View

Useful as consensus can be in assisting curriculum planning and the design of assessment and evaluation schemes, a number of questions should be asked. For example, is the apparent consensus deliberately pitched at such a trivial level that nobody could possibly quibble with it? Most of the items in the list are not specific to science, either individually or collectively. All human knowledge is tentative;

all forms of knowledge building are creative. This is not to say that these characteristics are not applicable to science; but it is to say that they do not distinguish it from several other human activities. It is the sheer banality and unhelpfulness of some of the items that many teachers find frustrating. For example, statements such as 'science is an attempt to explain natural phenomena' and 'science has played an important role in technology' – items in the consensus list developed by McComas et al. (1998) – do not claim anything particularly insightful or helpful for students trying to understand what science is all about. Of course, some would argue that a list of relatively trivial items is better than no list at all. Perhaps it is, although items in the consensus list can sometimes be very puzzling or even irrelevant to an understanding of scientific practice and the capacity to function as a scientist. For example, several writers who advocate the consensus view also argue that students should understand the functions of and relationships between theories and laws and draw a distinction between observation and inference. Drawing a distinction between laws and theories is certainly not a high priority for practising scientists, as informants in the study conducted by Wong and Hodson (2009) pointed out very clearly. As far as students are concerned, one is led to wonder in what ways knowledge of a supposed difference between a law and a theory would help them to make decisions on where they stand in relation to controversial socioscientific issues.

The naïve proposition that there is a crucial distinction between observation and inference is singularly unhelpful to students trying to make sense of contemporary technology-supported investigative work. Superficially the distinction sounds fine and seems to accord with what we consider to be good practice in scientific inquiry: having respect for the evidence and not claiming more than the data can justify. However, closer examination in the light of the theory-laden nature of scientific observation suggests that the supposed demarcation is not always as clear as some would claim. When a new theory appears or when new scientific instruments are developed, our notion of what counts as an observation and what counts as an inference may change. As Feyerabend (1962) points out, observation statements are merely those statements about phenomena and events to which we can assent quickly, relatively reliably and without calculation or further inference because we all accept, without question, the theories on which they are based. Thus, where individuals draw the line between observation and inference reflects the sophistication of their scientific knowledge, their confidence in that knowledge and their experience and familiarity with the phenomena or events being studied. When theories are not in dispute, when they are well understood and taken for granted, the theoretical language *is* the observation language, and we use theoretical terms in making and reporting observations. Terms like *reflection* and *refraction*, *conduction* and *nonconduction*, and *melting, dissolving* and *subliming*, all of which are used regularly in school science as observation terms, carry a substantial inferential component rooted in theoretical understanding. The key point is that unless some theories are taken for granted (and deemed to be no longer in dispute) and unless theory-loaded terms are used for making observations, we can never make progress. We would forever be trying to retreat to the raw data, to some position that we could regard as theory-free.

Too literal an interpretation of statements about the tentative nature of science can be counterproductive, leading students to regard *all* science as no more than temporary (Harding and Hare 2000). Scientific knowledge is tentative because it is based, ultimately, on empirical evidence that may be incomplete and because it is collected and interpreted in terms of current theory – theory that may eventually be changed as a consequence of the very evidence that is collected. In all these endeavours, the creative imagination of individual scientists is impacted by all manner of personal experiences and values. Moreover, the collective wisdom of the scientific community that supports the practice, scrutinizes the procedures and evaluates the products is also subject to complex sociopolitical, economic and moral-ethical forces. In consequence, there can be no certainty about the knowledge produced. However, to admit that absolute truth is an impossible goal is not to admit that we are uncertain about everything. We *know* many things about the universe even though we recognize that many of our theoretical systems are still subject to revision, or even rejection.

Regarding the issue of tentativeness, there are several closely related issues to consider. First, very specific claims about phenomena and events may be regarded as 'true' (in a scientific sense) even though the theories that account for the events are regarded as tentative. Because the whole necessarily extends beyond the parts of which it is comprised, the whole may be seen as tentative while the parts (or some of them) are regarded as certain. Most theories are tentative when first developed, but are accepted as true when they have been elaborated, refined and successfully used and when they are consistent with other theories and strongly supported by evidence. Teachers make a grave mistake when they encourage students to regard all science as tentative. Indeed, if scientists did not accept some knowledge as well established, we would be unable to make progress.

We should also ask whether the consensus list includes consideration of the 'big issues' with which philosophers of science have traditionally grappled. Apparently not, according to Abd-El-Khalick and BouJaoude (1997), Abd-El-Khalick, Bell and Lederman (1998) and Lederman et al. (2002), who state that while philosophers and sociologists might disagree on some aspects of NOS, these disagreements are irrelevant to K-12 students and their teachers. Many other scholars would disagree. Some of these disputes focus on the most interesting features of science, for example, the status of scientific knowledge in terms of realism and instrumentalism, the extent to which science is socially constructed/determined and the nature of scientific rationality. Another major concern with the consensus view is that it promotes a static picture of science and fails to acknowledge important differences among the sciences. In reality, the practices and procedures of science change over time. As a particular science progresses and new theories and procedures are developed, the nature of scientific reasoning changes. Indeed, we should seriously question whether views in the philosophy of science that were arrived at some years ago can any longer reflect the nature of twenty-first-century science, especially in rapidly developing fields such as genetics and molecular biology, where there is now substantial research related to the generation of data and subsequent data mining (e.g. generation of genomic sequences of a number of living things) rather than the kind of hypothesis-driven inquiry promoted by the consensus view – developments that are, of course, driven by technological advances.

In a little known but very insightful and educationally significant article, Michael Clough (2007) urges teachers to shift emphasis away from teaching the 'tenets of NOS', because they are easily misinterpreted, oversimplified and become something to be memorized rather than understood and utilized, and towards asking important questions such as the following: In what sense is scientific knowledge tentative and in what sense is it durable? To what extent is scientific knowledge socially and culturally embedded? In what sense does it transcend society and culture? How are observations and inferences different? In what sense can they not be differentiated? A recent essay by Michael Matthews (2012) subjects the consensus view (specifically, the 'Lederman Seven', as he calls it) to rigorous critical scrutiny, concluding that the items need to be 'much more philosophically and historically refined and developed' (p. 12) if they are to be genuinely useful to teachers and their students. As a way forward, he advocates a shift of terminology and research focus from the 'essentialist and epistemologically focussed 'Nature of Science' (NOS) to a more relaxed, contextual and heterogeneous 'Features of Science' (FOS)' (p. 4). Such a change, he argues, would avoid many of the pitfalls and shortcomings of current research and scholarship in the field – in particular, the confused conflation of epistemological, sociological, psychological, ethical, commercial and philosophical aspects of science into a single list of items to be taught and assessed, the avoidance of debate about contentious issues in HPS, the neglect of historical perspective and the failure to account for significant differences in approach among the sciences. In response to this and other criticism, Lederman, Antinck and Bartos (2012) state 'We (my colleagues and fellow researchers) *are not* advocating a definitive or universal definition of the construct [of NOS]. We have never advocated that that our "list" is *the* only list/definition… What we prefer readers to focus on are the understandings we want students to have. The understandings need not be limited to those we have selected' (p. 2).

28.5 Diversity Among the Sciences

Many philosophers of science hold that there is no universal nature of science because the sciences themselves have no unity. The best that can be said is that there is a 'family resemblance among the sciences' (Wittgenstein 1953), with common interests and some areas of methodological and conceptual agreement – what Loving (1997) calls a 'loose configuration of critical processes and conceptual frameworks, including various methods, aims, and theories all designed to shed light on nature' (p. 437). The consensus view specifically disallows consideration of diversity among the sciences and chooses to disregard the substantial differences between the day-to-day activities of palaeontologists and epidemiologists, for example, or between scientists researching in high energy physics and those engaged in molecular biology. There are significant differences among the subdisciplines of science in terms of the kind of research questions asked, the methods and technologies employed to answer them, the kind of evidence sought, the extent to which they use experimentation, the ways in which data for theory building are collected, the standards by which investigations and conclusions are judged and the kinds of arguments deployed. Jenkins (2007) puts it succinctly when he says that 'the criteria for deciding what counts as evidence, and thus the nature of an explanation that relies upon that evidence, may also be different' (p. 225). There are substantial differences in the extent to which mathematics is deployed (Knorr-Cetina 1999), and there may even be differences, as Cartwright (1999) notes, in the values underpinning the enterprise. In other words, the specifics of scientific rationality change between subdisciplines, with each subdiscipline playing the game of science according to its own rules, a view discussed at some length in Hodson (2008, 2009).

Like Sandra Harding (1986), Ernst Mayr (1988, 1997, 2004) has criticized the standard or consensus NOS views promoted in many curriculum documents on grounds that they are nearly always derived from physics. Biology, he argues, is markedly different in many respects, not the least significant of which is that many biological ideas are not subject to the kind of falsificationist scrutiny advocated by Karl Popper (1959) and given such prominence in school science textbooks: 'It is particularly ill-suited for the testing of probabilistic theories, which include most theories in biology… And in fields such as evolutionary biology… it is often very difficult, if not impossible, to decisively falsify an individual theory' (Mayr 1997, p. 49).

The procedures of investigation in a particular subdiscipline of science are deeply grounded in the field's substantive aspects and the specific purposes of the inquiry. For example, while physicists may spend time designing critical experiments to test daring hypotheses, as Popper (1959) states, most chemists are intent on synthesizing new compounds:

> Chemists make molecules. They do other things, to be sure – they study the properties of these molecules; they analyze… they form theories as to why molecules are stable, why they have the shapes or colors that they do; they study mechanisms, trying to find out how molecules react. But at the heart of their science is the molecule that is made, either by a natural process or by a human being. (Hoffmann 1995, p. 95)

Moreover, as a particular science progresses and new theories and procedures are developed, the nature of scientific reasoning may change. Indeed, Mayr (1988, 2004) has distinguished two different fields even within biology: *functional* or mechanistic biology and *evolutionary* biology, distinguished by the type of causation addressed. Functional biology addresses questions of proximate causation; evolutionary biology addresses questions of ultimate causation:

> The functional biologist is vitally concerned with the operation and interaction of structural elements, from molecules up to organs and whole individuals. His ever-repeated question is 'How?'… The evolutionary biologist differs in his method and in the problems in which he is interested. His basic question is 'Why?' (Mayr 1988, p. 25)

In similar vein, Ault (1998) argues that the geosciences are fundamentally historical and interpretive, rather than experimental. The goal of geological inquiry, he argues, is interpretation of geologic phenomena based on observations, carefully warranted inferences and integration or reconciliation of independent lines of inquiry, often conducted in diverse locations. These interpretations result in a description of historical sequences of events, *sometimes* accompanied by a causal model.

Elby and Hammer (2001) argue that the widely adopted consensus list of NOS items is too general and too broad and that it is neither philosophically valid nor productive of good learning of science: ‘a sophisticated epistemology does not consist of blanket generalizations that apply to all knowledge in all disciplines and contexts; it incorporates contextual dependencies and judgments’ (p. 565). Essentially the same point is made by Clough (2006) when he says that ‘while some characteristics [of NOS] are, to an acceptable degree uncontroversial… most are contextual, with important and complex exceptions’ (p. 463). In short, the differences in approach are just too extensive and too significant to be properly accounted for by generic models of inquiry. Instead of trying to find and promote broad generalizations about the nature of science, scientific inquiry and scientific knowledge, a position recently given renewed emphasis by Abd-El-Khalick (2012), teachers should be building an understanding of NOS from examples of the daily practice of diverse groups of scientists engaged in diverse practices and should be creating opportunities for students to experience, explore and discuss the differences in knowledge and its generation across multiple contexts. It is for this reason that NOS-oriented research needs to study the work of scientists active at the frontier of knowledge generation (Schwartz and Lederman 2008; Wong and Hodson 2009, 2010). Student understanding of the complexity and diversity of scientific practice would be immeasurably helped by adoption of the notion of a ‘family resemblance’ among the sciences, as in Irzik and Nola’s (2011) organization of the cognitive aspects of science into four categories: (i) *activities* (planning, conducting and making sense of scientific inquiries), (ii) *aims and values*, (iii) *methodologies and methodological rules*, and (iv) *products* (scientific knowledge) (see also Nola and Irzik 2013). These four categories of cognitive aspects could and perhaps should be extended to accommodate the noncognitive institutional and social norms which are operative within science and influence science (see below).

In brief, it is time to replace the consensus view of NOS, useful though it has been in promoting the establishment of NOS in the school science curriculum, with a philosophically more sophisticated and more authentic views of scientific practice, as advocated by Elby and Hammer (2001), Hodson (2008, 2009), Matthews (2012), Rudolph (2000) and Wong and Hodson (2013). Interestingly, children regard diversity of approach in scientific investigations as inevitable. They have no expectations of a particular method; it is the teachers who create the expectation of a single method through their continual reference to *the* scientific method (Hodson 1998) and, by extension, establish the belief that there are particular and necessary attributes (the so-called scientific attitudes) for engaging in it.

28.6 Some Recent NOS-Oriented Initiatives

The past decade has seen a remarkable growth in research and curriculum development in two important NOS-related areas: *scientific argumentation* and *modelling*. Both these aspects of NOS (as defined at the beginning of this chapter) warrant some attention here. My concerns relate to both students' knowledge of these processes as used by scientists and the development of their ability to use them appropriately and productively for themselves.

What is often unrecognized by science teachers, science textbooks and curricula, and by the wider public, is that *dispute* is one of the key driving forces of science. Real science is impregnated with claims, counter claims, argument and dispute. Arguments concerning the appropriateness of experimental design, the interpretation of evidence and the validity of knowledge claims are located at the core of scientific practice. Arguments are used to address problems, resolve issues and settle disputes. Moreover, our day-to-day decision-making with regard to socioscientific issues is based largely on the evaluation of information, arguments, conclusions, views, opinions and reports made available via newspapers, magazines, television, radio and the Internet. Citizens need to know the kinds of knowledge claims that scientists make and how they advance them. They need to understand the standards, norms and conventions of scientific argumentation in order to judge the rival merits of competing arguments and engage meaningfully in debate on SSI. In particular, they need a robust understanding of the form, structure and language of scientific arguments, the kind of evidence invoked, how it is organized and deployed and the ways in which theory is used and the work of other scientists cited to strengthen a case.

Neglect of scientific argumentation in the school science curriculum gives the impression that science is the unproblematic accumulation of data and theory. In consequence, students are often puzzled and may even be alarmed by reports of disagreements among scientists on matters of contemporary importance. They may be unable to address in a critical and confident way the claims and counter claims impregnating the SSI with which they are confronted in daily life. A number of science educators have recently turned their attention to these matters and to what had previously been a shamefully neglected area of research and curriculum development.[9] The research agenda focuses on the following questions: Why is argumentation important? What are the distinctive features of scientific argumentation? How can it be taught? What strategies are available? To what extent and in what

---

[9] For example, Arduriz Bravo (2013), Berland and Hammer (2012), Berland and Lee (2012), Berland and McNeill (2010), Berland and Reiser (2009, 2011), Böttcher and Meisertt (2011), Bricker and Bell (2008), Driver et al. (2000), Duschl (2008), Duschl and Osborne (2002), Erduran et al. (2004), Evagorou and Osborne (2013), Ford and Wargo (2012), Jiménez-Aleixandre and Erduran (2008), Khishfe (2012a), Kuhn (2010), Newton et al. (1999), Nielsen (2012a, b, 2013), Osborne (2001), Osborne and Patterson (2011), Osborne et al. (2004), Passmore and Svoboda (2012), Pluta et al. (2011), Sampson and Clark (2008, 2011), Sampson and Blanchard (2012), Sampson and Walker (2012), Sampson et al. (2011), Sandoval and Cam (2011), Sandoval and Millwood (2005, 2008), Simon et al. (2006), and Ryu and Sandoval (2012)

ways are the strategies successful? What problems arise and how can the difficulties be overcome? This research is discussed at length in Hodson (2009).

Another significant NOS-related growth area in recent years has been the focus on models and modelling. Because scientific literacy entails a robust understanding of a wide range of scientific ideas, principles, models and theories, students need to know something of their origin, scope and limitations; understand the role of models in the design, conduct, interpretation and reporting of scientific investigations; and recognize the ways in which a complex of cognitive problems and factors related to the prevailing sociocultural context influenced the development of key ideas over time. They also need to experience model building for themselves and to give and receive criticism in their own quest for better models. As Matthews (2012) comments, 'It is difficult to think of science without models' (p. 19).

The nature of mental models has long been an area of research in cognitive psychology, dating back to the seminal work of Johnson-Laird (1983) and Gentner and Stevens (1983), but in recent years, the topic of models and modelling has generated considerable interest among science educators.[10] This interest can be categorized into three principal areas of concern: the particular models and theories produced by scientists as explanatory systems, including the history of their development; the ways in which scientists utilize models as cognitive tools in their day-to-day problem solving, theory articulation and theory revision; and the role of models and modelling in science pedagogy.

The emergence of curricula oriented towards the consideration of socioscientific issues (SSI), in which NOS plays a key role, is discussed later in the chapter.

28.7 Assessing NOS Understanding

Given the perennial concern of education policy makers with assessment and accountability measures and the need for teachers to ascertain students' knowledge and understanding both prior to and following instruction, there has been a long-standing interest in researching students' NOS views. Also, given the commonsense understanding that teachers' views will inevitably and profoundly impact the kind of teaching and learning experiences they provide, interest has been high in ascertaining

(2002, 2004), and van Driel and Verloop (1999)

teachers' NOS views. Given suitable modification in terms of language and theoretical sophistication, the two tasks can utilize many of the same instruments.

Methods employed include questionnaires and surveys, interviews, small group discussions, writing tasks and classroom observations (particularly in the context of hands-on activities). Each has its strengths and weaknesses. Necessarily, researchers who use questionnaire methods must decide what counts as legitimate research data *before* the data collection process begins; those who use classroom observation (and, to a lesser extent, those who use interview methods) are able to make such decisions *during* or *after* data collection. They also have the luxury of embracing multiple perspectives and can readily update their interpretive frameworks to take account of changes in our understanding in history, philosophy and sociology of science.

More than 30 years ago, a review by Mayer and Richmond (1982) listed 32 NOS-oriented assessment instruments, among the best known of which are the *Test on Understanding Science* (TOUS) (Cooley and Klopfer 1961), the *Nature of Science Scale* (NOSS) (Kimball 1967), the *Nature of Science Test* (NOST) (Billeh and Hasan 1975) and the *Nature of Scientific Knowledge Scale* (NSKS) (Rubba 1976; Rubba and Anderson 1978), together with a modified version (M-NSKS) developed by Meichtry (1992). Instruments dealing with the processes of science, such as the *Science Process Inventory* (SPI) (Welch 1969a), the *Wisconsin Inventory of Science Processes* (WISP) (Welch 1969b) and the *Test of Integrated Process Skills* (TIPS) (Burns et al. 1985; Dillashaw and Okey 1980) could also be regarded as providing valuable information on some key aspects of NOS.

While questionnaires are the most commonly used research methods, largely because they are quick and easy to administer, they can be overly restrictive, incapable of accommodating subtle shades of meaning and susceptible to misinterpretation. Sometimes the complexity and subtlety of NOS issues makes it difficult to find appropriate language for framing questions. If it is difficult for the researcher to find the right words, how much more difficult is it for the respondent to capture the meaning they seek to convey? It cannot be assumed that the question and/or the answer will be understood in exactly the way it was intended, especially by younger students and those with poor language skills. Multiple-choice items and other objective instruments leave little or no scope for expressing doubt or subtle shades of difference in meaning and rarely afford respondents the opportunity to explain *why* they have made a particular response to a questionnaire item. It may even be that the same response from two respondents arises from quite different understanding and reasoning, while similar reasoning by two respondents results in different responses.

Further, many instruments are constructed in accordance with a particular philosophical position and are predicated on the assumption that all scientists think and behave in the same way. Hence, teacher and/or student responses that do not correspond to the model of science assumed in the test are judged to be 'incorrect', 'inadequate' or 'naïve'. Alters (1997a, b), Koulaidis and Ogborn (1995), Lucas (1975) and Lederman et al. (2002) provide extended discussions of this issue. It is also the case that many of the early instruments predated significant work in the philosophy and sociology of science, and so are of severely limited value in contemporary studies. Reviews by Lederman (1992, 2007), Lederman et al. (1998, 2000, 2013) describe several NOS instruments that take into account the work of more recent and even contemporary scholars in the philosophy and sociology of science, including *Conceptions of Scientific Theories Test* (COST) (Cotham and Smith 1981), *Views on Science-Technology-Society* (VOSTS) (Aikenhead et al. 1989), the *Nature of Science Survey* (Lederman and O'Malley 1990), the *Nature of Science Profile* (Nott and Wellington 1993) and the *Views of Nature of Science Questionnaire* (VNOS) (Lederman et al. 2002) and its several subsequent modifications (see Flick and Lederman 2004; Lederman 2004, 2007; Schwartz and Lederman 2008). A recent review by Deng and colleagues (2011) reports and critiques 105 research studies of students' NOS views, using a wide range of instruments, though lack of space precludes discussion here. Constraints on space also preclude discussion of the recent critical review by Guerro-Ramos (2012) of research approaches for ascertaining teachers' views of NOS and their relevance to classroom decision-making.

The designers of VOSTS attempted to circumvent some of the common questionnaire design problems identified by psychometricians by constructing a number of different 'position statements' (sometimes up to ten positions per item) derived from student writing and interviews, including 'I don't understand' and 'I don't know enough about this subject to make a choice' (Aikenhead et al. 1987; Aikenhead and Ryan 1992). It is the avoidance of the forced choice and the wide range of aspects covered (definitions, influence of society on science/technology, influence of science/technology on society, characteristics of scientists, social construction of scientific knowledge, social construction of technology, nature of scientific knowledge, and so on) that give the instrument its enormous research potential. Lederman and O'Malley (1990) utilized some of the design characteristics of VOSTS to develop the *Nature of Science Survey*, an instrument comprising just seven fairly open-ended items (e.g. 'Is there a difference between a scientific theory and a scientific law? Give an example to illustrate your answer'), to be used in conjunction with follow-up interviews to further explore and clarify students' responses.

At present, the most widely used and most extensively cited contemporary instrument for ascertaining students' NOS views is the *Views of Nature of Science Questionnaire* (VNOS). While it has provided much valuable information on both students' and teachers' NOS views, it suffers from all the drawbacks attending the so-called consensus view of NOS, as discussed earlier. The *Views on Science and Education* (VOSE) questionnaire, developed by Chen (2006) for use with preservice teachers, focuses on the same seven NOS elements as VNOS (tentativeness of scientific knowledge; nature of observation; scientific methods; hypotheses, laws and theories; imagination; validation of scientific knowledge; objectivity and subjectivity in science) but seeks to address some perceived weaknesses of VOSTS – principally, the overgeneralization and ambiguity of some items and its failure to fully ascertain the reasons underlying a respondent's choice of response. It also seeks to accommodate differences in student teachers' views about what science is likely to be in practice and what science ought to be and to distinguish between NOS views they hold and NOS views they seek to teach.

As Abd-El-Khalick and BouJaoude (1997) point out, VOSTS was conceived and written within a North American sociocultural context and, in consequence, may have limited validity in non-Western contexts. In response to such concerns, Tsai and Liu (2005) have developed a survey instrument that is more sensitive to sociocultural influences on science and students' views of science. It focuses on five characteristics of scientific knowledge and its development: (i) the role of social negotiations within the scientific community; (ii) the invented and creative nature of science; (iii) the theory-laden nature of scientific investigation; (iv) cultural influences on science; and (v) the changing and tentative nature of scientific knowledge. Rooted in similar concerns about the socioculturally determined dimensions of NOS understanding is the *Thinking about Science* instrument designed by Cobern and Loving (2002) as both a pedagogical tool (for preservice teacher education programmes) and a research tool for assessing views of science in relation to economics, the environment, religion, aesthetics, race and gender.

Before leaving this brief survey of questionnaire instruments, it is important to draw attention to the *Views of Scientific Inquiry* questionnaire (Schwartz et al. 2008), which speaks directly to the problems of NOS definition discussed at the beginning of this chapter and is designed to gather information on students' understanding of some key elements of NOS, including (i) scientific investigations are guided by questions and theoretical perspectives; (ii) there are multiple purposes for scientific inquiry and multiple methods for conducting them; (iii) there is an important distinction between data and evidence; (iv) the validation of scientific knowledge involves negotiation of meaning and achievement of consensus; and (v) scientific inquiry is embedded within multiple communities, each with its own standards, values and practices.

28.8 Alternatives to Questionnaires

Frustrated by the seemingly intractable problems of designing effective questionnaires, some researchers and teachers incline to the view that more useful information can be obtained, especially from younger students, by use of open-ended methods such as the Draw-a-Scientist Test (DAST) (Chambers 1983). In his initial study, Chambers used this test with 4,807 primary (elementary) school children in Australia, Canada and the United States. He identified seven common features in their drawings, in addition to the almost universal representation of the scientist as a man: laboratory overall; spectacles (glasses); facial hair; 'symbols of research' (specialized instruments and equipment); 'symbols of knowledge' (books, filing cabinets, etc.); technological products (rockets, medicines, machines); and captions such as 'Eureka' (with its attendant lighted bulb) and $E = mc^2$, and think bubbles saying 'I've got it' or 'A-ah! So that's how it is'.

In the years since Chambers' original work, students' drawings have changed very little,[11] with research indicating that the stereotype begins to emerge at about grade 2 and is well-established and held by the majority of students by grade 5.

---

[11] Barman (1997, 1999), Farland-Smith (2009a), Finson (2002), Fort and Varney (1989), Fralick et al. (2009), Fung (2002), Huber and Burton (1995), Jackson (1992), Losh et al. (2008), Mason et al. (1991), Matthews (1994a, 1996), Newton and Newton (1992, 1998), Rahm and Charbonneau (1997), Rosenthal (1993), She (1995, 1998), and Symington and Spurling (1990)

Not only are these images stable across genders, they seem to be relatively stable across cultural differences,[12] although Song and Kim (1999) suggest that Korean students produce 'slightly less stereotypical' drawings, especially with respect to gender and age, than students in the United States. Generally, they draw younger scientists than their Western student counterparts – drawings that probably reflect the reality of the Korean scientific community. In a study of 358 students in grades 1–7 in Southwest Louisiana, Sumrall (1995) found that African American students (especially girls) produced less stereotyped drawings than Euro-Americans with respect to both gender and race. Interestingly, the drawings of African American boys showed an equal division of scientists by race but an 84% bias in favour of male scientists. Many researchers have pointed out that girls are generally less stereotyped in their views about science and scientists than are boys. However, Tsai and Liu (2005) note that female Taiwanese students are less receptive than male students to the idea that scientific knowledge is created and tentative rather than discovered and certain. There are some encouraging indications that students, and especially male students in the age range 9–12, produce drawings with fewer stereotypical features following the implementation of gender-inclusive curriculum experiences (Huber and Burton 1995; Losh et al. 2008; Mason et al. 1991).

Of course, there is a strong possibility that researchers can be seriously misled by the drawings students produce. As Newton and Newton (1998) point out, 'their drawings reflect their stage of development and some attributes may have no particular significance for a child but may be given undue significance by an adult interpreting them' (p. 1138). Even though young children invariably draw scientists as bald men with smiling faces, regardless of the specific context in which the scientist is placed, it would be unwise to assume that children view scientists as especially likely to be bald and contented. As Claxton (1990) reminds us, children compartmentalize their knowledge and so may have at least three different versions of the scientist at their disposal: the everyday comic book version, the 'official' or approved version for use in school and their personal (and perhaps private) view. It is not always clear which version DAST is accessing or how seriously the drawer took the task. Simply asking students to 'draw a scientist' might send them a message that a 'typical scientist' exists (Boylan et al. 1992). There is also the possibility that students in upper secondary school or university use their drawings to make a sociopolitical point – for example, that there are too few women or members of ethnic minority groups engaged in science.

Scherz and Oren (2006) argue that asking students to draw the scientist's workplace can be helpful, while Rennie and Jarvis (1995) suggest that students should be encouraged to annotate their drawings in order to clarify meaning and intention. Further insight into students' views can be gained by talking to them about their drawings and the thinking behind them, asking them if they know anyone who uses science in their work (and what this entails), or presenting them with writing tasks based on scientific discovery. Miller (1992, 1993) advocates the

---

[12] Chambers (1983), Farland-Smith (2009b), Finson (2002), Fung (2002), Laubach et al. (2012), Parsons (1997), She (1995, 1998), and Walls (2012)

following approach: 'Please tell me, in your own words, what does it mean to study something scientifically?' When given the opportunity to discuss their drawings and stories with the teacher, even very young children will provide detailed explanations and rationales (Sharkawy 2006; Sumrall 1995; Tucker-Raymond and colleagues 2007). Interestingly, it is increasingly evident that young children's responses to open-ended writing tasks involving science, scientists and engineers are not stable and consistent: accounts and stories of science produced in science lessons are very different from those produced in language arts lessons (Hodson 1993). Students may even provide significantly different oral and written responses to nature of science questions (Roth and Roychoudhury 1994).

While less restrictive, instruments designed for more flexible and open-ended responses, such as the *Images of Science Probe* (Driver et al. 1996), concept mapping, small group discussion and situated-inquiry interviews (Ryder et al. 1999; Welzel and Roth 1998), sometimes pose major problems of interpretation for the researcher. So, too, do observation studies, unless supported by an interview-based follow-up capable of exploring the impact of context on student understanding. While interviews hold out the possibility of accessing underlying beliefs, their effectiveness can be severely compromised by the asymmetric power relationship between interviewer and interviewee, regardless of whether the interviewer is the teacher or an independent researcher. In an interview situation, some students may be shy or reluctant to talk; they may feel anxious or afraid; they may respond in ways that they perceive to be acceptable to the interviewer, or expected by them. Observation via audio or video recording of group-based tasks involving reading, writing and talking, practical work, role play, debating and drama constitute a less threatening situation for students, though even here there can be problems. Indeed, any classroom activity can be impacted by complex and sometimes unpredictable social factors. These complicating factors can mask or distort the NOS understanding we hope to infer from conversations and actions. In short, all approaches to ascertaining NOS views carry a risk that the characterization or description of science ascribed to the research subject is, in some measure, an artefact of the research method.

28.9 Problems Relating to Authenticity and Context

The context in which an interview question, questionnaire item or assessment task is set and, indeed, whether there is a specific context at all can have a major impact on an individual's response. Decontextualized questions (such as 'What is your view of a scientific theory?' or 'What is an experiment?') can seem infuriatingly vague to students and can be met with seeming incomprehension. Use of such questions can pose major problems of interpretation for the researcher. Conversely, context-embedded questions have domain-specific knowledge requirements that may sometimes preclude students from formulating a response that properly reflects their NOS views. Moreover, respondents may feel constrained by restriction of the question to one context and, in consequence, unable to communicate what they know about the many significant differences in the ways that scientists in different fields conduct investigations. Familiarity with the context, understanding of the underlying science concepts, interest in the situation and opportunity to utilize knowledge about other situations are all crucial to ensuring that we access students' authentic NOS understanding. Put simply, questions set in one context may trigger different responses from essentially the same questions set in a different context (Leach and colleagues 2000) – a finding that is especially significant in research that addresses NOS views in the context of scientific controversies (Smith and Wenk 2006) and socioscientific issues (Sadler and Zeidler 2004). It should also be noted that further important perspectives and issues relating to assessment are raised by recent curricular interest in scientific argumentation[13] and modelling,[14] though constraints on space preclude discussion here.

It would be surprising if students didn't have different views about the way science is conducted in school and the way science is conducted in specialist research establishments. Hogan (2000) refers to these different views as students' *proximal* knowledge of NOS (personal understanding and beliefs about their own science learning and the scientific knowledge they encounter and develop in science lessons) and *distal* knowledge of NOS (views they hold about the products, practices, codes of behaviour, standards and modes of communication of professional scientists). Sandoval (2005) draws a similar distinction between students' *practical* and *formal* epistemologies. Contextualized questions that ask students to reflect on their own laboratory experiences are likely to elicit the former, questions of a more general, de-contextualized nature ('What is science?' or 'How do scientists validate knowledge claims?') are likely to elicit the latter. The problem for the researcher is to gauge the extent to which these differences exist and how they are accessed by different research probes. The problem for the teacher is to ensure that students are aware of the crucial distinctions as well as the similarities between science in school and science in the world outside school. It may also be the case that students hold significantly different views of science as they perceive it to be and science as they believe it *should* be – a distinction that Rowell and Cawthron (1982) and Chen (2006) were able to accommodate in their research.

A further complication to ascertaining students' NOS views is the significant potential for mismatch between what individuals say about their NOS understanding and what they do in terms of acting on that understanding. Thus, the question arises: Should we seek to ascertain *espoused* views or views *implicit in actions?*

---

[13] Important literature sources include Duschl (2008), Erduran (2008), Erduran et al. (2004), Kelly and Takao (2002), Naylor et al. (2007), Osborne et al. (2004), Sampson and Clark (2006, 2008), Sandoval and Millwood (2005), Shwarz et al. (2003), Takao and Kelly (2003), and Zeidler et al. (2003).

[14] Suitable references include Acher et al. (2007), Chittleborough et al. (2005), Coll (2006), Coll and Treagust (2003a), Duschl et al. (2007), Hart (2008a), Henze et al. (2007a, b), Justi and Gilbert (2002a), Justi and van Driel (2005), Kawasaki et al. (2004), Lehrer and Schauble (2000), Lin and Chiu (2007), Maia and Justi (2009), Perkins and Grotzer (2005), Prins et al. (2008), Raghavan et al. (1998a, b), Saari and Viiri (2003), Schauble (2008), Smith et al. (2000), Taylor et al. (2003), Treagust et al. (2002, 2004), van Driel and Verloop (1999), and Webb (1994).

The former would probably be best served by questionnaires, writing tasks and interviews; the latter would require inferences to be drawn from observed behaviours and actions – for example, responding to scientific texts, searching the Internet and formulating reports of investigations. The crucial distinction between *teachers'* NOS views implicit in action and those supposedly revealed by pencil-and-paper tests is explored at length by Guerra-Ramos (2012). Of particular value for use with teachers and student teachers is Nott and Wellington's (1996, 1998, 2000) 'Critical Incidents' approach. In group settings, or in one-on-one interviews, teachers (or student teachers) are invited to respond to descriptions of classroom events, many related to hands-on work in the laboratory, by answering three questions: What would you do? What could you do? What should you do? Responses, and the discussion that ensues, may indicate something about the teachers' views of science and scientific inquiry and, more importantly perhaps, how this understanding is deployed in classroom decision-making. Similar approaches using video and multimedia materials have been used by Bencze and colleagues (2009a), Hewitt and colleagues (2003), Wong and colleagues (2006) and Yung and colleagues (2007).[15]

Even if we solve all these problems, we are still confronted with decisions about how to interpret and report the data. Should we adopt a *nomothetic* approach that focuses on the extent to which the students' or teachers' views match a prespecified 'ideal' or approved view? Attempts to distinguish 'adequate' NOS views from 'inadequate' views involve judgement about the rival merits of inductivism and falsificationism, Kuhnian views versus Popperian views, realism versus instrumentalism, and so on. None of these judgements is easy to make and may even be counterproductive to good NOS learning. Does it make more sense, then, to opt for an *ideographic* approach? Should we be satisfied to describe the views expressed by students and seek to understand them 'on their own terms'?

A major complicating factor is that students will not necessarily have coherent and consistent views across the range of issues embedded in the notion of NOS. Rather, their views may show the influence of several different and possibly mutually incompatible philosophical positions. As Abd-El-Khalick (2004) points out, what researchers see as inconsistencies in the NOS views of students at the undergraduate and graduate levels may be seen by the students as 'a collection of ideas that make sense within a set of varied and personalized images of science' (p. 418). Moreover, older students, with more sophisticated NOS understanding, will have recognized that inquiry methods vary between science disciplines and that the nature of knowledge statements varies substantially with content, context and purpose. Few research instruments are sensitive to such matters. By assigning total scores rather than generating a profile of views, the research conflates valuable data that could inform the design of curriculum interventions.

Rather than assigning individuals to one of several predetermined philosophical positions, it might make more sense to refer to their *Personal Framework of NOS*

---

[15] Other important studies of video-based teacher professional development programmes include Borko and colleagues (2008), Rosaen and colleagues (2008), Santagata and colleagues (2007) and Zhang and colleagues (2011).

Understanding and seek to highlight its interesting and significant features, an undertaking that could be facilitated by the use of repertory grids (as in the study by Shapiro 1996).[16] One such recent study by Ibrahim et al. (2009) seeks to consolidate data from a purpose-built questionnaire into NOS profiles. The questionnaire, *Views about Scientific Measureme*nt (VASM), which comprises six items addressing aspects of NOS and eight items dealing with scientific measurement, uses a common context (in earth sciences) and allows space for students to elaborate on their response or compose an alternative. The data, obtained from 179 science undergraduates, were found to cluster into four partially overlapping profiles, which the authors refer to as *modellers*, *experimenters*, *examiners* and *discoverers*. For *modellers*, theories are simple ways of explaining the often complex behaviour of nature; they are constructed by scientists and tested, validated and revised through experimentation. Creativity plays an important role in constructing hypotheses and theories and in experimentation. When there are discrepancies between theoretical and experimental results, both theory and the experimental data need to be scrutinized. *Experimenters* also believe that scientists should use experimental evidence to test hypotheses and theories but should do so in accordance with a strict scientific method. In situations of conflict, data have precedence over theories. *Examiners* regard the laws of nature as fixed and 'out there' waiting to be discovered through observation, rather than constructed by scientists. Experimental work is essential; it is not informed by theory. Scientists may use both the scientific method and their imagination, but experimental data always have precedence over theories. *Discoverers* also believe that the laws of nature are out there waiting to be discovered through observation. Only experiments using the scientific method can be used to generate laws and theories. If experimental data conflict with a previously established theory, then both the theory and the data need to be checked.[17] Profiling could solve many of the problems associated with the compilation and interpretation of data on NOS understanding among both students and teachers.

28.10 Some Current Emphases in NOS-Oriented Curricula

Despite the many caveats concerning the validity and reliability of research methods, it is incumbent on teachers, teacher educators and curriculum developers to pay attention to the rapidly growing number of studies indicating that both students and

---

[16] Repertory grids enable researchers to ascertain links between different facets of an individual's knowledge and understanding (and between understanding and actions) in quantitative form (Fransella and Bannister 1977). Using them over the lifetime of a research project enables a developmental record of students' (or teachers') views to be built up. Because repertory grids often produce surprising data and highlight inconsistencies in respondents' views, they provide a fruitful avenue for discussion and exploration of ideas. For these reasons, Pope and Denicolo (1993) urge researchers to use them as 'a procedure that facilitates a conversation' (p. 530).

[17] Interestingly, as a percentage of the total, the modeller profile was more common among students following a 4-year science foundation course than among physics majors.

teachers have inadequate, incomplete or confused NOS understanding.[18] Two points are worth making. First, the goal of improving NOS understanding is often prejudiced by stereotyped images of science and scientists consciously or unconsciously built into school science curricula[19] and perpetuated by science textbooks.[20] This should be a relatively easy problem to fix, and it is fair to say that the situation is not nearly so dire as it was a decade or so ago. Second, research has shown that, in general, an *explicit* approach is much more effective than an *implicit* approach in fostering more sophisticated conceptions of NOS.[21]

In an explicit approach, NOS understanding is regarded as curriculum content, to be approached carefully and systematically, just like any other lesson content. This does not entail a didactic or teacher-centred approach or the imposition of a particular view through exercise of teacher authority, but it does entail rejection of the belief that NOS understanding will just develop in students as a by-product of engaging in other learning activities. Most effective of all are approaches that have a substantial reflective component.[22] Adúriz-Bravo and Izquierdo-Aymerich (2009), Howe and Rudge (2005) and Rudge and Howe (2009) argue that an explicit reflective approach is particularly effective when historical case studies are used to engage students in the kinds of reasoning used by scientists originally struggling to make sense of phenomena and events and to construct satisfactory explanations, while Wong and colleagues (2008, 2009) have shown the value of embedding explicit teaching of NOS within a consideration of important socioscientific issues.

Other notable research studies include the finding by Schwartz et al. (2004) that preservice teachers' NOS understanding was favourably enhanced when their course included a research component and journal-based assignments; the report by Morrison et al. (2009) that substantial gains in NOS understanding are achieved when explicit, reflective instruction in NOS is augmented by opportunities to interview practising scientists about their work and/or undertake some job sharing; and the study by Abd-El-Khalick and Akerson (2009) that notes major gains in the NOS understanding of preservice elementary teachers when explicit, reflective instruction is supported by use of metacognitive strategies (especially concept mapping), opportunities to research the development of their peers' NOS understanding and the chance to discuss case studies of elementary science classes oriented towards NOS teaching. A further raft of studies point to the key role played by teachers' NOS-oriented pedagogical content knowledge, curriculum awareness, confidence, self-efficacy and access to appropriate curriculum resources (Hanuscin et al. 2011; Lederman et al. 2012; Ryder and Leach 2008). My own views on how we can build and implement a curriculum to achieve enhanced levels of NOS understanding are discussed at length in Hodson (2009).

It is both notable and disappointing that the gains in NOS understanding consequent on exposure to explicit, reflective instruction are considerably less substantial in relation to the sociocultural dimensions of science than for other NOS elements.[23] The drive to equip students with an understanding of science in its social, cultural, economic and political contexts is, of course, the underpinning rationale of the so-called science-technology-society (STS) approach – more recently expanded to STSE (where E stands for environment). STS(E) has always been a purposefully ill-defined field that leaves ample scope for varying interpretations and approaches, and much has changed over the years in terms of its priorities and relative emphases.[24]

Aikenhead (2005, 2006) describes how the early emphasis on values and social responsibility was systematized by utilizing a theoretical framework deriving from sociology of science and encompassing two key aspects of NOS: (i) the social interactions of scientists *within* the scientific community and (ii) the interactions of science and scientists with social aspects, issues and institutions *external* to the community of scientists. In the terms used by Helen Longino (1990), this is a distinction between the *constitutive* values of science (the drive to meet criteria of truth, accuracy, precision, simplicity, predictive capability, breadth of scope and problem-solving capability) and the *contextual* values that impregnate the personal, social and cultural context in which science is organized, supported, financed and conducted. Allchin (1999) draws a similar distinction between the *epistemic* values of science and the *cultural* values that infuse scientific practice. Both emphases

have remained strong, though much has changed with respect to the sociopolitical and economic contexts in which educators and scientists work, our understanding of key issues in the history, philosophy and sociology of science and our theoretical knowledge concerning concept acquisition and development.

Drawing on the metaphor deployed by Sauvé (2005) in her analysis of trends in environmental education, Pedretti and Nazir (2011) describe variations and shifts in the focus of STSE in terms of 'a vast ocean of ideas, principles, and practices that overlap and intermingle one into the other' (p. 603). The six currents identified are as follows: *application/design* (practical problem solving through designing new technology or adapting old technologies), *historical* (understanding the sociocultural embeddedness of science and technology), *logical reasoning* (using a range of perspectives, including many outside science, to understand scientific and technological developments), *value-centred* (addressing the multidimensionality of socioscientific issues, including moral-ethical concerns), *sociocultural* (recognizing and critiquing science and technology as social institutions) and *socio-ecojustice* (critiquing and addressing socioscientific issues through direct and indirect action). Five of these categories include elements of NOS, as defined above.

Concern with constitutive and contextual values, and the ways in which these values have shifted in recent years, has been the trigger for renewed interest in the changing nature of NOS – in particular, the key differences between contemporary practice at the cutting edge of scientific research and what might be called 'classical scientific research' (the focus for much of school science), especially with regard to methods, publication practices, sponsorship and funding. Forty years ago, sociologist Robert Merton (1973) identified four 'functional norms' or 'institutional imperatives' that govern the practice of science and the behaviour of individual scientists, whether or not they are aware of it. These norms are not explicitly taught; rather, newcomers are socialized into the conventions of scientific practice through the example set by more senior scientists. Merton argued that these norms constitute the most effective and efficient way of generating new scientific knowledge and provide a set of 'moral imperatives' that serves to ensure good and proper conduct:

- *Universalism* – science is universal (i.e. its validity is independent of the context in which it is generated or the context in which it is used) because evaluation of knowledge claims in science uses objective, rational and impersonal criteria rather than criteria based on personal, commercial or political interests and is independent of the reputation of the particular scientist or scientists involved.
- *Communality* – science is a cooperative endeavour and the knowledge it generates is publicly owned. Scientists are required to act in the common good, avoid secrecy and publish details of their investigations, methods, findings and conclusions so that all scientists may use and build upon the work of others.
- *Disinterestedness* – science is a search for truth simply for its own sake, free from political or economic motivation or strictures, and with no vested interest in the outcome.
- *Organized scepticism* – all scientific knowledge, together with the methods by which it is produced, is subject to rigorous scrutiny by the community of scientists in conformity with clearly established procedures and criteria.

In the traditional forms of basic or fundamental research, usually located in universities and/or government research institutes, the so-called pure scientists constitute their own audience: they determine the research goals, recognize competence, reward originality and achievement, legitimate their own conduct and discourage attempts at outside interference. In the contemporary world, universities are under increasing public pressure to deliver more obvious value for money and to undertake research that is likely to have practical utility or direct commercial value. There are increasingly loud calls for closer links between academia and industry. In this changed sociopolitical environment, scientists are now required to practice what Ziman (2000) calls *post-academic* science.[25] Because contemporary scientific research is often dependent on expensive technology and complex and wide-ranging infrastructure, it must meet the needs and serve the interests of those sponsors whose funds provide the resources. Research is often multidisciplinary and involves large groups of scientists, sometimes extending across a number of different institutions, working on problems that they have not posed, either individually or as a group. Within these teams, individual scientists may have little or no understanding of the overall thrust of the research, no knowledge of their collaborators at a personal level and no ownership of the scientific knowledge that results. A number of governments and universities have moved to privatize their research establishments, that is, sell institutes or laboratories engaged in potentially commercially lucrative research areas to industry and business interests or turn them into independent companies. In consequence, scientists have lost a substantial measure of autonomy. In many universities, the research agenda no longer includes so-called blue skies research (i.e. fundamental research), as emphasis shifts to *market-oriented research*, *outcome-driven research* and ever-shortening *delivery times*. Many scientists are employed on contracts that prevent them from disclosing all their results. Indeed, there is a marked trend towards patenting, privatization and commodification of knowledge. As Ziman (2000) comments, many scientists have been forced to trade the academic kudos of publication in refereed journals for the material benefit of a job or a share in whatever profit there might be from a patented invention.

Varma's (2000) study of the work of scientists in industry paints a vivid picture of disturbing changes in the way research is conducted: customization of research to achieve marketable outcomes, contract funding and strict budget constraints, flexible but strictly temporary teams of researchers assembled for specific projects and a shift in the criteria for research appraisal from the quality and significance of the science to cost-effectiveness. The vested interests of the military and commercial sponsors of research, particularly tobacco companies, the petroleum industry, the food processing industry, agribusiness institutions and pharmaceutical companies, can often be detected not just in research priorities but also in research design, especially in terms of what and how data are collected, manipulated and presented. More subtly, in what data are *not* collected, what findings are omitted from reports and whose

---

[25] While Ziman (2000) refers to contemporary scientific practice as *post-academic science*, Funtowicz and Ravetz (1993) call it *post-normal science,* and Gibbons and colleagues (1994) and Nowotny et al. (2003) use the term *mode 2 science*.

voices are silenced. Commercial interests may influence the way research findings are made public (e.g. press conferences rather than publication in academic journals) and the way in which the impact of adverse data is minimized, marginalized, hidden or ignored – issues explored at length in Hodson (2011).

In summary, science can no longer be regarded as the disinterested search for truth and the free and open exchange of information, as portrayed in many school textbook versions of science. Rather, it is a highly competitive enterprise in which scientists may be driven by self-interest and career building, desire for public recognition, financial inducements provided by business and commerce or the political imperatives of military interests. Some would argue that one of the most disturbing features of contemporary science is the effective privatization of knowledge. Science is increasingly conducted behind closed doors, in the sense that many procedures and findings remain secret or they are protected by patenting, thus removing them from critical scrutiny by the community of scientists. The scope of what can be patented has been progressively and systematically broadened, such that the very notion of public accessibility to the store of contemporary scientific knowledge is under threat (Mirowski and Sent 2008). It seems that the realities of contemporary science are in direct contradiction of three, if not all four, of the functional norms identified by Merton. Communality, disinterestedness and organized scepticism have been replaced by ‘the entrepreneurial spirit and economic growth, such that scientific intellectual creativity seems to have become synonymous with commodity’ (Carter 2008, p. 626). Our definitions of NOS and the teaching/learning activities we provide in school need to take account of these matters.

28.11 SSI-Oriented Teaching and Its Curriculum Implications

Interestingly, as consideration of the nature of science has become a much more prominent part of regular science curricula, even a central part in many educational jurisdictions, so emphasis in STSE education has shifted much more towards confrontation of socioscientific issues (SSI), what Pedretti and Nazir (2011) call the value-centred current in STSE. Zeidler and colleagues (2005) contrast this orientation with earlier forms of STS or STSE education in terms of its emphasis on developing habits of mind (specifically, developing scepticism, maintaining open-mindedness, acquiring the capacity for critical thinking, recognizing that there are multiple forms of inquiry, accepting ambiguity and searching for data-driven knowledge) and ‘empowering students to consider how science-based issues reflect, in part, moral principles and elements of virtue that encompass their own lives, as well as the physical and social world around them’ (p. 357). They argue that while STSE education emphasizes the impact of scientific and technological development on society, it does not focus explicitly on the moral-ethical issues embedded in decision-making: ‘STS(E) education as currently practiced… only ‘points out’ ethical dilemmas or controversies, but does not necessarily exploit the inherent pedagogical power of discourse, reasoned argumentation, explicit NOS considerations, emotive, developmental, cultural or epistemological connections within the issues themselves… nor does it consider the moral or character development of students' (p. 359).

Bingle and Gaskell (1994) had earlier noted that STS education tends to emphasize what Bruno Latour (1987) calls 'ready-made science' (with all its attendant implicit messages about certainty) rather than 'science in the making' (with its emphasis on social construction). Simmons and Zeidler (2003) argue that it is the priority given to science in the making through consideration of *controversial* SSI that gives the SSI approach its special character and its unique power to focus on NOS understanding: 'Using controversial socioscientific issues as a foundation for individual consideration and group interaction provides an environment where students can and *will* develop their critical thinking and moral reasoning' (p. 83, emphasis added). In a further attempt at delineation, Zeidler and colleagues (2002) claim that the SSI approach has much broader scope, in that it 'subsumes all that STS has to offer, while also considering the ethical dimensions of science, the moral reasoning of the child, and the emotional development of the student' (p. 344).[26] Robust understanding of NOS is a clear prerequisite for addressing SSI critically and systematically; importantly, enhanced NOS understanding (both *distal* and *proximal*) is also a significant learning outcome of an SSI-oriented approach (Schalk 2012).

If students are to address SSI thoroughly and critically and deal with the NOS issues they raise, they will need the language skills to access knowledge from various sources and the ability to express their knowledge, views, opinions and values in a form appropriate to the audience being addressed. Thus, teachers need to focus students' attention very firmly on the language of science, scientific communication and scientific argumentation and on students' capacity to become critical readers of a wide variety of texts. Because meaning in science is also conveyed through symbols, graphs, diagrams, tables, charts, chemical formulae and equations, 3-D models, mathematical expressions, photographs, computer-generated images, body scans and so on, Lemke (1998) refers to the language of science as 'multimodal communication'. Any one scientific text might contain an array of such modes of communication, such that it may be more appropriate to refer to the *languages* of science:

> Science does not speak of the world in the language of words alone, and in many cases it simply cannot do so. The natural language of science is a synergistic integration of words, diagrams, pictures, graphs, maps, equations, tables, charts, and other forms of visual mathematical expression. (Lemke 1998, p. 3)

Because much of the information needed to address SSI is of the science-in-the-making kind, rather than a well-established science, and may even be located at or near the cutting edge of research, it is unlikely that students will be able to locate it

in traditional sources of information like textbooks and reference books. It will need to be accessed from academic journals, magazines, newspapers, TV and radio broadcasts, publications of special interest groups and the Internet, thus raising important issues of *media literacy*. Being media literate means being able to access, comprehend, analyse, evaluate, compare and contrast information from a variety of sources and utilize that information judiciously and appropriately to synthesize one's own detailed summary of the topic or issue under consideration. It means recognizing that the deployment of particular language, symbols, images and sound in a multimedia presentation can each play a part in determining a message's overall impact and will have a profound influence on its perceived value and credibility. It means being able to ascertain the writer's purpose and intent, determine any subtext and implicit meaning and detect bias and vested interest. It means being able to distinguish between good, reliable information and poor, unreliable information. It involves the ability to recognize what Burbules and Callister (2000) call *misinformation*, *malinformation*, *messed-up information* and *useless information*. Students who are media literate understand that those skilled in producing printed, graphic and spoken media use particular vocabulary, grammar, syntax, metaphor and referencing to capture our attention, trigger our emotions, persuade us of a point of view and, on occasions, bypass our critical faculties altogether.

Many SSI are highly controversial, sometimes because the scientific information required to formulate a judgement is incomplete, insufficient, inconclusive or extremely complex and difficult to interpret, sometimes because judgement involves consideration of factors rooted in social, political, economic, cultural, religious, environmental, aesthetic and/or moral-ethical concerns, beliefs, values and feelings. In other words, controversy may be *internal* or *external* to science. Teachers need to make a decision about how they will handle such issues. Should they try to avoid controversy altogether, take a neutral position, adopt the devil's advocate role, try to present a balanced view or advocate a particular position? These questions are discussed at length in Hodson (2011). Further, almost any discussion of a topical SSI is likely to raise questions not only about what we *can* or *could* do but also about what is the *right* decision and what we *ought* to do. Because many SSI have this moral-ethical dimension, teachers will also need to foster students' moral development and develop their capacity to make ethical judgments. Helpful discussion of these matters and strategies that teachers might employ can be found in Fullick and Ratcliffe (1996), Jones et al. (2007, 2010) and Reiss (1999, 2003, 2010).[27]

It is also likely that addressing SSI in class will generate strong feelings and emotions, with students' views and assumptions being strongly influenced by personal experiences and the experiences of friends and family and by socioculturally determined predispositions and worldviews. A student's sense of identity, comprising

ethnicity, gender, social class, family and community relationships, economic status and personal experiences extending over many years, will necessarily impact on their values, priorities and preferences and influence the ways in which they engage in discussion and the conclusions they reach. Teachers introducing SSI into the curriculum need to be sensitive to these influences and will need to assist students in dealing with potentially stressful and disconcerting learning situations. It is here that notions of *emotional intelligence*, *emotional literacy* and *emotional competence* can be helpful.[28] Although these three terms are closely related, Matthews (2005) chooses to draw a distinction between the individualistic nature of emotional intelligence and the strongly social nature of emotional literacy. Thus, he argues emotional intelligence refers to an individual's ability to perceive, describe, appraise and express emotions, understand emotions and emotional knowledge, access and/or generate appropriate feelings when they facilitate thought or manage them productively when they might inhibit, while emotional literacy is the capacity to be receptive to a wide range of feelings, empathize with others and continuously monitor the emotional climate in which one is located. Emotional competence may be seen as an amalgam of the two. In general, the goal of emotional literacy is awareness and management of one's emotions in both joyful and stressful situations, the confidence and self-assurance to understand one's own emotions and the capacity to deal with them in a positive and intentional way. It is closely related to notions of self-awareness, self-image, self-esteem and sense of identity, and less directly with self-efficacy and agency.

28.12 Future Developments

In a chapter dealing with the origin, development, implications and shifting emphases of NOS-oriented curricula, it is perhaps appropriate to speculate on future developments or even to promote one's own ideas for further development. On this latter count, I count myself among those authors who argue that current conceptions of STSE or SSI-oriented science education do not go far enough, among those who advocate a much more radical, politicized form of SSI-oriented teaching and learning in which students not only address complex and often controversial SSI, and formulate their own position concerning them, but also prepare for, and engage in, sociopolitical actions that they believe will 'make a difference', asking critical questions about how research priorities in science are determined, who has access to science, how science could (and perhaps should) be conducted differently, how scientific and technological knowledge are deployed, whose voices are heard and whose reading

of a situation are considered.[29] It is a curriculum clearly rooted in notions of equity and social justice.

The likelihood of students becoming active citizens in later life is increased substantially by encouraging them to take action *now* (in school), providing opportunities for them to do so and giving examples of successful actions and interventions engaged in by others. Students need knowledge of actions that are likely to have positive impact and knowledge of how to engage in them. A key part of preparing for action involves identifying action possibilities, assessing their feasibility and appropriateness, ascertaining constraints and barriers, resolving any disagreements among those who will be involved, looking closely at the actions taken by others (and the extent to which they have been successful) and establishing priorities in terms of what actions are most urgently needed (and can be undertaken fairly quickly) and what actions are needed in the longer term. It is essential, too, that all actions taken by students are critically evaluated and committed to an action database for use by others. From a teaching perspective, it is important that care is taken to ensure both the appropriateness of a set of actions for the particular students involved and the communities in which the actions will be situated and the overall practicality of the project in terms of time and resources. It is also essential that students gain robust knowledge of the social, legal and political system(s) that prevails in the communities in which they live and develop a clear understanding of how decisions are made within local, regional and national government and within industry, commerce and the military. Without knowledge of where and with whom power of decision-making is located and awareness of the mechanisms by which decisions are reached, effective intervention is not possible. Thus, an issue-based and action-oriented curriculum requires a concurrent programme designed to achieve a measure of *political literacy*, including knowledge of how to engage in collective action with individuals who have different competencies, backgrounds and attitudes, but shares a common interest in a particular SSI. It also includes knowledge of likely sympathizers and potential allies and strategies for encouraging cooperative action and group interventions.

Desirable as this approach may be in meeting the needs of citizens in the early twenty-first century, converting such curriculum rhetoric into practical action in real classrooms is an extraordinarily tall order for teachers to undertake. It is a tall order for three reasons. First, because it radically changes the nature of the school curriculum and puts a whole raft of new demands on teachers. Second, because it challenges many of the assumptions on which schooling is traditionally based. Third, because it is predicated on a commitment to bringing about extensive and wide-ranging social change at local, regional, national and international levels. It will only occur when sufficient teachers, teacher educators, curriculum developers and curriculum policy makers are convinced of the importance, desirability and feasibility of

addressing SSI in the science classroom and encouraging sociopolitical action, and when there is commitment to teach and confidence in doing so through awareness of appropriate pedagogical strategies, capacity to organize the required classroom environment and access to suitable resources. The real breakthrough will come when individual teachers are able to find and work with like-minded colleagues to form pressure groups that can begin to influence key decision-making bodies. However, such matters are well outside the scope of this chapter.

28.13 Final Thoughts

The primary purpose of this chapter has been to convey something of the extraordinary rise and widening scope of curriculum interest in NOS understanding. From very humble beginnings (e.g. 'Let's ensure that we teach about the methods that scientists use as well as paying attention to content'), curriculum interest in NOS has developed into a major influence on science education in many parts of the world. Changing views of what counts as NOS knowledge have led to further extensive developments, including concern with the characteristics of scientific inquiry, the role and status of the scientific knowledge it generates, modelling and the nature of models, how scientists work as a social group, the linguistic conventions for reporting and scrutinizing knowledge claims, the ways in which science impacts and is impacted by the social context in which it is located and the centrality of NOS in addressing the science underpinning SSI. More recently, it has been extended in such a way that some educators see NOS as a central plank in citizenship education. In my view, the next development in the extension of NOS-oriented education is the establishment of an issue-based and action-oriented curriculum capable of directing critical attention to (i) the way contemporary research and development in science and technology is conceived, practised and funded and (ii) the ways in which scientific knowledge is accessed and deployed in establishing policy and priorities with respect to SSI.

A key issue concerns the NOS sophistication we should pursue via the school curriculum. It is unrealistic as well as inappropriate to expect students to become highly skilled philosophers, historians and sociologists of science. Rather, we should select NOS items for the curriculum in relation to important educational goals: the need to motivate students and assist them in developing positive but critical attitudes towards science, the need to pay close attention to the cognitive goals and emotional demand of specific learning contexts, the creation of opportunities for students to experience *doing* science for themselves, the capacity to address complex socioscientific issues with critical understanding, concern for values issues and so on. The degree of sophistication of the NOS items we include should be appropriate to the stage of cognitive and emotional development of the students and compatible with other long- and short-term educational goals. There are numerous goals for science education (and education in general) that can, will and *should* impact on decisions about the NOS content of lessons. Our concern is not just good philosophy of science, good sociology of science or good history of science, not just authenticity and preparation for sociopolitical action, but the educational needs and interests of the students – *all* students. Selection of NOS items should consider the *changing* needs and interests of students at different stages of their science education, as well as take cognizance of the views of 'experts' (philosophers of science, historians of science, sociologists of science, scientists, science educators) and the need to promote the wider goals of (i) authentic representation of science and (ii) pursuit of critical scientific literacy.

It is considerations like these that prompted Michael Matthews (1998) to advocate the pursuit of 'modest goals' concerning HPS in the school science curriculum. In his words, 'there is no need to overwhelm students with cutting edge questions' (p. 169). Perhaps so, but agreement with the notion of modest goals still raises a question of what they should comprise. At the very least, we should include the following: consideration of the relationship between observation and theory; the role and status of scientific explanations (including the processes of theory building and modelling); the nature of scientific inquiry (including experiments, correlational studies, blind and double-blind trials, data mining and all the other notable variations among the subdisciplines of science); the history and development of major ideas in science; the sociocultural embeddedness of science and the interactions among science, technology, society and environment; the distinctive language of science; the ways in which scientific knowledge is validated through criticism, argument and peer review; moral-ethical issues surrounding science and technology; error, bias, vested interest, fraud and the misuse of science for sociopolitical ends; and the relationship between Western science and indigenous knowledge. A number of these elements are present in some science curricula, but more often than not, they are implicit, part of the hidden curriculum, embedded in language, textbook examples, laboratory activities and the like, and so dependent, ultimately, on teachers' nature of science views.

This is a demanding prescription and I readily acknowledge that telling students too early in their science education that scientific inquiry is context dependent and idiosyncratic could be puzzling, frustrating and even off-putting. This is a similar point to Brush's (1974) concern that teaching history of science can have an adverse effect on young students by undermining their confidence in science and scientists. One approach is to take our cue from secondary school chemistry curricula, where we often begin with some very simple representations, such as 'elements are either metals or non-metals' or 'bonding is either covalent or electrovalent'. We then proceed to qualify these assertions in all manner of ways: 'there are varying degrees of metallic/non-metallic character, depending on atomic size and electron configuration' and 'there is a range of intermediate bond types, including polarized covalent bonds and lattices involving highly distorted ions, as well as hydrogen bonding, van der Waal's forces, and so on'. Similarly, in the early years, we may find it useful to characterize scientific inquiry as a fairly standard set of steps. Within this simple representation, we can emphasize the importance of making careful observations (using whatever conceptual frameworks are available and appropriate to the students' current stage of understanding), taking accurate measurements, systematically controlling variables, and so on. As students become more experienced, they can be introduced to variations in approach that are necessary as contexts change – for example, the startlingly different approaches adopted by experimental particle physicists, synthetic organic chemists and evolutionary biologists.

Matthews (2012) makes the same point when he states that students have 'to crawl before they can walk, and walk before they can run. This is no more than commonsensical pedagogical practice' (p. 21). The shift from nature of science (NOS) to features of science (FOS), with its inbuilt recognition of diversity among the sciences and the significant changes in constitutive values from 'classical' scientific research to contemporary, post-Mertonian scientific practice, would be a major step in assisting teachers to pitch their teaching at a level appropriate to the students and to the issues being addressed.

Derek Hodson is Emeritus Professor of Science Education at the Ontario Institute for Studies in Education (OISE), Professor of Science Education at the University of Auckland (part-time) and Visiting Professor of Science Education at the University of Hong Kong. After completing a B.Sc. in chemistry and a Ph.D. in synthetic organic chemistry at the University of Manchester and a M.Ed. degree at the University College of North Wales (Bangor), he taught chemistry and physics for 12 years in secondary schools in England, Scotland and Wales and spent 8 years in preservice education at the University of Manchester, 6 years at the University of Auckland, 17 years at OISE (including Directorship of the Imperial Oil Centre for Studies in Science, Mathematics and Technology Education) and four six-month periods at the University of Hong Kong. He was Founding Editor and General Manager of the *Canadian Journal of Science, Mathematics and Technology Education* – a position he held from 2001 to 2008. His research interests include history, philosophy and sociology of science and science education, science curriculum history, multicultural and antiracist education and action research approaches to science teacher education. Recently published books include *Towards Scientific Literacy: A Teachers' Guide to the History, Philosophy and Sociology of Science* (2008); *Teaching and Learning about Science: Language, Theories, Methods, History, Traditions and Values* (2009); and *Looking to the Future: Building a Curriculum for Social Activism* (2011) – all published by Sense Publishers.

Chapter 29
The Development, Use, and Interpretation of Nature of Science Assessments

Norman G. Lederman, Stephen A. Bartos, and Judith S. Lederman

29.1 Introduction

In the end, assessment becomes critical when considering the various goals of science curricula and instruction. This is as true for nature of scientific knowledge (NOS), typically considered synonymous with nature of science, as it is for any science subject matter. Hence, it is critical to delineate both the rationale for teaching the construct and its meaning.

The construct "nature of scientific knowledge" has been and continues to be an advocated goal of science education, as reflected in numerous US reform documents (e.g., American Association for the Advancement of Science [AAAS] 1990, 1993; National Research Council [NRC] 1996; National Science Teachers Association [NSTA] 1982) as well as other reform documents globally. Although conceptions of NOS, as reflected in these documents, have changed as much as the scientific knowledge they characterize, in general, an understanding of NOS is defended as being a critical component of scientific literacy. In spite of the arguments presented by a handful of researchers (e.g., Allchin 2011, 2012; Wong and Hodson 2009, 2010) contending that the views of NOS presented in these documents, and undergirding much of current NOS research, are not representative of the real work of scientists, it is important to note that the aspects of NOS outlined in the sections that follow are derived from careful examination of the writings of scientists, historians of science, and philosophers of science. Regardless, it is important not to lose sight of the audience for the often cited aspects of NOS, K-12 students. Consequently,

when one begins to consider what aspects of NOS should be included in school curricula, developmental appropriateness and relevance/importance to daily life must be addressed. Most importantly, there does exist a relatively clear consensus supporting a group of scientifically, developmentally, and educationally appropriate (K-12) aspects of NOS. But, before unpacking the construct, it would seem appropriate to first explicate what is meant by "scientific literacy."

The view of scientific literacy used here is informed by Roberts' (2007) two "visions" of literacy that have been exemplars within the science education community. The first, "science literacy," is related to an understanding of the traditional science content, namely, the specific knowledge, processes, and products of a discipline, as it focuses "inward at the canon of orthodox natural science" (Roberts 2007, p. 2). "Scientific literacy" includes the ability to apply this conceptual knowledge and understanding of the processes of science to help inform personal decision-making and participation in a scientifically and technology-driven culture and economy (AAAS 1993; NRC 1996). While formalized by Showalter (1974) and the National Science Teachers Association (1982), the various arguments regarding the importance of NOS in the development of scientific literacy can best be understood by examining Driver et al. (1996). Specifically, Driver and colleagues contended that understanding NOS is necessary (1) in helping individuals comprehend "everyday" science and the related technology and process of their lives (utilitarian), (2) to aid in making informed decision-making when confronted with socio-scientific issues (democratic), (3) in fostering an appreciation of the value that science adds to contemporary culture (cultural), (4) in helping cultivate an understanding of moral commitments of the scientific community and their value to society as a whole, and (5) in facilitating the learning of science subject matter.

While scientific literacy has arguably become a principal and overarching goal of science education worldwide (Roberts 2007), unfortunately, and in spite of the preponderance of NOS as an objective of science education for over 100 years (Central Association of Science and Mathematics Teachers 1907; Kimball 1967–68; Lederman 1992), it is largely intuition that underpins these five arguments in favor of developing learners' understandings of NOS. Little empirical support can be found in the science education literature to support the various rationales for developing understandings of NOS. This is due, in no small part, to the challenges of improving individual's conceptions of NOS, as "the longevity of this educational objective has been surpassed only by the longevity of students' inability to articulate the meaning of the phrase 'nature of science,' and to delineate the associated characteristics of science" (Lederman and Niess 1997, p. 1). The obstacles involved in seeing teachers' informed views of NOS translated into their classroom practice further complicate this process. Moreover, without a sufficient number of NOS-informed individuals, there is no way to know if or how NOS contributes to the development of a scientifically literate populace. Unfortunately, existing data concerning understandings of NOS still support Shamos (1984) who, when speaking to the necessity of developing students' understandings of what we now refer to as NOS, concluded that "in spite of taking science classes, few students come through this experience with more than a fleeting glimpse of science, and fewer still retain any lasting impression of the scientific world" (p. 333).

29.2 What Is Nature of Scientific Knowledge?

Fortunately, in spite of the dearth of research specifically relating NOS to the development of scientific literacy, there is over 60 years of research on NOS that has, in part, sought to assess teachers' and students' understandings of NOS and investigate the efficacy of various approaches to improving these conceptions (Lederman 2007). But, irrespective of this ever growing body of research, the continued support for NOS in the science education and scientific communities and explicit statements regarding NOS in various reform documents, there are still unproductive disagreements regarding the meaning of NOS. Prior to delineating the specific conception of NOS espoused here, a few issues must be clarified.

First, the myriad views of NOS reflected on the pages of refereed journals and conference proceedings, which almost invariably contradict the aforementioned reform documents, do not provide direct support for the contention that there is, therefore, no consensus about the meaning of NOS as some have contended (e.g., Alters 1997). Not only is there more consensus than disagreement about the definition and/or meaning of NOS (Smith et al. 1997; Smith and Scharmann 1999), these disagreements, while providing fodder for a lively argument among philosophers, historians, or science educators, are irrelevant to K-12 classroom practice (Lederman 1998, 2007). What is necessary when considering NOS, as is the case with typical science content, is its educational and developmental appropriateness, as well as its presentation in a way that is connected with students' lives, but at an acceptable level of generality, as reflected in the aforementioned authors as well as others (e.g., Elby and Hammer 2001; Rudolph 2003). Little disagreement exists among philosophers, historians, and science educators for the characteristics of NOS that fit these criteria.

Second, it is important to stress that a definitive description of NOS, contrary to the assumptions of our critics (Irzik and Nola 2011; Matthews 2012), is not presented here or elsewhere. It is recognized, and it should be obvious, that other researchers may include or delete various aspects of NOS resulting in equally valid representations of NOS that are educationally and developmentally appropriate for learners (Osborne et al. 2003; Smith and Scharmann 1999). Far too much time has recently been spent arguing about what aspects of NOS should and should not be included in various lists of desired outcomes and standards. The discussion should be more centered on the value of the knowledge that is being considered, not the construction of a definitive definition of NOS. The focus here is not to simply promote the definition of the construct provided by favored colleagues and fellow researchers[1] but to assist the reader in delineating NOS from both the process of science and the scientific knowledge that results. The conflation of the processes of science (scientific inquiry), with the characteristics of scientific knowledge that are inherently derived from these processes (nature of science scientific knowledge, NOS), is an avoidable, yet common, characteristic of research done on NOS.

---

[1] See, for instance, Abd-El-Khalick (2005), Akerson et al. (2000), Bell and Lederman (2003), Khishfe and Abd-El-Khalick (2002), Lederman and Neiss (1997), and Schwartz and Lederman (2002).

Lastly, it should be reiterated that a focus on learning outcomes that are developmentally appropriate have a preponderance of empirical support for inclusion in K-12 curricula and are arguably essential if students are to achieve the goal of scientific literacy should be in the forefront of discussions about NOS. Furthermore, at this level of appropriate generality, there are few disagreements about aspects of NOS, as evidenced by their congruence with numerous reform documents worldwide. Consider the issue of the existence of an objective reality versus that which is purely phenomenal. This debate may certainly be situated in a philosophy of science class but is misplaced, misaligned, and counterproductive to the goals and objectives of K-12 science curricula. The reader is reminded that the goal of the K-12 science teacher is not to create philosophers of science, but rather to develop informed citizens so decisions can be made concerning personal and societal issues that are scientifically based. This goal is sometimes overlooked by participants in NOS disputes.

29.3 The Nature of Scientific Knowledge (NOS)

In general, the phrase "nature of scientific knowledge" or NOS refers to the characteristics of scientific knowledge that are inherently derived from the manner in which it is produced (i.e., scientific inquiry). These general characterizations aside, philosophers and historians of science, scientists, and science educators do not, nor should they be expected to, share a common consensus on a specific definition of NOS. This, as previously mentioned, should not be cause for alarm, as over the last century conceptions of NOS have changed just as conceptions of science have done, with the definition of NOS changing as much as the knowledge it intends to characterize.[2]

It is of utmost importance that the 1980s saw the phrase "nature of scientific knowledge" shortened to "nature of science," a modification that may have introduced some unnecessary confusion. In the research literature, "nature of science" more aptly refers to "nature of scientific knowledge" and is consistent with the definition used in the current chapter. Lastly, to reiterate, the "list" of characteristics of scientific knowledge that will be explicated in what follows is educationally and developmentally appropriate and has a wealth of evidence in support of their inclusion in K-12 science instruction – they should not be construed as representing the definitive "NOS catechism," as some have decreed (Matthews 2012). Furthermore, while some researchers have maintained that these aspects of NOS do not present the "whole picture" of science as it is practiced by scientists (e.g., Allchin 2011, 2012; Wong and Hodson 2009, 2010), these aspects are, the reader is reminded, derived

---

[2] As evidenced by AAAS (1990, 1993), Center of Unified Science Education (1974), Central Association for Science and Mathematics Teachers (1907), Klopfer and Watson (1957), and NSTA (1982).

from the writings and recommendations of scientists and are not intended to help inform efforts to create a new population of bench scientists, but to aid K-12 classroom science teachers and science education researchers in the development of a scientifically literate populace. With these caveats, let us return to unpacking the construct of NOS.

First, learners should develop an understanding of the crucial distinction between observation and inference. In the K-12 science classroom, observations are presented as descriptive statements about natural phenomena that are "directly" accessible to the senses, or extensions of the senses, and for which observers can reach consensus with relative ease (e.g., an object, once released, falls to the floor). Inferences, by contrast, are statements that are not "directly" accessible to the senses and can only accessed and/or measured though related manifestations or effects (e.g., gravity). Beyond developing explanations, at a higher level, scientists can infer models and/or mechanisms that serve to explain observations of complex phenomena (e.g., weather modeling, evolution).

Second is the distinction between scientific theories and laws, a pair of categories of scientific knowledge that is closely related to the distinction between observation and inference. This point is critical as the majority of individuals hold a simplistic, hierarchical view of the relationship between theories and laws, whereby theories, once they have "accumulated" sufficient supportive evidence, become laws. It follows from this misconception that scientific laws have a higher status than scientific theories, when in fact scientific theories and laws are different types of knowledge. A theory is not formulated with the hope that someday it will acquire the status of "law," as theories are not developed or transformed into laws, nor is a law ever demoted to being "just a theory." Scientific laws are statements or descriptions of the relationships among observable phenomena. Boyle's law, which relates the pressure of a gas to its volume at a constant temperature, is a case in point. Scientific theories, by contrast (and in contrast to the common usage of the word "theory"), are inferred explanations for observable phenomena. The kinetic molecular theory, which explains Boyle's law, is one example. Moreover, theories are as legitimate a product of science as laws. Scientific theories, in their own right, serve important roles, such as guiding investigations and generating new research problems, in addition to explaining relatively huge sets of seemingly unrelated observations in more than one field of investigation. For example, the kinetic molecular theory serves to explain phenomena that relate to changes in the physical states of matter, others that relate to the rates of chemical reactions, and still other phenomena that relate to heat and its transfer, to mention just a few. While some philosophers and historians of science (e.g., Allchin 2012; Wong and Hodson 2009, 2010) may contend that these descriptions of laws and theories leave something to be desired, this level of generality has evidenced itself as appropriate and accessible to K-12 science students. Indeed, these same critics of including the distinction of theories and laws under the rubric of NOS base their positions on the idea that scientists do not enter discussions about such differences in knowledge claims. In spite of this, the audience of such NOS instruction cannot be ignored. The commonly held misconception that "evolution is just a theory" is case in point. Although the distinction between theories and laws may not be important to scientists, it is certainly important for the general public, teachers, and students.

Third, the development of scientific knowledge involves human imagination and creativity. Science, contrary to common belief, does not rely solely on observations of the natural world (i.e., empirically based), nor is it totally lifeless, rational, and orderly. In addition to devising creative investigatory methodologies and data reduction techniques, science involves the invention of explanations and the generation of ideas that involve considerable creativity by scientists. The “leap” from atomic spectral lines to Bohr’s model of the atom with its elaborate orbits and energy levels is one example. This aspect of science, coupled with its inferential nature, entails that scientific concepts, such as atoms, black holes, and species, are functional theoretical models rather than faithful copies of reality.

Fourth, scientific knowledge, owing to scientists’ theoretical commitments, beliefs, previous knowledge, training, experiences, and expectations, is unavoidably subjective. These background factors form a mind-set that affects the problems scientists investigate and how they conduct their investigations, what they observe (and do not observe), what they consider as evidence, and how they make sense of and interpret their observations. It is this (sometimes collective) individuality or mind-set that accounts for the role of subjectivity in the production of scientific knowledge. It is noteworthy that, contrary to common belief, science rarely starts with neutral observations (Chalmers 1982). Observations (and investigations) are motivated by, guided by, and acquire meaning in reference to questions or problems, which, in turn, are derived from within certain theoretical perspectives. Often, hypothesis or model testing serves as a guide to scientific investigations. For example, a researcher operating from a Darwinian framework might focus his/her efforts on the location of transitional species. By contrast, from a punctuated equilibrist perspective, transitional species would not be expected, nor would what a Darwinian considered a transitional species be considered as such (see Gould and Eldridge 1977).

Fifth, science as a human enterprise is practiced in the context of a larger culture, and its practitioners (scientists) are the product of that culture. Science, it follows, affects and is affected by the various elements and intellectual spheres of the culture in which it is embedded. These elements include, but are not limited to, social fabric, power structures, politics, socioeconomic factors, philosophy, and religion. Telling the story of the evolution of humans (*Homo sapiens*) over the course of the past seven million years is central to the biosocial sciences and serves to illustrate how social and cultural factors impact scientific knowledge. Scientists have formulated several elaborate and differing story lines about this evolution. Until recently, the dominant story was centered about “the man-hunter” and *his* crucial role in the evolution of humans to the form we now know (Lovejoy 1981). This scenario was consistent with the white-male culture that dominated scientific circles up to the 1960s and early 1970s. As the feminist movement grew stronger and women were able to claim recognition in the various scientific disciplines, the story about hominid evolution started to change. One story that is more consistent with a feminist approach is centered about “the female-gatherer” and *her* central role in the evolution of humans (Hrdy 1986). It is noteworthy that both story lines are consistent with the available evidence.

Sixth, it follows from the previous discussions that scientific knowledge is never absolute or certain. This knowledge, including "facts," theories, and laws, while durable, is tentative and subject to change. Scientific claims change as new evidence, made possible through advances in *theory* and technology, is brought to bear on existing theories or laws or as old evidence is reinterpreted in the light of new theoretical advances or shifts in the directions of established research programs. It should be emphasized that tentativeness in science does not only arise from the fact that scientific knowledge is inferential, creative, and socially and culturally embedded. There are also compelling logical arguments that lend credence to the notion of tentativeness in science. Indeed, contrary to common belief, scientific hypotheses, theories, and laws can *never* be absolutely "proven." This holds irrespective of the amount of empirical evidence gathered in the support of one of these ideas or the other (Popper 1963, 1988). For example, to be "proven," a certain scientific law should account for *every single instance* of the phenomenon it purports to describe *at all times*. It can logically be argued that one such future instance, of which we have no knowledge whatsoever, may behave in a manner contrary to what the law states. As such, the law can never acquire an absolutely "proven" status. This equally holds in the case of hypotheses and theories. This philosophical aside, while not intended for inclusion with younger learners, can help highlight both the tentative nature of certain scientific knowledge and the durability of other knowledge as a function of the weight of empirical evidence.

Before moving on to specifically address the development, use, and interpretation of various NOS assessments, it is important to note that science educators and science education researchers often conflate NOS with science processes, practices, or scientific inquiry (SI). Although these aspects of science overlap and interact in important ways, it is nonetheless important to distinguish between them. Scientific processes are activities related to collecting and analyzing data and drawing conclusions (AAAS 1990, 1993; NRC 1996). For example, observing and inferring are scientific processes. More complex than individual processes, scientific inquiry involves various science processes used in a cyclical manner. On the other hand, NOS refers to the epistemological underpinnings of the activities of science and the characteristics of the resulting knowledge. As such, realizing that observations are necessarily theory-laden and are constrained by our perceptual apparatus belongs within the realm of NOS. Distinguishing NOS from SI for the purpose of providing focus to this chapter should in no way be construed to mean that NOS is considered more important for students to learn about. Certainly, NOS and SI, although different, are intimately related and are both important for students to understand, though making a distinction between NOS and SI is not meant to imply that the two constructs are distinct. Furthermore, there is much evidence that NOS is best taught within a context of SI or activities that are reasonable facsimiles of inquiry. That is, inquiry experiences provide students with foundational experiences upon which to reflect about aspects of NOS.

The conflation of NOS and SI has plagued research on NOS from the beginning. Hence, the reader will note that many NOS assessments are actually more focused on SI than NOS. These studies are nevertheless reviewed, rather than excluded, since they have become an accepted part of the history of research on assessment of NOS. The definition used by these studies for NOS is just not consistent with current usage of the construct. Again, the aspects of NOS presented here are not meant to be exhaustive, as other listings certainly exist. However, what has been presented is directly consistent both with what current reform documents state students should know about NOS and also with the perspective taken by an overwhelming majority of the research literature.

Lastly, and as has been communicated previously, NOS can be a moving target, as it becomes clear to anyone who considers the works of Popper (1959), Kuhn (1962), Lakatos (1970), Feyerabend (1975), Laudan (1977), and Giere (1988) that perceptions of NOS are as tentative, if not more so, than scientific knowledge itself. NOS is, in effect, analogous to scientific knowledge. Some individuals, unfortunately, have dwelled too heavily on such differing perceptions (e.g., Alters 1997) without consideration of the overarching goal of research on improving conceptions of NOS. The recognition that our collective views of NOS have changed and will continue to change is not a justification for ceasing all NOS-related research until total agreement is reached or for avoiding recommendations or identifying what we think students should know. As educators, we have no difficulty including certain theories and laws within our science curricula even though we recognize that these may change in the near or distant future. What is important is that students understand the evidence for current beliefs about natural phenomena and are aware that evidence has similarly lead to our current beliefs about NOS. Just as with “traditional” subject matter, these perceptions may change as additional evidence is collected or the same evidence is viewed in a different way.

Regardless of the various “problems” associated with reaching consensus on specific aspects of NOS, and issues created by the tentativeness of the construct itself, NOS has been the object of systematic educational research for approximately 60 years. While there have been numerous reviews of research related to the teaching, learning, and assessment of nature of scientific knowledge (e.g., Abd-El-Khalick and Lederman 2000; Lederman 1992, 2007; Meichtry 1992), this review will focus on assessment of NOS. For practical reasons, the research reviewed is restricted to published reports and to those studies with a primary focus on NOS and to those assessments that have at least attempted to establish validity and/or reliability.

29.4 Assessing Conceptions of NOS

The development and assessment of students’ and teachers’ conceptions of nature of scientific knowledge has been a concern of science educators for nearly 60 years and arguably constitutes a line of research in its own right. Although there have been numerous criticisms of the validity of various assessment instruments over the years, students' and teachers' understandings have consistently been found lacking. This consistent finding, regardless of assessment approach, supports the notion that student and teacher understandings are not at the desired levels.

The history of assessment of NOS mirrors the changes that have occurred in both psychometrics and educational research design over the past few decades. The first formal assessments, beginning in the early 1960s, emphasized quantitative approaches, as was characteristic of the overwhelming majority of science education research investigations. Prior to the mid-1980s, with few exceptions, researchers were content to develop instruments that allowed for easily "graded" and quantified measures of individuals' understandings. In some cases, standardized scores were derived. Within the context of the development of various instruments, some open-ended questioning was involved in construction and validation of items. More recently, emphasis has been placed on providing an expanded view of an individual's knowledge regarding NOS. In short, in an attempt to gain more in-depth understandings of students' and teachers' thinking, educational researchers have resorted to the use of more open-ended probes and interviews. The same has been true with the more contemporary approaches to assessment related to NOS. Unfortunately, and in accordance with the pressures of high-stakes testing, momentum appears to be building for a return to more quantitative measures of NOS, which allows for large-scale administration and assessment of students' and teachers' understandings. In addition to this shift back to more "traditional" assessments, the *Next Generation Science Standards* (NRC 2011) in the USA are improvements over the original but, by a large degree, still ignore the long-standing empirical research on NOS, equating the "doing of science" with developing understandings about NOS. Consequently, the resulting assessment is likely not to be a valid measure of what has been known as NOS.

Although critical evaluations of assessment instruments have been provided elsewhere (Lederman 2007; Lederman et al. 1998), the purpose here is to summarize the various instruments and identify trends in the assessment of NOS. Table 29.1 presents a comprehensive list of the more formal instruments constructed and validated to assess various aspects of NOS. Most of the instruments address only certain aspects of NOS and often inappropriately confuse the issue by addressing areas other than NOS, including science process skills and attitudes toward science. Instruments considered to have poor validity have the following characteristics:

1. Most items concentrate on a student's ability and skill to engage in the process of science (e.g., to make a judgment and/or interpretation concerning data).
2. Emphasis is on the affective domain (the realm of values and feelings) rather than knowledge (i.e., over 50 % of items deal with attitude toward or appreciation of science and scientists).
3. Primary emphasis is placed upon "science as an institution" with little or no emphasis placed upon the epistemological characteristics of the development of scientific knowledge.

As mentioned before, the validity of many of these instruments is questionable because their primary focus is on areas beyond the scope of "nature of scientific knowledge." Those instruments with questionable validity (as measures of NOS) include the Science Attitude Questionnaire (Wilson 1954); Facts About Science

Table 29.1 Nature of science instruments

Date	Instrument	Author(s)
1954	Science Attitude Questionnaire	Wilson
1958	Facts About Science Test (FAST)	Stice
1959	Science Attitude Scale	Allen
1961	Test on Understanding Science (TOUS)	Cooley and Klopfer
1962	Processes of Science Test	BSCS
1966	Inventory of Science Attitudes, Interests, and Appreciations	Swan
1967	Science Process Inventory (SPI)	Welch
1967	Wisconsin Inventory of Science Processes (WISP)	Scientific Literacy Research Center
1968	Science Support Scale	Schwirian
1968	Nature of Science Scale (NOSS)	Kimball
1969	Test on the Social Aspects of Science (TSAS)	Korth
1970	Science Attitude Inventory (SAI)	Moore and Sutman
1974	Science Inventory (SI)	Hungerford and Walding
1975	Nature of Science Test (NOST)	Billeh and Hasan
1975	Views of Science Test (VOST)	Hillis
1976	Nature of Scientific Knowledge Scale (NSKS)	Rubba
1978	Test of Science-Related Attitudes (TOSRA)	Fraser
1980	Test of Enquiry Skills (TOES)	Fraser
1981	Conception of Scientific Theories Test (COST)	Cotham and Smith
1982	Language of Science (LOS)	Ogunniyi
1987	Views on Science-Technology-Society (VOSTS)	Aikenhead, Ryan, and Fleming
1990	Views of Nature of Science A (VNOS-A)	Lederman and O'Malley
1992	Modified Nature of Scientific Knowledge Scale (M-NSKS)	Meichtry
1995	Critical Incidents	Nott and Wellington
1998	Views of Nature of Science B (VNOS-B)	Abd-El-Khalick, Bell, and Lederman
2000	Views of Nature of Science C (VNOS-C)	Abd-El-Khalick, and Lederman
2002	Views of Nature of Science D (VNOS-D)	Lederman and Khishfe
2004	Views of Nature of Science E (VNOS-E)	Lederman and Ko
2006	Student Understanding of Science and Scientific Inquiry (SUSSI)	Liang et al.

Test (Stice 1958); Science Attitude Scale (Allen 1959); Processes of Science Test (BSCS 1962); Inventory of Science Attitudes, Interests, and Appreciations (Swan 1966); Science Support Scale (Schwirian 1968); Test on the Social Aspects of Science (Korth 1969); Science Attitude Inventory (Moore and Sutman 1970); Science Inventory (Hungerford and Walding 1974); Test of Science-Related Attitudes (Fraser 1978); the Test of Enquiry Skills (Fraser 1980); and the Language of Science (Ogunniyi 1982). Recently, Allchin (2012) proposed a prototype to assess what he called "whole science," but the instrument was never fully developed and it clearly conflated NOS with scientific inquiry. Hence, it is not discussed further here.

The remaining instruments have generally been considered to be valid and reliable measures of NOS by virtue of their focus on one or more ideas that have been traditionally considered under the label of "nature of scientific knowledge," as well as their reported validity and reliability data. These instruments have been used in numerous studies, and even the more traditional instruments (e.g., TOUS) continue to be used even though there is a significant movement away from such types of paper-and-pencil assessments. The validity of some of the assessment instruments listed and briefly described below has been justifiably criticized in the past few years. However, they are presented here as being the most valid (in terms of assessment focus) attempts to assess understandings of NOS using a written response format. What follows is a brief discussion of each instrument.

29.4.1 Test on Understanding Science (TOUS)

This instrument has been the most widely used assessment tool in NOS research (Cooley and Klopfer 1961). It is a four-alternative, 60-item multiple-choice test. In addition to an "overall" or "general" score, three subscales can be scored regarding understandings about (I) the scientific enterprise, (II) the scientist, and (III) the methods and aims of science. During the past few decades, the content of the *TOUS* has been criticized and has fallen into disfavor.[3]

29.4.2 Wisconsin Inventory of Science Processes (WISP)

The WISP consists of 93 statements that the respondent evaluates as "accurate," "inaccurate," or "not understood." However, in scoring the exam, "inaccurate" and "not understood" responses are combined to represent the opposite of "accurate." The WISP was developed and validated for high school students (Scientific Literacy Research Center 1967). Although this instrument has excellent validity and reliability data, a few concerns should be considered prior to its use. Of primary concern is its length. The 93-item test takes over an hour to administer, which precludes it from use in a single class period. In addition, this instrument does not possess discrete subscales, which, unfortunately, means that only unitary scores can be calculated.

29.4.3 Science Process Inventory (SPI)

This instrument is a 135-item forced-choice inventory (agree/disagree) purporting to assess an understanding of the methods and processes by which scientific knowledge evolves (Welch 1967; Welch and Pella 1967–1968). The content of the

---

[3] See Aikenhead (1973), Hukins (1963), Welch (1969), and Wheeler (1968), among others.

SPI is almost identical to that of WISP and TOUS subscale III. The validation of the SPI was achieved in the usual manner for such instruments: literature review, devising a model, employing the judgment of "experts," getting feedback from pilot studies, and testing the instrument's ability to distinguish among different groups of respondents. The length (135 items) is a concern as well as its forced-choice format. Students are unable to express "neutral" or uncertain answers. Finally, like the WISP, the SPI does not possess subscales.

29.4.4 Nature of Science Scale (NOSS)

This instrument was developed to determine whether science teachers have the same view of science as scientists (Kimball 1968). It consists of 29 items to which the respondent may "agree," "disagree," or register a "neutral" response. Kimball's model of NOS is based upon the literature of the nature and philosophy of science and is consistent with the views of Bronowski (1956) and Conant (1951). The specific content of the NOSS was validated by nine science educators who judged whether the items were related to the model. The development, validation, and reliability measures were carried out with college graduates. Thus, it lacks reliability and validity data with respect to high school populations. Another concern is that the instrument lacks subscales and is, therefore, subject to the same criticism as any other unitary measure of the nature of scientific knowledge.

29.4.5 Nature of Science Test (NOST)

This instrument consists of 60 multiple-choice items addressing the following components of NOS: assumptions of science (8 items), products of science (22 items), processes of science (25 items), and ethics of science (5 items) (Billeh and Hasan 1975). The test consists of two types of items. The first type measures the individual's knowledge of the assumptions and processes of science and the characteristics of scientific knowledge. The second type of question presents situations that require the individual to make judgments in view of his/her understanding of NOS. The major shortcoming of this instrument is not its content, but, rather, that no subscales exist. Again, only a global or unitary score can be calculated.

29.4.6 Views of Science Test (VOST)

This instrument was developed specifically to measure understanding of the tentativeness of science (Hillis 1975). It consists of 40 statements that are judged to imply that scientific knowledge is either tentative or absolute. Respondents express their agreement with either view using a five-option Likert scale response format.

29.4.7 Nature of Scientific Knowledge Scale (NSKS)

This instrument is a 48-item Likert scale response format consisting of five choices (strongly agree, agree, neutral, disagree, and strongly disagree) (Rubba 1976). The test is described as an objective measure of secondary students' understanding of NOS. The NSKS and its subscales are based upon the nine factors of NOS specified by Showalter (1974). Rubba (1976) listed these nine factors as tentative, public, replicable, probabilistic, humanistic, historic, unique, holistic, and empirical. He noted a certain amount of shared overlap between the factors and proceeded to collapse them into a six-factor or six-subscale model of the nature of scientific knowledge. These six factors are amoral, creative, developmental (tentative), parsimonious, testable, and unified. The instrument was developed, validated, and found to be reliable for high school level students. The five-option Likert scale response format affords maximum freedom of expression to the respondent. The *NSKS* has generally been viewed positively by the research community; however, there is reason for some concern about its face validity. Many pairs of items within specific subscales are identical, except that one item is worded negatively. This redundancy could encourage respondents to refer back to their answers on previous, similarly worded items. This cross-checking would result in inflated reliability estimates which could cause erroneous acceptance of the instrument's validity.

29.4.8 Conceptions of Scientific Theories Test (COST)

The structure of this instrument was dictated by the developers' concern that previously existing instruments were based on single (supposedly enlightened) interpretations of NOS (Cotham and Smith 1981). Thus, the COST supposedly provides for nonjudgmental acceptance of alternative conceptions of science. The instrument is an attitude inventory consisting of 40 Likert scale items (with four options) and four subscales, each corresponding to a particular aspect of scientific theories. These include (I) ontological implications of theories, (II) testing of theories, (III) generation of theories, and (IV) choice among competing theories. The COST provides a theoretical context for four-item sets by prefacing each set with a brief description of a scientific theory and some episodes drawn from its history. The items following each theory description refer to that description. The four theoretical contexts are (1) Bohr's theory of the atom, (2) Darwin's theory of evolution, (3) Oparin's theory of abiogenesis, and (4) the theory of plate tectonics. A fifth context contains items that refer to general characteristics of scientific theories and is, therefore, not prefaced by a description. Two concerns must be addressed prior to using COST as an instrument to assess high school students' understandings of NOS. The first of these is the cognitive level of the instrument. It was designed for teachers and validated with undergraduate college students. The four theory descriptions used to provide context for the items are presented at a level that may be above the capabilities of many high school students.

A second concern with the COST instrument rests with the authors' claim that it, as opposed to all extant instruments, is sensitive to alternative conceptions of science. However, the authors actually specify which subscale viewpoints are consistent with a tentative and revisionary conception of science. Thus, although they claim to place no value judgments upon the various conceptions of science, Cotham and Smith actually do just that by linking certain viewpoints to the "highly prized" tentative and revisionary conception of scientific knowledge.

29.4.9 Views on Science-Technology-Society (VOSTS)

The VOSTS was developed to assess students' understanding of nature of scientific knowledge, technology, and their interactions with society (Aikenhead et al. 1987). It consists of a "pool" of 114 multiple-choice items that address a number of science-technology-society (STS) issues. These issues include Science and Technology, Influence of Society on Science/Technology, Influence of Science/Technology on Society, Influence of School Science on Society, Characteristics of Scientists, Social Construction of Scientific Knowledge, Social Construction of Technology, and Nature of Scientific Knowledge. The VOSTS was developed and validated for grades 11 and 12 students. A fundamental assumption underlying the development of this instrument was that students and researchers do not necessarily perceive the meanings of a particular concept in the same way. Aikenhead and Ryan (1992) recognized the importance of providing students with alternative viewpoints based upon student "self-generated" responses to avoid the "constructed" responses offered by most of the previous nature of scientific knowledge assessment instruments. Unlike most other instruments, the VOSTS does not provide numerical scores; instead it provides a series of alternative "student position" statements. Extensive work was done on the careful validation of the instrument over a period of 6 years.

29.4.10 Views of Nature of Science, Form A (VNOS-A)

In an attempt to ameliorate some of the problems that each of the seven items focused on different aspects of tentativeness noted by Aikenhead et al. (1987) during the development of the VOSTS and those noted in the use of the NSKS (Rubba 1976) relative to the use of paper-and-pencil assessments, Lederman and O'Malley developed an open-ended survey consisting of seven items (Lederman and

O'Malley 1990). This instrument was designed to be used in conjunction with follow-up interviews and in science. Several problems were noted in the wording of some of the questions, resulting in responses that did not necessarily provide information on students' views of "tentativeness." The authors claimed that follow-up interviews alleviated this problem.

29.4.11 Modified Nature of Scientific Knowledge Scale (M-NSKS)

This instrument is a modified NSKS instrument with 32 statements from four of the NSKS subscales (Meichtry 1992). These subscales are (I) creative, (II) developmental, (III) testable, and (IV) unified. M-NSKS was developed, with reliability and validity reported, for use with 6th, 7th, and 8th graders.

29.4.12 Critical Incidents

The use of "critical incidents" to assess teachers' conceptions of NOS was a significant departure from the usual paper-and-pencil assessment (Nott and Wellington 1995). In particular, Nott and Wellington are of the opinion that teachers do not effectively convey what they know about nature of scientific knowledge in "direct response to abstract, context-free questions of the sort, 'What is science?'" (Nott and Wellington 1995). Instead, they created a series of "critical incidents" that are descriptions/scenarios of actual classroom events. Teachers are expected to respond to the incidents by answering the following three questions: (1) What would you do?, (2) What could you do?, and (3) What should you do? Although the use of critical incidents appears to be an excellent instructional tool to generate meaningful discussions in preservice and in-service courses, whether the teachers' responses are related to their views about NOS is still questionable. In short, the approach is based on the assumption that teachers' views of NOS automatically and necessarily influence classroom practice, an assumption that is simply not supported by the existing literature.

29.4.13 Views of Nature of Science B, C, D, E (VNOS-B, VNOS-C, VNOS-D, VNOS-E)

This series or buffet of instruments has stemmed from the same research group and was meant to be variations and improvements upon the original VNOS-A (Lederman and O'Malley 1990). In particular, each instrument contains open-ended questions that focus on various aspects of NOS with the differences being either the additional context-specific questions in forms B and C or the developmental appropriateness and language of VNOS-D. From a practical standpoint, VNOS-B and VNOS-C are too lengthy to be administered easily during a regular class period. Consequently, VNOS-D and VNOS-E were created with the aid of focus groups of secondary ($n = 10$) and elementary ($n = 10$) teachers and their students. The resulting instruments are easily administered in less than one hour and yield the same results as the longer VNOS-B and VNOS-C. VNOS-E is the most recently developed instrument and it has been designed for very young students (grades K-3). The items can also be used with students that cannot read or write (using a focus group format), and it represents the first measure of NOS designed for such a young audience.

29.4.14 Student Understanding of Science and Scientific Inquiry (SUSSI)

This instrument was developed, as was the case with the majority of standardized, quantitative approaches to assessing NOS, to overcome the time constraints and provide a potential tool for large-scale assessments (Liang et al. 2006). The SUSSI targets tentativeness, observations and inferences, subjectivity, creativity, social and culturally embeddedness, theories and laws, and scientific methods. Extensive evidence for the validity of the SUSSI is provided by its authors. The SUSSI is a combination of four Likert-scaled items followed by an open-response question similar in nature to the VNOS. As such, the SUSSI does not alleviate the time constraints associated with scoring the VNOS or similar instruments yet complicates the development of individual profiles of NOS understandings by introducing issues regarding interpretation of quantitative results and understandings of NOS. The SUSSI does not appear to be capable of providing meaningful inferences at the grain size that their developers intend. Although offering a means to utilize inferential statistics to assess instructional interventions, the guidelines for interpreting these quantitative data, and how the results of the two components of the questionnaire (i.e., Likert and free response) are "married," are not clearly explicated.

29.5 Development of Assessments for NOS

It should go without saying that any assessment instrument for NOS, or anything for that matter, should go through a systematic and extensive process for the establishment of both validity and reliability. Unfortunately, this has not been the case during the more than 50 years of assessment development. The establishment of reliability of any assessment is a fairly straightforward process; however, the establishment of validity is more complicated than most consider it to be. Simply gathering a group of "experts" together to chime in on whether the assessment items measure what the assessment developer intends is not the whole story. Pursuing construct validity in addition to the aforementioned content validity does not complete the picture either. The context and the target audience for the assessment are critical for any assessment. This has been an area in need of much attention. In specific, researchers would be better served by focusing on what is appropriate for K-12 students to know and be able to do, in contrast to arguing about why "lists" of outcomes or outcomes derived from others than scientists are anathema.[4]

29.5.1 Why Can't We Agree to Disagree?

Far too much discussion and journal pages have focused on the lack of consensus on a definition or characterization of NOS. In short, scholars would rather argue about the need to reach consensus before an assessment of NOS can be developed. Why is NOS held to a higher standard than other content in science? How many of the concepts and ideas in science have achieved absolute consensus before we attempt to teach them to students and assess what they have learned? As previously discussed, when one considers the developmental level of the target audience (K-12 students), the aspects of NOS stressed herein are at a level of generality that is not at all contentious. Nevertheless, if one is not willing to let go of the idea that the various aspects of NOS lack consensus and that assessment of NOS is, therefore, problematic, the "problem" is easily handled. One's performance on a NOS assessment can simply be used to construct a profile of what the student knows/believes about scientific knowledge. In terms of the aspects of NOS to be assessed, there is no reason to require that all assessments measure the exact same understandings. If the focus is just upon the assessment of understandings that are considered to be important for scientifically literate individuals to know, then there is no reason to require an agreed upon domain of NOS aspects. Different assessments may stress, to one degree or another, different aspects of NOS. This is no different than assessing students' understandings of the human heart. Different valid and reliable assessments stress and include different structures.

29.5.2 What Is So Bad About Lists?

Many researchers point out that lists are problematic (e.g., Allchin 2012; Matthews 2012), but lists serve an important function as they help provide a concise organization of the often complex ideas and concepts they include. Each item on a list is just a label or symbol for a much more in-depth and detailed elaboration. If "tree" is included in a list, it is simply a referent for all the structures and process that are involved in what is involved in being a "tree." There is the temptation to think that

---

[4] As evidenced in Allchin (2012), Duschl and Grandy (2012), Irzik and Nola (2011), and Wong and Hodson (2009, 2010), among others.

lists are defined as consisting of very short (1–2 word) entries. There are numerous science education reform documents that specify and delineate what students should know and be able to do (i.e., standards). These are also lists of learning outcomes, even though the standards can be as long as a paragraph. The only problem with a list is how it is often used. If students are asked to simply and mindlessly memorize the list, then there is a problem. But, the problem is with pedagogy and not with the list. Irzik and Nola (2011) claim to have produced a depiction of NOS that is much more informative and comprehensive than a list. However, it is no different than a list. Their outcomes are formatted as a matrix as opposed to a linear format, but it is still a list.

Other researchers, most notably Duschl and Grandy (2012), label these "Consensus-based Heuristic Principles" as out-of-date and too general, in contrast to their "scientific practices in domain-specific contexts." Their description of how these lists are used unfortunately not consistent with the way they are intended to guide classroom practice, and it is difficult to image a thoughtful teacher using the aspects of nature of science in the manner assumed by Duschl and Grandy. On the contrary, the researchers criticized by Duschl and Grandy (e.g., Abd-El-Khalick 2012; Lederman et al. 2002; Niaz 2009) strongly advocate NOS as an overarching instructional theme that permeates not simply a single activity but hopefully an entire school science curriculum.

29.5.3 Knowing Versus Doing

There has been a perennial problem with developing assessments of nature of science that is connected to the research literature. All too often assessments include students' performance or inquiry skills/procedures within instruments on NOS. In spite of over a half century of research on NOS, some science education researchers (Allchin 2011, 2012) continue to conceptualize NOS as a skill as opposed to knowledge and espouse the belief that engagement in the practices of science is sufficient for developing understandings of NOS. The view that NOS is a skill, thus conflating it with scientific inquiry, minimizes the importance of understanding both of these constructs and their related characteristics and further obfuscates their associated nuances and interrelationships. Moreover, this view is not consistent with the National Science Education Standards (NRC 1996) and the Benchmarks for Science Literacy (AAAS 1993), which both describe NOS as knowledge, or the NRC's Framework for K-12 Science Education (NRC 2011). While focusing on scientific inquiry, the Benchmarks stress that students should develop understandings about SI beyond the ability to do SI, as this understanding is sine qua non to being scientifically literate, as is the case for understandings of NOS. Unfortunately the Next Generation Science Standards (NGSS) derived from the new framework are not so clear regarding their "vision" for promoting understandings of NOS. Although aspects such as tentativeness, creativity, and subjectivity in science are included in the framework, no clear distinction is made in the NGSS regarding how NOS explicitly fits into the crosscutting themes.

NOS has been a central theme underling science reforms since the 1950s for a good reason: NOS understandings (irrespective of how these are defined at the time of reform) are central to scientific literacy because NOS is metacognitive knowledge about science. Almost every other meaningful theme underlying past reform documents, such as AAAS Benchmark, NRC Standards, and NSTA Framework, appear in the NGSS, but the same cannot be said for NOS. This exclusion is simply not justified, nor is it justifiable. Unfortunately, regarding assessments of NOS, we may indeed be heading forward…into the past.

The conflation described is inherently linked to the assumption that NOS is learned by having students DO science. That is, if students are involved in authentic scientific investigations, they will also come to an understanding about NOS. The empirical research has consistently shown this assumption to be false for the past three decades (Lederman 2007). Clearly, students' ability to DO science is an important educational outcome, but it is not the same as having students reflect on what they have done. In terms of developing assessments of NOS, there must be a more concerted effort to realize that NOS is a cognitive outcome, not a "performance" outcome.

Related to this last issue is that a small minority of individuals (e.g., Sandoval 2005) insist that students' and teachers' understandings of NOS are best assessed through observations of behavior during inquiry activities (i.e., knowledge in practice). The literature clearly documents the discrepancies that often exist between one's beliefs/knowledge and behavior. More concretely, if an individual believes that scientific knowledge is tentative (subject to change) and another individual believes the knowledge to be absolute/static, how would this be evident in their behavior during a laboratory activity? If a student recognizes that scientific knowledge is partly subjective, how would this student behave differently during a laboratory investigation than a student with differing beliefs? This assessment approach adds an unnecessary layer of inference to one's research design. In the end, we must not forget that NOS is a cognitive outcome, not a behavior as some continue to insist (Allchin 2012). Hence, understandings of NOS are not appropriately assessed through observation of behaviors.

29.6 Uses and Interpretations of NOS Assessments

29.6.1 How Should Assessments Be Used?

Over the history of research on NOS, assessments have been primarily used as summative as opposed to formative assessments. There are few studies that make a systematic attempt to use assessment results to guide the development and enactment of instructional strategies related to NOS. The literature is replete with studies indicating that teachers and students do not possess what are considered adequate conceptions of NOS. It is safe to say that the research community can accurately predict what kinds of understandings teachers and students have about

NOS prior to instruction. Hence, the field needs to move forward and focus more attention on specific strategies to improve conceptions and to assess progressions of understandings, over time, from less to more sophisticated understandings. Unfortunately, there remains a consistent perceived need by researchers to develop an assessment instrument that can be administered to the masses in a short period of time and scored just as easily. Within all of us, it appears, is an "inherent" need to make our lives easier. Interviews and open-ended assessments are time-consuming to conduct and score. However, a quick perusal of recent programs from the Annual Meeting of the National Association for Research in Science Teaching indicates that the desire to create an instrument that can be mass administered and scored in a short period of time or allows for efficient scoring of existing ones continues (e.g., Abd-El-Khalick et al. 2012). Again, what is driving this approach is the perceived need for a more efficient summative assessment. Overall, we must not forget the current needs of researchers and the uses of assessments. It does not appear that there is a warranted need or justification for more traditional paper-and-pencil assessments of NOS.

29.6.2 The Devil Is in the Details: Interpreting the Data We Collect

Much has been said in this chapter about the problems with "traditional" paper-and-pencil assessments of an individual's understanding of NOS. One solution has advocated more open-ended questions followed by interviewing of respondents. Naturally, this approach directly contradicts the desire by some researchers to have easily administered and scored assessments. Although not a new insight, Lederman and O'Malley's (1990) investigation clearly highlighted the problem of paper-and-pencil assessments. They documented discrepancies between their own interpretations of students' written responses and the interpretations that surfaced from actual interviews of the same students. This unexpected finding (i.e., the purpose of the interviews was to help validate the paper-and-pencil survey that was used) was quite timely, as it occurred when educational researchers were making a serious shift toward more qualitative, open-ended approaches to assess individuals' understanding of any concept. Although the VNOS-A was created to avoid some of the concerns about "traditional" assessments (as were the subsequent series of VNOS forms), the problem of researchers interpreting responses differently than intended by the respondent remains to this day. The problem exists at all age levels (K-adult), with increasing levels of uncertainty as the age of the respondent decreases. It is for this reason that researchers should not abandon the interviewing of individuals about their written responses. Consequently, a clear issue when it comes to assessment of such complex constructs as NOS is that we get the most valid data possible. Just using paper-and-pencil assessments increases the possibility of a misinterpretation of respondents' understandings. In summary, the issue of using interviews as part of one's assessment of NOS is relevant to the development, use, and interpretation of assessments.

There has been an ongoing debate about the scoring and representation of data on understandings of NOS. In the early history of assessment development (i.e., 1960–1980), there were strong concerns about the bias inherent in each instrument (Cotham and Smith 1981; Lederman 2007). In particular, the value given to particular responses was directly related to whether the respondent held a view consistent with one philosophical view or another. Given the ever changing conceptualization of the construct NOS (Lederman 1992), many were concerned that scoring responses as if they were correct or incorrect was inappropriate. The solution to this problem was fairly easy, as the "scores" could simply be used to construct a profile of what an individual believes as opposed to a measure of whether they had an informed view of NOS. This approach seems valid, but it ignores the reality that educational systems have goals that specify what we want students to know. Even though conceptions of NOS may change (as is true with any science knowledge), at any point in time, we have an understanding we want our students to develop. In short there are "correct" and "incorrect" answers. Some profiles are more acceptable than others.

Perhaps a more important problem with interpretation is whether it is more accurate to develop numerical scores to represent what an individual knows or whether to develop profiles and then categorize the profiles as informed, naïve, etc. Numerical values allows for easy statistical analysis, but as with any numerical value assigned to a complex construct, much information is lost if we simply have a number. Consequently, it seems wise to have rich descriptions of what individuals know and how this knowledge becomes more or less sophisticated as opposed to simply providing a numerical value.

29.7 What a Long and Tortured Journey This Has Been

Research on students' and teachers' understandings of NOS has been pursued in earnest since 1957 (Mead and Métraux 1957). Naturally, an assortment of assessments for NOS has been developed to support this long line of research. The first assessment was rather informal with the most formalized, even standardized, assessment (i.e., TOUS) appearing in 1961 (Cooley and Klopfer 1961). This review, and others, clearly has shown that assessments of NOS began as more traditional convergent paper-and-pencil tests and then slowly transitioned to the use of more open-ended questionnaires that provide respondents more freedom to express their views. Finally, the past two decades have been characterized by open-ended questionnaires followed by interviews. The interviews, it is believed, help to clarify respondents' written answers as well as avoid some of the problems associated with researchers' misinterpretations of respondents' written answers. Although this chapter is focused on assessment, the discussion of assessment is inextricably connected to the scholarship on NOS, its conceptualization, instructional approaches, etc. As such and as long as this assessment journey has been, we are at a crossroad that threatens to transform assessments into tools that are irrelevant to the question at hand, namely, measuring K-12 students' and teachers' understandings of NOS.

Only a summary of the most critical issues facing NOS assessments discussed in this chapter will be highlighted here. Because of the inextricable link between assessments and the body of research on NOS understandings, these same issues are relevant to the direction of future research as well.

29.7.1 NOS Is a Cognitive Outcome, Not a Behavior

NOS is often confused with, or combined with, scientific inquiry (SI). NOS refers to characteristics of scientific knowledge and SI refers to what scientists do to develop scientific knowledge. Both are clearly important, but assessments of knowledge are different than assessments of performance behaviors, and we know from volumes of research that it is quite difficult to infer knowledge from behavior. Some of the current efforts to assess NOS knowledge based on students' performance of laboratory activities and participation in argumentation about ideas are a step backwards, and they ignore the results of over 50 years of empirical research. NOS is a complex construct that does not lend itself to easily administered and scored assessments.

Although this has been recognized by the trends we have seen over the years in how NOS is assessed, there is a continued desire to develop assessments that are convergent, easily administered to large samples, and easily scored. Moving in this direction is another step backwards. Is the goal expediency or accurately assessing what students and teachers know?

29.7.2 Do Not Lose Sight of the Target Audience, K-12 Students and Teachers

There is a continuing debate about "whose NOS we are measuring." This discussion began with Alters (1997), and it continues with the recent writings of Wong and Hodson (2009, 2010). In the end, the argument always rests on the voice of scientists, and how what they think is important regarding NOS is not being heard or used. Actually, the international reform documents specifying outcomes regarding NOS have had strong input from the scientific community. More importantly, the audience for which these outcomes have been specified is the consumers of science, not scientists. We need to continually remind ourselves for whom the NOS outcomes have been written. What has been specified is not directed at scientists, historians, or philosophers. The knowledge specified is what is considered important for the attainment of scientific literacy by the general citizenry. To dissect the construct of NOS down to its very esoteric levels reveals a construct that is far too abstract for the general public. This really is no different than why we do not expect all high school graduates to understand the most in-depth aspects of the dark reactions of photosynthesis.

There is little doubt that the arguments described in this chapter will continue. At times it appears that our goal in academia is more about the debate than the purpose we are trying to accomplish. It is not all productive to argue about what should be included under the rubric of SI and NOS. It makes little sense to argue about whether lists are good or bad. The focus of our attention should always be on what we consider important for students and teachers and the general public to know, not the label we put on the knowledge. And when we consider the knowledge to be known and assessed, let us not forget the audience, their emotional and cognitive developmental levels, and their needs as citizens.

Norman G. Lederman is chair and professor of mathematics and science education at the Illinois Institute of Technology. Dr. Lederman received his Ph.D. in science education and he possesses M.S. degrees in both biology and secondary education. Prior to his 20+ years in science teacher education, Dr. Lederman was a high school teacher of biology and chemistry for 10 years. Dr. Lederman is internationally known for his research and scholarship on the development of students' and teachers' conceptions of nature of science and scientific inquiry. He has been author or editor of 10 books, written 15 book chapters, published over 200 articles in professional journals, and made over 500 presentations at professional conferences around the world. He is the coeditor of the recently published *Handbook of Research on Science Education* (Routledge 2014).

Dr. Lederman is a former president of the National Association for Research in Science Teaching (NARST) and the Association for the Education of Teachers in Science (AETS). He has also served as director of teacher education for the National

Science Teachers Association (NSTA). He has received the Illinois Outstanding Biology from the National Association of Biology Teachers and the Outstanding Mentor Award from AETS. Most recently, he has been named a fellow of the American Association for the Advancement of Science and the American Educational Research Association and has received the Distinguished Career Award from the National Association for Research in Science Teaching.

Stephen A. Bartos is an associate professor in science education at Middle Tennessee State University, Murfreesboro, Tennessee. He is a certified teacher in mathematics and physics, with over a decade of classroom experience, and has worked extensively with preservice mathematics and science teachers. His research interests include improving students' and teachers' conceptions of nature of science and scientific inquiry and how teachers translate and communicate their subject matter during instruction (pedagogical content knowledge). Among his recent presentations and publications is a paper about using socio-scientific issues arising in genetics (Lederman N.G., Antink, A., & Bartos, S., 2012. Nature of Science, Scientific Inquiry, and Socio-Scientific Issues Arising From Genetics: A Pathway to Developing a Scientifically Literate Citizenry. *Science & Education*, online first, DOI 10.1007/s11191-012-9503-3) and how teachers include NOS in their classroom practice (Lederman, J.S., Bartos, S.A, Lederman, N.G., Meyer, D.Z., Antink-Meyer, A., & Holliday G., 2012. Interaction of knowledge and pedagogical decisions in teaching NOS. Paper presented at the NARST Annual International Conference, Indianapolis, IN.)

Judith S. Lederman is an associate professor in science education and director of teacher education in the Department of Mathematics and Science Education at Illinois Institute of Technology, Chicago, Illinois. Dr. Lederman received her Ph.D. in science education from Curtin University in Perth, Australia, and an M.S. degree in natural sciences from Worchester Polytechnic Institute. Her experience with informal education includes her work as curator of education at the Museum of Natural History and Planetarium in Providence, RI. Prior to her work in science teacher education, Dr. Lederman taught secondary and middle level physics and biology, as well as bilingual elementary science.

Dr. Lederman is known nationally and internationally for her work on the teaching and learning of scientific inquiry and nature of science in both formal and informal settings. She has over 600 presentations/publications on scientific literacy. She has authored an elementary science education methods textbook as well as an elementary (K-5) science textbook series for National Geographic Press. In 2008, Dr. Lederman was awarded a Fulbright Fellowship to work with South African university faculty, museum educators, and science teachers to develop research and curriculum that connects informal education to K-12 science classrooms. She has served on the Board of Directors of the National Science Teachers Association (NSTA) and is past president of the Council for Elementary Science International (CESI). She is currently chair of the NSTA International Advisory Board and the NSTA Task Force on International Outreach and the NARST Outstanding Dissertation Award. Her honors include Rhode Island State Teacher of the Year and the Milken Foundation National Educators Award.

Chapter 30
New Directions for Nature of Science Research

Gürol Irzik and Robert Nola

30.1 Introduction

Calls for the inclusion of the nature of science (NOS for short) into science education have a long history. A number of distinguished scientists, philosophers and education theorists such as John Dewey, James Conant, Gerald Holton, Leo Klopfer, Joseph Schwab, James Robinson, James Rutherford, Michael Martin, Richard Duschl, Derek Hodson, Norman Lederman, Michael Matthews and Norman McComas throughout the twentieth century emphasised the importance of teaching science's conceptual structure and its epistemological aspects as part of science education (Matthews 1998a; McComas et al. 1998). Today, science education curriculum reform documents in many parts of the world underline that an important objective of science education is the learning of not only the content of science but its nature.[1] The rationale is that scientific literacy requires an understanding of the nature of science, which in turn facilitates students' learning of the content of science, helps them grasp what sort of a human enterprise science is, helps them appreciate its value in today's world and enhances their democratic citizenship, that is, their ability to make informed decisions, as future citizens, about a number of controversial issues such as global warming, how to dispose nuclear waste, genetically modified food and the teaching of

intelligent design in schools.[2] Allchin expressed this idea succinctly: 'Students should develop an understanding of how science works *with the goal of interpreting the reliability of scientific claims in personal and public decision making*' (Allchin 2011, p. 521; emphasis original).

There is a voluminous literature on what NOS is, how to teach it and what views of NOS students and teachers hold. The aim of this chapter is not to review this literature. The interested reader can refer to other chapters of this handbook and earlier useful surveys (Abd-El-Khalick and Lederman 2000; Deng 2011 and others; Lederman 2007). Teachers' and students' views of NOS are also beyond the scope of this chapter, in which we focus exclusively on what NOS is. In the next section we summarise the consensus NOS theorising in science education has produced. Making use of the existing consensus, we then provide, in Sect. 30.3, a structural description of all the major aspects of science in terms of eight categories. Applying the idea of family resemblance to these categories, we obtain what we call 'the family resemblance approach'. We articulate it in some detail in Sect. 30.5. We believe that the family resemblance approach provides a systematic and unifying account of NOS. We discuss this and other virtues of the family resemblance approach in Sect. 30.6. We end the chapter by making some suggestions about how to use this approach in the classroom.

We would like to emphasise that the present chapter does not deal with empirical matters such as what teachers and pupils might understand of NOS. Rather, our task is one within the theory of NOS: it is to provide a new way of thinking about what is meant by the 'nature of science'. Nevertheless, we do hope that theorists of science education and science teachers familiar with NOS discussions will find our approach not only theoretically illuminating but also pedagogically useful.

30.2 Consensus on NOS

NOS research in the last decade or so has revealed a significant degree of consensus amongst the members of the science education community regarding what NOS is and which aspects of it should be taught in schools at the precollege level. This consensus can be highlighted as follows.

Based on considerations of accessibility to students and usefulness for citizens, Lederman and his collaborators specified the following characteristics of NOS:

- Scientific knowledge is empirical (relies on observations and experiments).
- Is reliable but fallible/tentative (i.e. subject to change and thus never absolute or certain).
- Is partly the product of human imagination and creativity.

---

[2] This point is commonly made, for example, in Driver et al. (1996), McComas et al. (1998), Osborne 2007, and Rutherford and Ahlgren (1990).

- Is theory-laden and subjective (i.e. influenced by scientists' background beliefs, experiences and biases).
- Is socially and culturally embedded (i.e. influenced by social and cultural context).[3]

They also emphasised that students should be familiar with concepts fundamental to an understanding of NOS such as observation, inference, experiment, law and theory and be also aware of the distinctions between observing and inferring and between laws and theories and of the fact that there is no single scientific method that invariably produces infallible knowledge. Others added that science is theoretical and explanatory; scientific claims are testable and scientific tests are repeatable; science is self-correcting and aims at achieving values such as high explanatory and predictive power, fecundity (fruitfulness), parsimony (simplicity) and logical coherence (consistency) (Cobern and Loving 2001; Smith and Scharmann 1999; Zeidler and others 2002).

A number of researchers propose a similar list of characteristics by studying the international science education standards documents. These documents also indicate substantial consensus on two further matters: the ethical dimension of science (e.g. scientists make ethical decisions, must be open to new ideas, report their findings truthfully, clearly and openly) and the way in which science and technology interact with and influence one another (McComas et al. 1998; McComas and Olson 1998). Based on a Delphi study of an expert group consisting of scientists, science educators and science communicators, philosophers, historians and sociologists of science, Osborne and others (2003) found broad agreement on the following eight themes:

- Scientific method (including the idea that continual questioning and experimental testing of scientific claims is central to scientific research)
- Analysis and interpretation of data (the idea that data does not speak by itself, but can be interpreted in various ways)
- (Un)certainty of science (i.e. scientific knowledge is provisional)
- Hypothesis and prediction (the idea that formulating hypotheses and drawing predictions from them in order to test them is essential to science)
- Creativity in science (the idea that since scientific research requires much creativity, students should be encouraged to create models to explain phenomena)
- Diversity of scientific thinking (the idea that science employs different methods to solve the same problem)
- The historical development of scientific knowledge (i.e. scientific knowledge develops historically and is affected by societal demands and expectations)
- The role of cooperation and collaboration in the production of scientific knowledge (i.e. science is a collaborative and cooperative activity, as exemplified by teamwork and the mechanism of peer review).

---

[3] See Abd-El-Khalick (2004), Abd-El-Khalick and Lederman (2000), Bell (2004), Khishfe and Lederman (2006), Lederman (2004, 2007). Note that all of these characteristics pertain to scientific knowledge. For that reason, Lederman suggested replacing the phrase 'nature of science' with 'nature of scientific knowledge' in his recent writings (Lederman 2007).

Wong and Hodson (2009, 2010) came up with very similar themes (but with slightly different emphasis) on the basis of in-depth interviews with well-established scientists from different parts of the world who worked in different fields:

- Scientific method (different disciplines employ different methods of investigation)
- Creativity in science (creative imagination plays an important role in every stage of scientific inquiry from data collection to theory construction, and absolute objectivity in the sense of freeing oneself from biases completely is impossible)
- The importance of theory in scientific inquiry (scientific activity is highly theoretical)
- Theory dependence of observation (scientific data is theory laden and can be interpreted in various ways)
- Tentative nature of scientific knowledge (science does not yield certainty)
- The impact of cultural, social, political, economic, ethical and personal factors on science (such factors greatly influence the direction of scientific research and development and may cause biased results and misconduct) and the importance of cooperation, peer review and shared norms (such as intellectual honesty and open mindedness) in knowledge production

The overlap between the findings of these studies indicates a substantial consensus regarding NOS amongst education theorists. However, there has been some debate as to whether processes of inquiry (such as posing questions, collecting data, formulating hypotheses, designing experiments to test them) should be included in NOS. While Lederman (2007) suggested leaving them out, other science education theorists disagreed arguing that they constitute an inseparable part of NOS (Duschl and Osborne 2002; Grandy and Duschl 2007). Indeed, research summarised in the above two paragraphs do cite processes of inquiry as an important component of NOS.

Of course, much depends on how the various aspects and themes of NOS are spelled out. Osborne and his collaborators warn that various characteristics of NOS should not be taken as discrete entities, so they emphasise their interrelatedness (Osborne and others 2001, 2003, p. 711). In a similar vein, others note that blanket generalisations about NOS introduced out of context do not provide a sophisticated understanding of NOS (Elby and Hammer 2001; Matthews 2011); rather, the items within NOS ought to be elucidated in relation to one another in 'authentic contexts'. Accordingly, many science educators have called for 'an authentic view' of science, which aims to contextualise science and focuses on science-in-the-making by drawing either on science-technology-society (STS) studies or on the interviews with scientists themselves about their day-to-day activities; this underlines the heterogeneity of scientific practices across scientific disciplines through historical and contemporary case studies.[4]

---

[4] See Ford and Wargo (2007), McGinn and Roth (1999), Rudolph (2000), Samarapungavan et al. (2006), Wong and Hodson (2009, 2010), and Wong et al. (2009).

A number of science education theorists also urged that issues arising from science-technology-society interactions, the social norms of science and funding and fraud within science all be allotted more space in discussions of NOS; a focus on these is especially pertinent when educating citizens who will often face making hard decisions regarding socio-scientific problems in today's democracies. These topics have been raised earlier in some detail (Aikenhead 1985a, b; Kolsto 2001; Zeidler and others 2002) and are receiving increasing attention in recent years, in line with calls for an authentic view of science.[5]

30.3 NOS Categories: A Structural Description

The consensus on NOS highlighted above reveals that science is a multifaceted enterprise that involves (a) processes of inquiry, (b) scientific knowledge with special characteristics, (c) methods, aims and values and (d) social, historical and ethical aspects. Indeed, science is many things all at once: it is an investigative activity, a vocation, a culture and an enterprise with an economic dimension and accordingly has many features (cognitive, social, cultural, political, ethical and commercial) (Weinstein 2008; Matthews 2011). What is needed then is a systematic and unifying perspective that captures not just this or that aspect of science but the 'whole science' (Allchin 2011). This is no easy task, and there is certainly more than one way of carrying it out. Our suggestion is to begin with a broad distinction between *science as a cognitive-epistemic system of thought and practice* on the one hand and s*cience as a social-institutional system* on the other. This distinction is actually implicit in the aspects of NOS expressed (a) through (d) above: science as a cognitive-epistemic system incorporates (a), (b) and (c), while science as a social-institutional system captures (d). We hasten to add that we intend this as an analytical distinction to achieve conceptual clarity, not as a categorical separation that divides one from the other. In practice, the two constantly interact with each other in myriad ways, as we will see.

30.3.1 Science as a Cognitive-Epistemic System

We spell out science as a cognitive-epistemic system in terms of four categories obtained by slightly modifying (a)–(c): processes of inquiry, aims and values, methods and methodological rules and scientific knowledge. We explain these categories briefly below.[6]

---

[5] See Sadler (2011), Weinstein (2008), Wong and Hodson (2010), Zemplen (2009); see also the special issue of the journal *Science & Education* vol. 17, nos. 8–9, 2008.

[6] For a more detailed discussion of these, see Nola and Irzik (2005, Chaps. 2, 4, 6, 7, 8, 9, and 10).

30.3.1.1 Processes of Inquiry

This includes posing questions (problems), making observations, collecting and classifying data, designing experiments, formulating hypotheses, constructing theories and models and comparing alternative theories and models (Grandy and Duschl 2007).

30.3.1.2 Aims and Values

This will include items such as *prediction*, *explanation*, *consistency*, *simplicity* and *fruitfulness*; these are amongst the well-known aims of science recognised in the science education literature, as we saw in the previous section. With regard to prediction and explanation, we would like to make two points, which the science education literature tends to neglect. First, scientists value *novel* predictions more than other kinds of predictions because novel predictions of a theory give greater support to it than those that are not (Nola and Irzık 2005, pp. 245–247). (A prediction is novel if it is a prediction of a phenomenon that was unknown to the scientists at the time of the prediction.) Second, although there are different kinds of explanations and therefore different models of explanations, all scientific explanations are naturalistic in the sense that natural phenomena are explained in terms of other natural phenomena, without appealing to any supernatural or occult powers and entities (Lindberg 1992, Chap. 1; Pennock 2011).[7]

Other aims of science include the following: *viability* (von Glasersfeld 1989), *high confirmation* (Hempel 1965, Part I), *testability* and *truth* or at least *closeness to truth* (Popper 1963, 1975) and *empirical adequacy* (van Fraassen 1980). Aims of science are sometimes called (cognitive-epistemic) values since scientists value them highly in the sense that they desire their theories and models to realise them (Kuhn 1977). Values in science can also function as shared criteria for comparing theories and be expressed as methodological rules. For example, we can say that given two rival theories, other things being equal, the theory that has more explanatory power is better than the one that has less explanatory power. Expressed as a methodological rule, it becomes, given two rival theories, other things being equal, *choose*, or *prefer*, the theory that is more explanatory. Similar rules can be derived from other values. These enable scientists to compare rival theories about the same domain of phenomena rationally and objectively (Kuhn 1977).

30.3.1.3 Methods and Methodological Rules

Science does not achieve its various aims randomly, but employs a number of methods and methodological rules. This point emerges clearly in many studies on NOS. Historically, there have been proposals about scientific method from Aristotle,

---

[7] See Godfrey-Smith (2003) for a succinct summary of different models of explanations in science.

Bacon, Galileo, Newton to Whewell, Mill and Peirce, not to mention the many theories of method proposed in the twentieth century by philosophers, scientists and statisticians. For many of them, deductive, inductive and abductive reasoning form an important part of any kind of scientific method. Additional methods for testing hypotheses include a variety of inductive and statistical methods along with the hypothetico-deductive method (Nola and Sankey 2007; Nola and Irzık 2005, Chaps. 7, 8, and 9). The idea of scientific methodology also includes methodological rules; these have not received sufficient attention in the science education literature. Methodological rules are discussed at length by a number of philosophers of science such as Popper (1959) and Laudan (1996, Chap. 7). Here are some of them:

- Construct hypotheses/theories/models that are highly testable.
- Avoid making ad hoc revisions to theories.
- Other things being equal, choose the theory that is more explanatory.
- Reject inconsistent theories.
- Other things being equal, accept simple theories and reject more complex ones.
- Accept a theory only if it can explain all the successes of its predecessors.
- Use controlled experiments in testing casual hypotheses.
- In conducting experiments on human subjects, always use blinded procedures.

Two general points about scientific methods and methodological rules are in order. First, although they certainly capture something deep about the nature of methods employed in science, it should not be forgotten that they are highly idealised, rational constructions. As such, they do not faithfully mirror what scientists do in their day-to-day activities; nor can they always dictate to them what to do at every step of their inquiry. Nevertheless, they can often tell them when their moves are, or are not, rational and do explain (at least partially) the reliability of scientific knowledge. Second, we presented the above rules of method as if they are categorical imperatives. This needs to be qualified in two ways. The first is that some of the rules can, in certain circumstances, be abandoned. Spelling out the conditions in some antecedent clause in which the rules can be given up is not an easy matter to do; so such rules are best understand to be defeasible in unspecified circumstances. The second is that such categorical rules ought to be expressed as hypothetical imperatives which say: rule R ought to be followed if some aim or value V will be (reliably) achieved (see Laudan 1996, Chap. 7). Often reference to the value is omitted or the rule is expressed elliptically. For example, the rule about ad hocness has an implicit value or aim of high testability. So, more explicitly it would look like: ‘If you aim for high testability, avoid making *ad hoc* revisions to theories’. When rules are understood in this way, then the link between the methodological rules of category 3 and the aims of category 2 becomes clearly visible.

30.3.1.4 Scientific Knowledge

When processes of inquiry achieve their aims using the aforementioned methods and methodological rules, these processes culminate in some ‘product’, viz.

scientific knowledge. Such knowledge ‘end products’ are embodied in laws, theories and models as well as collections of observational reports and experimental data. Scientific knowledge is the most widely discussed category of NOS, as we have seen in the previous section.

30.3.2 Science as a Social-Institutional System

Science as a social-institutional system is investigated less than science as a cognitive-epistemic system, and for that reason it is harder to categorise. We propose to study it in terms of the following categories: professional activities, the system of knowledge certification and dissemination, scientific ethos and finally social values. We discuss them in some detail below, taking into account the findings of the NOS research on this topic indicated in Sect. 30.2.

As decades of science-technology-society studies have shown, science not only is a cognitive system but is, at the same time, both a cooperative and a competitive community practice that has its own ethos (i.e. social and ethical norms) and its own system of knowledge certification and dissemination. It is a constantly evolving social enterprise with intricate relationships with technology and with the rest of the society, which both influences and is influenced by it. Scientists form a tight community and are engaged in a number of professional activities, interacting both with each other and the larger public. In short, science is a historical, dynamic, social institution embedded within the larger society. Categories of science as social-institutional system can be described as follows.

30.3.2.1 Professional Activities

Scientists do not just carry out scientific research. Qua being scientists, they also perform a variety of professional activities such as attending academic meetings, presenting their findings there, publishing them, reviewing manuscripts and grant proposals, writing research projects and seeking funds for them, doing consulting work for both public and private bodies and informing the public about matters of general interest. In this way, they perform various cognitive-epistemic and social functions such as certifying knowledge and serving certain social goals. Whether they are engaged in cognitive-epistemic or professional activities, they are expected to conform to a number of social and ethical norms. We discuss these below.

30.3.2.2 The Scientific Ethos

Part of the meaning of the claim that science is a social institution is that it has its own social (institutional) and ethical norms, which refer to certain attitudes scientists are expected to adopt and display in their interactions with their fellow scientists as well as in carrying out their scientific activities. We call them 'the scientific ethos' (or, equivalently, 'the ethos of science') for convenience, a phrase coined by the famous sociologist of science Robert Merton. However, as we will see below, the scientific ethos as we understand it is not confined to what is known as the 'Mertonian norms' in the literature. Merton was one of the first to study the institutional norms of science in the 1930s and formulated some of them as follows, based on his extensive interviews with scientists (Merton 1973, Chap. 13):

- *Universalism*: Science is universal in the sense that scientific claims are evaluated according to pre-established objective, rational criteria so that characteristics of scientists such as ethnic origin, nationality, religion, class and gender are irrelevant when it comes to evaluation.
- *Organised scepticism*: Scientists subject every claim to logical and empirical scrutiny on the basis of clearly specified procedures that involve scientific reasoning, testability and methodology and suspend judgement until all the relevant facts are in and bow to no authority except that of critical argumentation.
- *Disinterestedness*: Scientists should evaluate and report their findings independently of whether they serve their personal interests, ideologies and the like. The norm of disinterestedness has the function of preventing scientists from hiding or fudging the results of their inquiries even when they go against their personal biases, interests and favoured ideology.
- *Communalism* refers to the common ownership of scientific discovery or knowledge. The rationale is that science is a cooperative endeavour: new scientific knowledge always builds upon old knowledge and that scientific discoveries owe much to open and free discussion and exchange of ideas, information, techniques and even material (such as proteins).

Although Merton arrived at these norms through an empirical study, we should not lose sight of the fact that they can be taken as both descriptive and prescriptive *qua* being norms. In other words, they tell us how scientists ought to behave, not just how they do behave when they do science. Their normative nature and power is evident from the fact that scientists often face the sanctions of the scientific community when they violate them.[8]

In time, the scientific community has become increasingly self-conscious of the norms of conduct in science, as a result of which they have proliferated and been codified under the banner 'ethical codes of conduct'. There is now a whole subfield called the 'ethics of science' devoted to this topic. Amongst other things, these norms include the following (Resnik 2007, Chap. 2):

- Intellectual honesty (or integrity): Scientists should not fabricate, distort or suppress data and should not plagiarise. They should bow to no authority except that of evidence and critical argumentation.

---

[8] STS scholars are generally critical of Mertonian norms and claim that there is a counter-norm for every Mertonian norm, with the implication that Mertonian norms do not guide scientific practice and therefore are simply functionless. See, for example, Sismondo (2004, Chap. 3) and the literature cited therein. However, there are also excellent critiques of these critiques such as Radder (2010).

- Respect for research subjects: Scientists should treat human and animal subjects with respect and dignity. This involves getting the informed consent of human subjects and not inflicting unnecessary pain on animal subjects and the like.
- Respect the environment: Avoid causing harm to the environment.
- Freedom: Scientists should be free to pursue any research, subject to certain constraints (e.g. as implied by the previous two ethical principles).
- Openness: Scientists should be open to free and critical discussion and to share ideas, data, techniques and even materials (such as proteins). They should be willing to change their opinion when presented with good reasons.

Today many scientific institutions (universities, academies, funding organisations, etc.) have such ethical codes which they announce on their websites.

None of this is meant to suggest that there is no misconduct, fraud, data suppression or misrepresentation and the like, or fierce competition, especially for scarce resources such as funding, which sometimes results in secrecy (the opposite of openness) in science. Scientists are not saints. Nevertheless, when they violate the norms of science, they often face sanctions. Science has developed a social mechanism of certification and dissemination to eliminate or at least reduce misconduct and promote collaboration amongst scientists.

30.3.2.3 The Social Certification and Dissemination of Scientific Knowledge

When a scientist or a team of scientists completes their research, they are hardly finished with their work. Their findings need to be published; this requires a process of peer review. When published, they become public and are now open to the critical scrutiny of the entire community of relevant experts. Only when they prove their mettle during this entire ordeal are their findings accepted into the corpus of scientific knowledge and can, amongst other things, be taught at schools. This is in a nutshell the *social* system of certification and dissemination of scientific knowledge, which involves the collective and collaborative efforts of the scientific community (Kitcher 2011, Chap. 4). This system functions as an effective *social quality control* over and above the *epistemic control* mechanisms that include testing, evidential relations and methodological considerations described in Sect. 30.3.1. They jointly work to help reduce the possibility of error and misconduct.

30.3.2.4 Social Values of Science

Science embodies not only cognitive-epistemic values but also social ones. Some of the most important social values are freedom, respect for the environment and social utility broadly understood to refer to improving people's health and quality of life as well as to contributing to economic development. Without sufficient freedom of research, scientific development would be stifled. Respect for the environment involves both the negative duty of not damaging it and the positive duty of protecting it by saving biodiversity and reducing carbon emissions that cause climate change. As a species we are unlikely to survive if we do not respect the environment. Science that does not contribute to better lives for people would not enjoy their support; the social legitimation of science today depends crucially on its social utility. Social utility then serves as an important social goal of science.

This completes our description of the eight categories of science which can be tabulated as below.

Science							
Science as a cognitive-epistemic system				Science as a social system			
1	2	3	4	5	6	7	8
Processes of inquiry	Aims and values	Methods and methodological rules	Scientific knowledge	Professional activities	Scientific ethos	Social certification and dissemination of scientific knowledge	Social values

Although we believe that the categories that make up science as a cognitive-epistemic system are pretty exhaustive, we admit the possibility that other categories might perhaps be added or new categories might emerge as science develops. We do not think, however, that categories of science as a social system is exhaustive in any way. Nor do we claim that this is the only or the best way of describing science as a social system. Others may carve it out differently. Nevertheless, we do believe that it captures an important part of science as social practice. Similarly, we do not pretend to have listed all the items that fall under each of the eight categories above. In fact, we consider them open-ended; that is, the characteristics of science that fall under each category are not fixed and develop historically. Overall, we believe that the eight categories capture the structural features of NOS in a systematic and comprehensive way.

30.4 Clarifying the Meaning of 'Nature of Science' and the Idea of Family Resemblance

Although we suggested that the above eight categories characterise nature *of science*, we have not explored the meaning of term 'nature' that occurs in that phrase. What do we mean by '*nature* of science'? To our knowledge, this is a question that is hardly raised in the science education literature. Here we briefly mention three conceptions of what such a nature might be.

First, the *nature* of science could be taken to be the specification of a natural kind of thing which has an essence, where an essence is a set of properties which a thing *must* have and without which it is *not possible* for that thing exist and to be that *kind* of thing. Triangles have an essence in this sense, but it is very doubtful that science has an essence of this sort. We can agree with Rorty's negative answer to the title of his paper 'Is natural science a natural kind?' (Rorty 1991, pp. 46–62).

A second suggestion about 'nature' is to claim that it is a (small) set of necessary and sufficient properties that something should possess if it is to be deemed science. Here strong modal claims found in the essentialist approach mentioned above are downplayed or eschewed in favour of the mere possession of the set of features shared by all sciences and only by them. However, so far all attempts to define science in terms of necessary and sufficient conditions have failed. Some have restricted their approach to the nature of science by focusing narrowly on just the fourth category of science, viz. scientific knowledge, and then have attempted to define what is to count as science as what is verifiable (some positivists) or what is falsifiable (Popper) and so on.[9] This is not the approach we advocate here in characterising science.

A third approach might be simply to list a number of items falling under the concept of science without pretending to give a set of necessary and sufficient properties or to specify essence for science. Thus one common approach to the *nature* of science in science education lists some salient features of science as in Sect. 30.2. This is also the approach we have adopted by setting out the eight categories of science and listing the items that fall under each. However, there is a problem to be tackled: not all sciences share these features or items all at once. Indeed, a number of science education theorists have drawn attention to important differences amongst scientific disciplines (Samarapungavan et al. 2006; Wong and Hodson 2009). If some sciences lack some of the features others share, what justifies the label 'science' for them? Merely providing a list of preferred items is powerless to answer this question.

Luckily, there is a satisfactory answer within philosophy that invites one to have a quite different approach to what counts as a 'nature' in talk of 'NOS'. In fact it takes us well away from the three ways of understanding 'nature' listed above in using the important idea of family resemblance (Eflin and others 1999; Hacking 1996; Dupre 1993). In a nutshell, the nature of science consists of a set of family resemblances amongst the items that fall under the eight categories of science. In an earlier article, we articulated this approach in some detail for the purposes of science education (Irzik and Nola 2011). In this chapter, we develop it further.

The idea of family resemblance was developed by the philosopher Ludwig Wittgenstein in recognition of the fact that not all terms can be defined in terms of necessary and sufficient conditions or by specifying essences or natures (Wittgenstein 1958, Sects. 66–71). To see this, compare 'triangle' with 'game'. The former can be defined explicitly as a closed plane figure with three straight sides. This definition not only gives six characteristics that specify the necessary and sufficient conditions for being a triangle but also determines the 'essence' of being a triangle or the analytic meaning of the term 'triangle'. In this definition, those properties that are shared by all triangles and only by triangles are specified explicitly. By contrast,

---

[9] See some of the following who may be, in addition, critical of the idea of the demarcation of science from non-science but whose focus in so doing is just upon the fourth category, viz. what is to count as a scientific statement: (Alters 1997; Hacking 1996; Laudan et al. 1986; Stanley and Brickhouse 2001; Ziman 2000).

Wittgenstein argued, the term ‘game’ cannot be defined in this way. Any attempt to define the term ‘game’ must include games as different as ball games, stick games, card games, children’s games that do not involve balls, sticks or cards (such as tag or hide-and-seek), solo games (hopscotch) and mind games. Unlike the term ‘triangle’, there is no fixed set of necessary and sufficient conditions which determine the meaning of ‘game’ and thus no set of properties that cover all games and at the same time admit nothing which is not a game.[10] Nevertheless, Wittgenstein argued, all games form ‘a family resemblance’, forming a complicated network of similarities, overlapping and criss-crossing. It is these similarities that justify the use of the term ‘game’ to all those diverse activities from baseball to hopscotch.

Consider a set of four characteristics {A, B, C, D}. Then one could imagine four individual items which share any three of these characteristics taken together such as (A&B&C) or (B&C&D) or (A&B&D) or (A&C&D); that is, the various family resemblances are represented as four disjuncts of conjunctions of any three properties chosen from the original set of characteristics. This example of a polythetic model of family resemblances can be generalised as follows. Take any set S of n characteristics; then any individual is a member of the family if and only if it has all of the n characteristics of S, or any (n-1) conjunction of characteristics of S, or any (n-2) conjunction of characteristics of S, or any (n-3) conjunction of characteristics of S and so on. How large n may be and how small (n-x) may be is something that can be left open as befits the idea of a family resemblance which does not wish to impose arbitrary limits and leaves this to a ‘case by case’ investigation. In what follows we will employ this polythetic version of family resemblance (in a slightly modified form) in developing our conception of science.

Consider the following limiting case. Suppose an example like that above but in which there is a fifth characteristic E which is common to all the disjunctions of conjunctions as in the following: (A&B&C&E) or (B&C&D&E) or (A&B&D&E) or (A&C&D&E). Would this be a violation of the kind of family resemblance definition that Wittgenstein intended? Not necessarily. We might say as an example of characteristic E in the case of games that games are at least activities (mental or physical). Nevertheless, being an activity is hardly definitional of games, nor does it specify a criterion of demarcation; there are many activities that are not games, such as working or catching a bus.

We will see in the case of science that there are characteristics common to all sciences, but are such that they cannot be definitional of it. They cannot be used for demarcating science from other human endeavours either. An example would be observing. We cannot think of a scientific discipline which does not involve making or relying on observations at some point. But then not everything that involves observing is a science (such as being observant when crossing a road in heavy traffic). Similarly, we cannot think of a science that does not involve making some

---

[10] John Searle has disputed this example, arguing that ‘game’ can be defined as follows: a series of attempts to overcome certain obstacles that have been created for the purpose of overcoming them (Searle 1995, 103). However this dispute is resolved, there might still be other cases where the family resemblance idea gets some traction, as we think it does in the case of the term ‘science’.

kinds of inference at some point; if it did not, it would not get beyond naive data collecting. Nevertheless, as before, inferring, though common to the sciences, is not exclusive to them. Judges in a court or speculators on the stock market make inferences as well, but they are not doing science.

In the light of these points we can say that there are a few core characteristics that all sciences share (collecting data and making inferences, for instance). Nevertheless, even though they are generic, they are not sufficient either to define science or to demarcate it from other human endeavours. It is the other characteristics that accompany observing and inferring that make an important contribution to the family-forming characteristics that characterise scientific disciplines. It is this modified version of polythetic family resemblance that we will employ in what follows.

30.5 The Family Resemblance Approach to Science

There are many items called ‘science’, ranging from archaeology to zoology. (Here we will exclude the special case of mathematics from our discussion because of its non-empirical character.) So what do these many things called ‘science’ have in common? The idea of family resemblance will tell us that this is a wrong question to ask. What we need to do is to investigate the ways in which each of the sciences are similar or dissimilar, thereby building up from scratch polythetic sets of characteristics for each scientific discipline. The science categories we have introduced in Sect. 30.3 will come in handy for this task.

Begin with the items data collecting, making inferences and experimenting that fall under the category ‘processes of inquiry’. Although all disciplines employ the first two and most (such as particle physics and chemistry) are experimental, there are a few disciplines that are not. Astronomy and earthquake science are cases in point since experiments are simply impossible in these fields. We cannot manipulate celestial objects; nor can we carry out experiments in earthquake science by manipulating earthquakes (though there are elaborate techniques for seismic detection which are not strictly experimental in the sense of experimentation as manipulation that we intend). Consider next the category ‘aims and values’ and the item prediction falling under it. Again, most sciences aim to make predictions, especially novel ones, but not all of them succeed. For example, astronomy is very good indeed in predicting planetary positions. In contrast, even though earthquake science does a good job of predicting the approximate locations of earthquakes, it fails badly with respect to predicting the time of their occurrence. Medicine can statistically predict the occurrence of many diseases under certain conditions without being able to tell who will develop them and when.

Let us now explore the similarities and differences amongst various scientific disciplines in terms of the items under the category ‘methods and methodological rules’. Many sciences employ the hypothetico-deductive method, which can be roughly described as drawing out observable consequences of theories and then checking them against observational or experimental data. For example, particle physics and earthquake science use this method, but there does not appear to be any place for randomised double-blind experiments in these disciplines. In contrast, in evidence-based clinical medical science, the hypothetico-deductive method appears not to be of common use, while the methods of randomised double-blind experiments are the ubiquitous gold standard for testing. Similarly, some very important scientific research projects like sequencing the human genome do not involve much hypothesis testing, but rather are data-driven, inductive inquiries where most of the work is done by computer technologies.

Finally, consider the category of scientific knowledge and the items like laws, theories and models that fall under them. The idea of family resemblance applies here as well since not all sciences may have laws. For example, while there are clearly laws in physics, it is a contested issue as to whether there are laws in biology (Rosenberg 2008).

In the above we have mentioned a number of individual sciences and a number of characteristics. As can be seen for any chosen pair of these sciences, one will be similar to the other with respect to some of these characteristics and dissimilar to one another with respect to other characteristics. If we think of these characteristics as candidates for defining science, then no definition in terms of necessary and sufficient conditions would be forthcoming. If we take a family resemblance approach, however, things look very different and promising. To see this more concretely, let us represent data collection, inference making, experimentation, prediction, hypothetico-deductive testing and blinded randomised trials as D, I, E, P, H and T, respectively. Then we can summarise the situation for the disciplines we have considered as follows:

$$\begin{aligned}&\textit{Astronomy} = \{D, I, P, H\}; \textit{Particle physics} = \{D, I, E, P, H\};\\&\textit{Earthquake science} = \{D, I, P', H\}; \textit{Medicine} = \{D, I, P'', E, T\},\\&\textit{where } P' \textit{ and } P'' \textit{ indicate differences in predictive power as indicated}.\end{aligned}$$

Thus, none of the four disciplines has all the six characteristics, though they share a number of them in common. With respect to other characteristics, they partially overlap, like the members of closely related extended family. In short, taken altogether, they form a family resemblance.

Note that in order to convey the core idea that ‘science’ is a family resemblance concept, we have so far considered characteristics of science understood only as a cognitive-epistemic system. Does the idea of family resemblance apply to science as a social-institutional system as well? We believe that it does, at least to some degree. All scientific disciplines have a peer review system and a system of knowledge certification and dissemination. However, not all of them share exactly the same social values or the same elements of the scientific ethos. For example, the norm ‘respect human and animal subjects’ would not apply to disciplines such as physics and chemistry that do not deal with human and animal subjects, but ‘avoid damaging the environment’ certainly would. Similarly, although many sciences serve social utility, there are some fields (such as cosmology and parts of particle physics such as unified field theory) that are not obviously socially useful in any way; they are practised merely to satisfy our curiosity about the workings of nature. In short, the sciences form a polythetic family resemblance set with respect to their social and ethical dimensions as well.

30.6 Virtues of the Family Resemblance Approach

We believe that the family resemblance approach to science has several virtues, both theoretical and pedagogical. Perhaps the most important theoretical virtue of this approach is the systematic and comprehensive way it captures the major structural features of science and thereby accommodates, in a pedagogically useful way, almost all of the findings of NOS research in science education summarised in Sect. 30.2. As we shall illustrate in the next section, both the categories themselves and the items that fall under them do not dangle in the air as discrete entities; rather, they are tightly related to each other in a number of ways, forming an integrated whole. Thus, we can say that

> Science is a cognitive and social system whose investigative activities have a number of aims that it tries to achieve with the help of its methodologies, methodological rules, system of knowledge certification and dissemination in line with its institutional social-ethical norms, and when successful, ultimately produces knowledge and serves society.

This generic description is not meant as a definition of science, but rather as indicating how various aspects of science can be weaved together systematically as a unified enterprise.

By including science as a social institution as part of the family resemblance approach, the social embeddedness of science emphasised in the NOS literature in science education is captured in a novel way. A significant part of what it means to say that science is socially embedded is to say that noncognitive values are operative in science and influence science. No social institution, not even science, exists in a vacuum, so all kinds of social, cultural, historical, political and economic factors may influence it. Just to give an obvious example, funding strongly affects the choice of scientific problems and research agendas. Noncognitive factors of all sorts (gender biases, ideologies, economic considerations, etc.) may influence data description, hypotheses and even evidential relations in certain areas such as primatology and research on sex differences, as noted by feminist scientists and philosophers (Longino 1990). Sometimes these factors may cause scientists to deviate from the ethical norms of science (they may, e.g. fabricate or suppress data) and thus have a distorting effect on scientific conduct. However, not all social factors have a negative impact on science. Indeed, one of the most important functions of the ethos of science and mechanisms like peer review along with open and free critical discussion is precisely to minimise the negative effects on science. The ethos of science and the social system of scientific knowledge production contribute to the reliability of scientific knowledge as much as scientific methods and methodological rules do.

In practice, scientific inquiry is always guided by both cognitive-epistemic and social-institutional 'rules of the game', so to speak. This gives substance to our earlier claim that the distinction between science as a cognitive-epistemic system and science as a social institution is a conceptual one introduced for analytical purposes; but in practice the two are inseparable.

The historical, dynamic and changing nature of science can be accommodated naturally by the family resemblance approach through its open-ended categories that allow for the emergence of new characteristics of science within each category. For example, from a historical perspective we see that many scientific disciplines such as physics, chemistry, electricity and magnetism became mathematical only after the scientific revolution that occurred in the sixteenth and seventeenth centuries. Similarly, the hypothetico-deductive method was first clearly formulated and became established during the same period. New methodological rules like the one that tells the scientist to use blind procedures in conducting experiments on human subjects in life sciences came about only in the twentieth century. So did many ethical norms of science. The family resemblance approach therefore incorporates the dynamic, open-ended nature of science.

A unique virtue of the family resemblance approach is that it does justice to the differences amongst scientific disciplines and yet at the same time explains their unity by emphasising the similarities and partial overlaps amongst them. It is the existence of these 'family ties' that justify the label 'science' that we apply to various disciplines from archaeology to zoology. The unity of science is a unity-within-diversity. Earlier we pointed out that observing and inferring are common to all scientific disciplines even though they are not unique to the sciences. Another particularly important common feature of all scientific disciplines is the naturalism inherent in them—a feature that has not received sufficient attention in the NOS literature. We have touched upon this in discussing the notion of scientific explanation in Sect. 30.3.1 and are now in a position to articulate it more fully.

Science appeals to only natural entities, processes and events; its mode of explanation, aims and values, ethos, methods and methodological rules and the system of knowledge certification contain nothing that is supernatural or occult. Scientific naturalism is not an addendum to science invented by philosophers; rather, it is inherent to science. As Robert Pennock aptly puts it, it is a 'ground rule' of science so basic that it seldom gets mentioned explicitly (Pennock 2011, p. 184). One of the important science reform documents that does draw attention to this aspect of science is the National Science Teachers Association's statement on NOS: 'Science, by definition, is limited to naturalistic methods and explanations and, as such, is precluded from using supernatural elements in the production of scientific knowledge' (quoted from Pennock 2011, p. 197). Scientific naturalism pervades the whole of science from A to Z. As such, it describes a core aspect of science that contributes to its unity.

A final virtue of the family resemblance approach is that it is free of philosophical commitments such as realism, positivism, empiricism and constructivism. One can adopt any one of these, depending on how one wants to spell out each item that falls under each category of the family resemblance approach. For example, while realist educators may wish to emphasise truth as an aim of science with respect to both observable and unobservable entities, those who are sympathetic to constructivism may settle for viability, provided that they inform students of the existence of alternative views on this issue. Thus, they can add content to the family resemblance approach according to their philosophical orientation or else completely avoid discussing these philosophical issues due to the pressure of limited time, the level of the class and so on.

30.7 Teaching the Family Resemblance Approach: Some Suggestions

Teaching NOS from the perspective of family resemblance can begin by introducing the categories of science and then showing how they are related to one another. A natural place to start is processes of inquiry since all students are engaged in them to varying degrees. A host of interesting questions can be pursued in this context. Is observing a passive activity (raised to illustrate the point that data collection is often driven by scientific problems and theories)? How does observation differ from experimentation? What are the different ways in which a given set of data be interpreted? And so on. Next, the teacher can explore the connection between processes of inquiry, aims and hypotheses (or models and theories). This could be motivated very naturally since processes of inquiry are activities and virtually all activities have some aim or other. Some of the questions that can be asked are as follows. What is the point of doing an experiment? How are observational and experimental data related to hypotheses, theories and models? Does this theory explain that set of data? How would an experiment be set up to test some claim? These and similar questions enable the teacher to make several points: data provide evidence for or against hypotheses, theories and models; experiments are conducted to test them; testing can be done (as in the hypothetico-deductive method) by deducing test predictions from them. The aforementioned questions also provide excellent opportunities for the teacher to discuss key scientific notions like ‘testing’, ‘experiment’, ‘theory’, ‘law’ and ‘model’.

Another fruitful question that prompts the exploration of the relationships amongst various science categories is to ask how science achieves its aims. This may lead to the idea of scientific method and methodological rule. In this context, at least three points can be made. First, science does not achieve its various aims haphazardly, but by employing a number of methods and methodological rules. With their help, science produces reliable (though fallible) knowledge. The hypothetico-deductive method, in particular, enables students to see this clearly. Scientific predictions do not always come out right, and when that is the case, it means that scientists have made a mistake somewhere and they must revise some of their claims. In this way, science can eliminate its errors and produce more reliable results.

Second, methods and methodological rules do not dictate to scientists what to do at every step of their inquiry. A discussion of this point may help students appreciate the fact that scientific methods and rules are not mechanical procedures that generate theories (or models) from data. Hence, theory construction always requires much imagination and creativity. To stimulate creativity, students may be invited to come up with different hypotheses that fit or explain the same data.

Third, despite the existence of methods, methodological rules and values functioning as criteria for evaluating rival theories, scientists may sometimes come to reach different conclusions on the basis of the same body of evidence. This may happen when no single theory embodies all the cognitive-epistemic values equally well and when different scientists place different emphasis on them when faced with a choice amongst rival theories. One scientist may give more weight to fruitfulness, say, and another may value simplicity more due to the priority given to aesthetic considerations (in which case there will be disagreement about which theory is the better one). A historical example that comes close to this scenario is the debate scientists had between Aristotelian-Ptolemaic geocentric system and the Copernican heliocentric system during the early stages of the scientific revolution. The teacher may discuss this case as example of *rational disagreement* amongst scientists, a disagreement which in no way implies that they are acting arbitrarily, though they might have subjective (personal) preferences in weighing values. Properly understood, then, being subjective does not mean acting arbitrarily, which is the whole point of Kuhn (1977). In this way, students can see how both personal (subjective) and intersubjective (objective) factors play a role in scientific theory choice.

Once the students grasp the categories ‘processes of inquiry’, ‘aims and values’ and ‘methods and methodological rules’, then the fourth category can be introduced in a straightforward way: scientific knowledge, especially in the form of theories and models, is the end product of successful scientific inquiry pursuing the aims of truth, testability, prediction and the like under the guidance of scientific methods and methodological rules. The teacher can then draw attention to and explain the characteristics of scientific knowledge which have emerged (such as its empirical, objective and subjective nature, its reliability or tentativeness, its dependence on creativity).

As for the teaching of science as a social-institutional system, we foreground two categories: the scientific ethos and the social certification of scientific knowledge. What must be especially emphasised with respect to these categories is their function in scientific knowledge production. Students must understand that ethical norms like intellectual honesty and openness and social mechanisms of peer review and free and critical discussion are as important as processes of inquiry such as experimenting or in using methods, like the hypothetico-deductive method of testing, in producing *reliable* knowledge. This point can be made forcefully by inviting students to think about what happens if scientists were to fabricate data or to accept an idea or a theory without sufficient critical discussion.

30.8 Conclusion

The main point of this chapter is to suggest a new way of understanding the term ‘nature’ as it gets employed in the phrase ‘nature of science’ (NOS). The word ‘science’ is a broad umbrella term which, in the context of science education, cannot be unproblematically captured by proposing accounts of ‘nature’ which are essentialist or by specifying a set of necessary and sufficient conditions for science. Nor can it be captured by drawing up some small list of features. The problem with a list is that it remains arbitrary as to why some features are included on the list and not others; and it remains unclear how, when given such a list, one is to go on to features not mentioned on the list. Our answer is to suggest the family resemblance or cluster account of a definition—an account developed within philosophy to overcome problems with essentialism, necessary and sufficient conditions and lists already mentioned. As such our enterprise is more philosophical and is not directed upon empirical matters such as the kinds of understanding teachers and pupils might have of NOS, or what level matters pertaining to NOS might be discussed in classrooms. Nevertheless, the family resemblance conception of ‘nature’ that we have proposed is not irrelevant to these empirical matters. What it does is ‘free up’ one’s approach to them in what we hope is an illuminating way which a too rigid conception of ‘nature’ might obscure.

Gürol Irzik is a professor of philosophy at Sabanci University, Turkey. He has published papers in philosophy of science, social aspects of science and science education. His books include the following: with co-author Robert Nola, *Philosophy, Science, Education and Culture* (Dordrecht, Springer, 2005) and, with co-editor Güven Güzeldere, *Turkish Studies in the History and Philosophy of Science* (Dordrecht, Springer, 2005). He edited a special issue of the journal *Science & Education* on the topic of commercialisation of academic science (vol. 22, no. 10, 2013).

Robert Nola is a professor of philosophy at The University of Auckland, New Zealand. He has published papers in philosophy of science, metaphysics, the sociology of science and science education. His recent books include the following: with co-author Gurol Irzik, *Philosophy, Science, Education and Culture* (Dordrecht, Springer, 2005); with co-author Howard Sankey, *Theories of Scientific Method* (Chesham, Acumen Press 2007); and with co-editor David Braddon-Mitchell, *Conceptual Analysis and Philosophical Naturalism* (Cambridge MA, MIT Press, 2009). His current work continues in philosophy of science with emphasis on scientific naturalism and the religion/science conflict.

Chapter 31
Appraising Constructivism in Science Education

Peter Slezak

31.1 Part I: Psychological or "Radical" Constructivism

Referring to von Glasersfeld's (1995a) radical theories, Cobb (1994a, p. 4) writes of the "fervor that is currently associated with constructivism" and Ernest (1995, p. xi) has described it as "the most important theoretical perspective to emerge," receiving "widespread international acceptance and approbation." A review of research in mathematics education noted "In the second half of the 1980s public statements urging the introduction of radical constructivist ideas in school mathematics programs also began to assume bandwagon proportions" (Ellerton and Clements 1991, p. 58). And Catherine Twomey Fosnot observed "Most recent reforms advocated by national professional groups are based on constructivism" (Fosnot 1996, p. x). For example, she cites the National Council of Teachers of Mathematics and the National Science Teachers Association. Fosnot's account has been supported by many other researchers:

> As any glance at contemporary educational literature demonstrates, the concept of "constructivism" carries with it enormous appeal. Contemporary literature also reveals that many current educational reform initiatives encourage teaching practices that many people refer to as constructivist (Null 2004, p. 80).

Denis Phillips (1997a, p. 152) has said of this kind of radical or psychological constructivism, "arguably it is the dominant theoretical position in science and mathematics education," and he remarks, "Across the broad fields of educational theory and research, constructivism has become something akin to a secular religion" (Phillips 1995, p. 5). Indeed, Tobin (1991, p. 1) explains the transformative effects of the doctrine which becomes "a referent for thoughts and actions" that "assume a higher value than other beliefs."

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_31,

Despite its significant influence among educationalists,[1] radical constructivism has generated severe controversy and polarization (see contributions to Matthews (1998) and Phillips (2000)). Indeed, von Glasersfeld himself has remarked “to introduce epistemological considerations into a discussion of education has always been dynamite” (quoted in Ernest (1995, p. xi)). Critics including Kelly (1997), Suchting (1992), Matthews (1998, 2000, 2012), Nola (1998), Olssen (1996), Small (2003), and Slezak (2010) have argued that the “radical constructivism” of von Glasersfeld has serious, if not fatal, philosophical problems, and further, it can have no benefit for practical pedagogy or teacher education. Indeed, there are well-conducted studies showing that constructivist-type teaching has a deleterious effect on student learning in science and mathematics (Kirschner et al. 2006; Mayer 2004).[2]

31.1.1 Recoiling into Metaphysical Fantasy

von Glasersfeld (1995a) sees the origins of radical constructivism in Kant, Berkeley, and Piaget, among others. However, the range of philosophical issues raised in the constructivist literature includes abstruse questions whose relevance to practical or theoretical problem in education has been questioned. Thus, among the topics discussed include Berkeleyan idealism, Cartesian dualism, Kantian constructivism, Popperian falsifiability, Kuhnian incommensurability, Quinean underdetermination, truth, relativism, instrumentalism, rationalism, and empiricism, inter alia. Gale (1995, p. xii) identifies “Cartesian epistemology” and the “mind–body split” as having educational relevance. He suggests that constructivist approaches “differed from the Cartesian model in viewing knowledge in a nondualistic manner so as to avoid the mind–body split of endogenic (mind-centered) and exogenic (reality-centred) knowledge” (Gale 1995, p. xiii).

Arguably, good educational theory and practice have flourished despite the persistent obduracy of these problems. Indeed, there is a sharp contrast between such esoteric philosophical matters and the practical recommendations taken to follow from them. Thus, drawing the morals of his constructivism, von Glasersfeld says “Rote learning does not lead to understanding” (Cardellini 2006, p. 182). Similarly, he suggests “after a while they [i.e. students] will become interested in why certain things work and others do not; and it is then that teachers can help to foster this interest that leads to understanding” (Cardellini 2006, p. 182). Critics of constructivism note that such insights are familiar to teachers who are ignorant of constructivism or any other philosophy, for that matter (Nola 1998, p. 33).

von Glasersfeld suggests that his conception of constructivism arose “out of a profound dissatisfaction with the theories of knowledge in the tradition of Western philosophy” and he has suggested that adopting his constructivism “could bring

---

[1] See Niaz et al. (2003).

[2] See also Gil-Pérez et al. (2002). Nevertheless, the practical question remains controversial with positive evidence also available.

about some rather profound changes in the general practice of education" (Glasersfeld 1989, p. 135). For example, he recommends, "Give up the requirement that knowledge represents an independent world" (Glasersfeld 1995b, p. 6–7). This is, of course, Berkeley's notorious idealism. von Glasersfeld has addressed objections invited by his frequent allusions to Berkeley. He complains "superficial or emotionally distracted readers of the constructivist literature have frequently interpreted this stance as a denial of 'reality'" (von Glasersfeld quoted by Phillips 1995, p. 6).

However, von Glasersfeld himself encourages the attribution of idealism where he misleadingly claims "all the great physicists of the twentieth century … did not consider [… their theories] descriptions of an observer-independent ontological reality" (quoted in Cardellini 2006, p. 181). Evidently endorsing von Glasersfeld's constructivism, John Shotter (1995, p. 41) says "We also take it for granted that it no longer makes sense to talk of our knowledge of an absolute reality – of our knowledge of a world independent of us – because for us there is no 'external world,' as it used to be called." von Glasersfeld (1989, p. 121) writes of a person's "cognitive isolation from reality" and says Berkeley's insight

> … wipes out the major rational grounds for the belief that human knowledge could represent a reality that is independent of human experience (von Glasersfeld 1995a, p. 34).

However, Putnam (1994, p. 446) has warned that we must find a way "to do justice to our sense that knowledge claims are responsible to reality without recoiling into metaphysical fantasy."

von Glasersfeld's worry appears to address what Rorty has called "the philosophical urge," namely, the urge to say that assertions and actions must not only cohere with other assertions and actions but "correspond" to something apart from what people are saying and doing (Rorty 1979, p. 179). By contrast, in the spirit of Putnam's (1994) "second naiveté," Rorty says that a Quinean naturalism questions

> … whether, once we understand … when and why various beliefs have been adopted or discarded, there is something left called 'the relation of knowledge to reality' left over to be understood (Rorty 1979, p. 178).

In the same vein, Quine has written:

> … it is meaningless, I suggest, to inquire into the absolute correctness of a conceptual scheme as a mirror of reality. Our standard for appraising basic changes of conceptual scheme must be, not a realistic standard of correspondence to reality, but a pragmatic standard (Quine 1961b, p. 79).

von Glasersfeld is evidently led into his idealist worries by failing to distinguish questions concerning the warrant for our beliefs from questions of metaphysics about the existence of a mind-independent world (von Glasersfeld 1989, p. 122).

However constructivism is to be understood, it remains that the relevance of these matters to education remains unclear at best. Ruhloff (2001, p. 64) concludes "There are no compelling reasons … to draw a lesson or practical pedagogical instruction from the results of skeptical analysis." Indeed, in the same spirit, Kant himself wrote, "The only thing necessary is not theoretical learning, but the Bildung [education] of human beings, both in regard to their talents and their character."

31.1.2 *Piaget's "Construction of Reality"?*

Although the title of Piaget's (1999) book *The Construction of Reality in the Child* is suggestive of von Glasersfeld's doctrines, Piaget's own text leaves little doubt about the significant difference between these two. Piaget clearly acknowledges a knowable objective world beyond our sense-data. Despite possibly "flirting with idealism," Piaget (1972a, p. 57) says that his epistemological position is "very close to the spirit of Kantianism," both in its constructivism and in its sensitivity to the need to avoid Berkeleyan idealism. Thus, Margaret Boden writes:

> Piaget is aware that as a constructivist he must be careful to avoid idealism – or, to put it another way, that he must answer the sceptic's challenge that perhaps all our so-called 'knowledge' is mind-dependent illusion. He tries to buttress his commonsense realism by appealing to the biological basis of knowledge (Boden 1994, p. 79).

Piaget himself explains clearly that his views are not an idealistic overestimation of the part played by the subject:

> … the organism is not independent of the environment but can only live, act, or think in interaction with it (Piaget 1971, p. 345).

Thus, while von Glasersfeld is at pains on every occasion to emphasize the unknowability of reality and the need to abandon notions of objectivity and truth, Piaget by contrast writes of "The Elaboration of the Universe" and he asks how the world is constructed by means of the instrument of the sensorimotor intelligence. In particular, Piaget speaks of the shift from an egocentric state to one "in which the self is placed … in a stable world conceived as independent of personal activity" (Piaget 1999, p. 395). Piaget explains:

> The universe is built up into an aggregate of permanent objects connected by causal relations that are independent of the subject and are placed in objective space and time …
>
> … step by step with the coordination of his intellectual instruments … [the child] discovers himself in placing himself as an active object among the other active objects in a universe external to himself (Piaget 1999, p. 397).

Elsewhere, Piaget writes:

> The theory of knowledge is therefore essentially a theory of adaptation of thought to reality … (Piaget 1972b, p. 18).

Although invoking Piaget, these are ways of talking that von Glasersfeld has repudiated.

31.1.3 *The Philosophical Urge*

von Glasersfeld sees his version of constructivism as a departure from traditional conceptions. Meyer (2008) notes that von Glasersfeld and followers such as Gergen (1995) view constructivism "as a replacement for a whole field of philosophy." von

Glasersfeld (1995a) explains that radical constructivism is "an unconventional approach to the problem of knowledge and knowing" that

> … starts from the assumption that knowledge, no matter how it is defined, is in the heads of persons, and that the thinking subject has no alternative but to construct what he or she knows on the basis of his or her own experience (Glasersfeld 1995a, p. 1).

However, we might ask: Who has ever doubted that knowledge is in the head? von Glasersfeld appears to have fallen victim to a notorious problem in philosophy concerning the "veil of ideas" that is supposed to intervene between the mind and the world as the direct objects of perception and knowledge. Von Glasersfeld explains:

> One of Vico's basic ideas was that epistemic agents can know nothing but the cognitive structures they themselves have put together. … God alone can know the real world … In contrast, the human knower can know only what the human knower has constructed.
>
> For constructivists, therefore, the word knowledge refers to a commodity that is radically different from the objective representation of an observer-dependent world that the mainstream of the Western philosophical tradition has been looking for. Instead, knowledge refers to conceptual structures …. (von Glasersfeld 1989, p. 123).

It is precisely this idea that we know only our own ideas or "conceptual structures" directly rather than the world that is the source of the traditional puzzle since the seventeenth century. Putnam (1994) provides a succinct diagnosis of this "disastrous idea":

> … our difficulty in seeing how our minds can be in genuine contact with the 'external' world is, in large part, the product of a disastrous idea that has haunted Western philosophy since the seventeenth century, the idea that perception involves an interface between the mind and the 'external' objects we perceive (Putnam 1994).

31.1.4 Epistemology or Pedagogy?

In an interview, von Glasersfeld was asked whether constructivism is to be understood as an epistemology or pedagogy. His answer is most revealing for von Glasersfeld simply restates the formula of Berkeley as if this serves as an answer to the question: "there is no way of checking knowledge against what it was supposed to represent. One can compare knowledge only with other knowledge" (Glasersfeld 1993, p. 24). Other interviewer questions sought to clarify the "differences between constructivism and idealism," but again, von Glasersfeld reiterates that "we can only know what our minds construct" and that "the "real" world remains unknowable" and that "I could be one of Leibniz' monads" (ibid., p. 28). We might reasonably wonder how this insight could help teachers in the classroom.

When pressed on the question concerning "the implications of constructivism for a theory of instruction," von Glasersfeld suggests that there are many. These include the following: "It is … crucial for the teacher to get some idea of where [the students] are," that is, "what concepts they seem to have and how they relate them" (von Glasersfeld 1993, p. 33). This modest recommendation is far from the “rather profound changes” promised. Similarly, von Glasersfeld says:

> … asking students how they arrived at their given answer is a good way of discovering something about their thinking (von Glasersfeld 1993, p. 33).
>
> Whatever a student says in answer to a question (or ‘problem’) is what makes sense to the student at that moment. It has to be taken seriously as such, regardless of how odd or ‘wrong’ it might seem to the teacher. To be told that it is wrong is most discouraging and inhibiting for the student (ibid., p. 33).
>
> If you want to foster students’ motivation to delve further into questions that, at first, are of no particular interest (from the students’ point of view), you will have to create situations where the students have an opportunity to experience the pleasure inherent in solving a problem (ibid., p. 33).

We may assume that such insights are what Tobin (1993, p. ix) has in mind when he refers to constructivism as “a paradigm for the practice of science education.” Tobin has his own contributions to offer:

> A most significant role of the teacher, from a constructivist perspective, is to evaluate student learning. In a study of exemplary teachers, Tobin and Fraser found that these teachers routinely monitored students in three distinctive ways: they scanned the class for signs of imminent off task behavior, closely examined the nature of the engagement of students, and investigated the extent to which students understood what they were learning. If teachers are to mediate the learning process, it is imperative that they develop ways of assessing what students know and how they can represent what they know (Tobin and Tippins 1993, p. 12).

In brief, good teachers make sure students pay attention and understand the lesson. We may wonder how differently a teacher might do things if not operating “from a constructivist perspective.”

31.1.5 From the Metaphysical to the Mundane

von Glasersfeld had promised that constructivism “could bring about some rather profound changes in the general practice of education.” (von Glasersfeld 1989, p. 135). Elsewhere he has suggested that, “taken seriously,” radical constructivism “is a profoundly shocking view” that requires that “some of the key concepts underlying educational practice have to be refashioned.” However, among these “profoundly shocking” recommendations, he suggests the following:

> … students will be more motivated to learn something, if they can see why it would be useful to know it (von Glasersfeld 1995a, p. 177).
>
> Teaching and training are two practices that differ in their methods and, as a consequence, have very different results. … rote learning does not lead to ‘enlightenment’ (ibid., p. 178).
>
> …in order to modify students’ thinking, the teacher needs a model of how the student thinks (ibid., p. 186).
>
> Students should be driven by their own interest (ibid., p. 188).

> …talking about the situation is conducive to reflection (ibid., p. 188).
>
> To engender reflective talk requires an attitude of openness and curiosity on the part of the teacher, a will to 'listen to the student' (ibid., p. 188).

These are all undoubtedly sound, indeed platitudinous, recommendations, though hardly deserving to be regarded as "profoundly shocking." In this regard, the writing of Driver and colleagues (1995) is instructive:

> …learning science involves being initiated into scientific ways of knowing. scientific entities and ideas, which are constructed, validated, and communicated through the cultural institutions of science, are unlikely to be discovered by individuals through their own empirical inquiry; learning science thus involves being initiated into the ideas and practices of the scientific community and making these ideas and practices meaningful at an individual level. The role of the science educator is to mediate scientific knowledge for learners, to help them make personal sense of the ways in which knowledge claims are generated and validated, rather than to organize individual sense-making about the natural world (Driver et al. 1995, p. 6).

Following the model of C.W. Mills' (1959), Slezak (2010) argues that the passage may be reduced without remainder to the following brief claim: "Learning science involves learning science. Individuals cannot rediscover science by themselves. So, the role of teachers is to teach." Such illustrations have been offered by critics to indicate a tendency to recast truisms in pretentious jargon to create the illusion of deep theory. Tobin and Tippins (1993) provide another typical illustration:

> Constructivism suggests that learning is a social process of making sense of experience in terms of what is already known. In that process learners create perturbations that arise from attempts to give meaning to particular experiences through the imaginative use of existing knowledge. The resolution of these perturbations leads to an equilibrium state whereby new knowledge has been constructed to cohere with a particular experience and prior knowledge (Tobin and Tippins 1993, p. 10).

Translation: Students sometimes learn new things. Tobin and Tippins conclude their article with the following remarks:

> … it is our contention that constructivism is an intellectual tool that is useful in many educational contexts. …We do not claim that use of constructivism as a referent is the only way to initiate changes of … a comprehensive and significant scope, but from our experience we can assert that constructivism can assume a dialectical relationship with almost every other referent in a process that culminates in a coherent world view consisting of compatible referents for action (Tobin and Tippins 1993, p. 20).

Translation: Constructivism is consistent with some other theories.

Constructivist terms have ordinary synonyms which reveal the truisms they assert. Instead of merely saying "talking among teachers and students," we can refer to "the discursive practices that support the coconstruction of scientific knowledge by teachers and students" (Driver et al. 1994, p. 9). Instead of saying simply that "teachers explain new ideas," we can say the "teacher's role is characterized as that of mediating between students' personal meanings and culturally established mathematical meanings of wider society" (Cobb 1994b, p. 15). Rather than the truism "teachers and students exchange ideas," we can say that "speaking from the sociocultural perspective, [we] define negotiation as a process of mutual appropriation in which the teacher and students continually coopt or use each others' contribution" (Cobb 1994b, p. 14). Saying that "students learn different things at different times" may be recast as "Rather than successive equilibrations, … learning may be better characterized by parallel constructions relating to specific contexts" (Cobb 1994a, p. 7).[3]

Such translations make an important point that goes beyond mere ridicule. They reveal what has been referred to as the "paradox of pedagogy." In a survey of the psychological literature, Slezak (2007) suggests that theories taken to be important for education are without bearing despite the ritual claims of relevance. As foregoing truisms suggest, teaching and learning are among the natural, intuitive mental skills that humans display through a tacit knowledge rather than explicit theory or doctrine. In the light of centuries of successful teaching, it seems clear that teachers and learners manage effectively without knowing modern theories of psychology, much less epistemology or metaphysics. Teacher and learner are perhaps best conceived on the analogy of speaker and hearer in a conversation. von Glasersfeld himself makes the more modest point:

> … in summary, the best teachers have always known and used all this information, but they have known and used it more or less intuitively and often against the official theory of instruction. Constructivism does not claim to have made earth-shaking inventions in the area of education; it merely claims to provide a solid conceptual basis for some of the things that, until now, inspired teachers had to do without theoretical foundation (von Glasersfeld 1995b, p. 15).

It is noteworthy that the foremost advocate of von Glasersfeld's constructivism, Ken Tobin, has published an article titled "Constructivism in Science Education: Moving On" in which he writes:

> The critical mass of science educators are still making sense of their praxis in terms of constructivism, but in a short time we will be in another theoretical epoch (Tobin 2000, p. 250).

But nevertheless:

> As an axiom, however, constructivism is the ether for an expanding constellation of theories that illuminate my praxis in science education (p. 251).

Who knows what "is the ether" might mean, but hopefully "the critical mass" of those "illuminating their praxis" by the new "constellation of theories" might subject these new theories to more informed philosophical appraisal than has been evident in the embrace of von Glasersfeld's psychological constructivism.

31.2 Part II: Social Constructivism

Phillips (1995, p. 5) distinguishes the sociological form of constructivism from the psychological variety, and he observes, "It is the work of the social constructivists that had drawn the most dramatic attention in recent years; clearly they have touched

---

[3] For further examples, see Matthews (2000).

a raw nerve" (1997a, p. 154). Indeed, the sociological variety of constructivism has been described by Laudan (1990a, x) as "the most prominent and pernicious manifestation of anti-intellectualism in our time" and has been at the center of the "science wars." The book *Higher Superstition* (Gross and Levitt 1994) brought the polemics surrounding social constructivism to wide popular attention. Adding to the controversy, a scandal arose surrounding the "Sokal Hoax" (Sokal and Bricmont 1997)—the unwitting publication of an article by the mathematical physicist Alan Sokal, which was deliberately nonsense, written in the postmodern style.

Although not concerned primarily with educational matters, inevitably, social constructivism has dramatic implications for pedagogy (see Slezak 1994a, b, 2000, 2007). As Phillips notes, "There is a lot at stake. For it can be argued that if the more radical of the sociologists of scientific knowledge … are right, then the validity of the traditional philosophic/epistemological enterprise is effectively undermined, and so indeed is the pursuit of science itself" (1997b, p. 86). The doctrines of social constructivism take scientific theories to reflect the social milieu in which they emerge, and therefore, rather than being founded on logic, evidence, and reason, beliefs are taken to be the causal effects of the historically contingent, local context. Accordingly, if knowledge is intrinsically the product of "external" factors rather than "internal" considerations of evidence and reason, then it is an illusion to imagine that education might serve to instill a capacity for critical thought or rational belief. On these views, education becomes indoctrination, pedagogy is propaganda, and ideas are merely conventional conformity to social consensus. There could be no more fundamental challenge to education than the one posed by social constructivism, since it purports to overturn the very conception of knowledge in the Western tradition: The self-advertising grandiosely proclaims, "The foundations of modern thought are at stake here" (Pickering 1992).

Even among the more temperate critiques in the academic literature, the disputes have been unusually acrimonious. For example, Mario Bunge (1991) has described most of the work in the field as "a grotesque cartoon of scientific research." In a similar vein, the philosopher David Stove (1991) has written of these doctrines as a form of lunacy which is "so absurd, that it eludes the force of all argument," a "philosophical folly," and "a stupid and discreditable business" whose authors are "beneath philosophical notice and unlikely to benefit from it." In his scathing remarks, Stove describes such ideas as an illustration of the "fatal affliction" and "corruption of thought" in which people say things which are bizarre and which even they must know to be false.

31.2.1 Ideas or Ideology? Pedagogy or Propaganda?

Laudan's (1990) charge of anti-intellectualism points to the source of concern for educators. Where traditional views see scientific knowledge as involving insight, inspiration, creativity, and aesthetic judgment, sociologists see something more prosaic and utilitarian. Thus, Collins and Pinch (1992), writing specifically on science education in schools, suggest, "It is nice to know the content of science—it helps one to do a lot of things such as repair the car, wire a plug, build a model aeroplane." This conception leaves out the intellectual dimension and the creative role of the mind in providing an understanding of the world. Instead of conceiving science education as fostering understanding and critical thinking, Collins and Pinch (1992, p. 150) recommend that science education should attend to the social negotiation, "myths," and "tricks of frontier science" as "the important thing."

Above all, the relativism inherent in social constructivist theories makes it impossible for teachers to offer the usual intellectual grounds for distinguishing science from nonsense. Since the rational, cognitive virtues of theories are taken to be irrelevant to their status, one cannot complain that some views are false or implausible or otherwise lacking intellectual, explanatory merit. For example, one cannot teach that Soviet Lysenkoism or Hitler's racialism were perversions of scientific truth. Their success in winning consensus must count ipso facto as exemplary scientific achievement according to social constructivist doctrines. Pseudosciences such as parapsychology and astrology are merely unfashionable rather than scientifically wrong.

31.2.2 What Is Social Constructivism?

The sociology of science and its constructivist doctrines emerged with post-Positivist developments in the philosophy of science and as elaboration of themes found in Kuhn's (1962) influential book *The Structure of Scientific Revolutions*.[4] However, as Zammito (2004, p. 181) notes, Kuhn himself emphatically repudiated these ideas as "absurd," as "deconstruction gone mad," and he "willingly enlisted in the 'science wars' on the side of the scientists."

David Bloor's (1976) book *Knowledge and Social Imagery* launched the so-called Edinburgh Strong Program in the sociology of scientific knowledge (SSK). Bloor was heralding a radical enterprise intended to displace traditional philosophy and epistemology. The essential, astonishing stance was the rejection of "the very idea" of science as a distinctive enterprise, effacing any distinction or boundaries between science and other institutions as merely "rhetorical accomplishments." Typically, Woolgar rejects the traditional "core assumption," namely, "The persistent idea that science is something special and distinct from other forms of cultural and social activity" (Woolgar 1988). A further "assumption" to be rejected is the curiously persistent view "that the objects of the natural world are real, objective and enjoy an independent pre-existence" (Woolgar 1988, p. 26). In place of the traditional "misconceptions" about science and the independent preexistence of the world, social constructivism proposed an amalgam of idealism and relativism according to which scientific theories are merely "fictions," the product of social

---

[4] The most comprehensive account of post-Positivism and sociology of science is Zammito (2004).

forces, interests, and other contingent, historical aspects of the milieu in which they arise. That is, the very substantive ideas and content of scientific theories are not explanatory or descriptive of the world, but are socially negotiated by some community of discourse and constituted entirely by social consensus. Even scientific discovery is a matter of "interpretative practice," and "genius has no bearing on the pattern of discovery in science."

Sociologists had a ready explanation for the predictable incredulity of philosophers. Bloor's preface to the first edition of his book hints darkly that the inevitable resistance by philosophers to his doctrines will be due not to the implausibility of the ideas but to uncomfortable secrets that philosophers would wish to hide. Bloor asserts that his approach to science from a sociological point of view encounters resistance because "some nerve has been touched." He announces his intention to "despoil academic boundaries" which "contrive to keep some things well hidden" (Bloor 1976, p. ix). In retrospect, this is somewhat ironic in view of Bloor's own deceptive attempt to hide the commitments of his Strong Program (see Slezak 1994c). Despite making substantive changes in the second edition of his book designed to avoid fatal criticisms by Laudan (1981), in his preface, Bloor denies that he had made any alterations (Bloor 1991). Bloor devotes an entire chapter of his landmark book to a kind of psychoanalysis of his opponents by speculating about the "sources of resistance" to the Strong Program which he attributes to hidden, indeed primitive, motives involving the fear of sociology's desacralizing of science and its mysteries.

One might suggest alternative reasons for the resistance to his sociological doctrines, but Bloor sees only repressed impulses concerning the "sacred" and the "profane" leading to "a superstitious desire to avoid treating knowledge naturalistically" (Bloor 1976, p. 73). Bloor imagines that the "threatening" nature of any investigation into science itself has been the cause of a "positive disinclination to examine the nature of knowledge in a candid and scientific way" (Bloor 1976, p. 42). However, this disinclination to examine knowledge and the need to keep it mystified is difficult to reconcile with the fact that every philosopher since Plato has been centrally concerned with the problem of knowledge and its justification.

31.2.3 "Knowledge as Such": Contexts, Contents, and Causes

In his manifesto, Bloor (1976, p. 3) had declared that the central claims of the Strong Program were "beyond dispute," and Barry Barnes (1981, p. 481) begins an article asserting that in the short time since its advent "developments have occurred with breathtaking speed" and "the view that scientific culture is constructed like any other is now well elaborated and exemplified."

This level of self-congratulatory hyperbole prompted critics such as Gieryn (1982, p. 280) to comment upon such "defenses and reaffirmations" as "expressions of hubris" and "exaggerations passing as fact." Gieryn (1982, p. 293) has suggested that the radical findings of the new sociology of science "are 'new' only in a fictionalized reading of antecedent work." In particular, Robert Merton's (1957) chapter on "The Sociology of Knowledge" had specifically enunciated the very central doctrine of the Strong Program. Merton wrote:

> The "Copernican revolution" in this area of inquiry consisted in the hypothesis that not only error or illusion or unauthenticated belief but also the discovery of truth was socially (historically) conditioned…The sociology of knowledge came into being with the signal hypothesis that even truths were to be held socially accountable, were to be related to the historical society in which they emerged (Merton 1957, p. 456).[5]

Since the Logical Positivists have been a particular target of criticism by social constructivists, it is noteworthy that the Positivist Philipp Frank remarked that in judging the philosophy of science, "we must not ignore the extrascientific factors" since "Every satisfactory philosophy of science has to combine logic of science with sociology of science" (Frank 1949 quoted in Perla and Carifio 2009).

Though it had appeared earlier in different guises in Hegel, Marx, and Durkheim, the radical idea at the heart of the Strong Program was to go beyond those sociological studies which stopped short of considering the actual substantive content, the ideas, of scientific theories as an appropriate domain for sociological investigation. Previously, sociological studies paid attention only to such things as institutional politics, citation patterns, and other such peripheral social phenomena surrounding the production of science, but had not ventured to explain the cognitive contents of theories in sociological terms. Since this crucial point has been obscured, its importance for appreciating subsequent developments cannot be overstated. The opening sentence of Bloor's book asks, "Can the sociology of knowledge investigate and explain the very content and nature of scientific knowledge?"—that is, of "knowledge as such, as distinct from the circumstances of production" (Bloor 1976, p. 1).

The failure of previous sociological studies to touch on the contents of scientific belief was portrayed by Bloor as a loss of nerve and a failure to be consistent. Karl Mannheim, among the founders of the sociology of knowledge, is characterized as failing to make the logical extension of his approach from knowledge of society to the knowledge of nature as well. The epistemological pretensions of the Strong Program—its relativist challenge—derive from this thoroughgoing application of the sociological principle which seeks to explain the hitherto exempted knowledge claims. The ambitions of Bloor's program are explicit from the outset, for he complains that previous sociologists, in "a betrayal of their disciplinary standpoint," had failed to "expand and generalize" their claims to all knowledge: "the sociology of knowledge might well have pressed more strongly into the area currently occupied

---

[5] The work of Merton and others who had already formulated the ideas of the current sociology of science are largely ignored today, and so, there is some irony in Merton's remarks which acknowledge, "The antecedents of *Wissenssoziologie* only go to support Whitehead's observation that 'Everything of importance has been said before by somebody who did not discover it'" (1957, p. 456).

by philosophers, who have been allowed to take upon themselves the task of defining the nature of knowledge" (Bloor 1976, p. 1).

31.2.4 Causes and Case Studies

The extensive body of case studies repeatedly invoked by sociologists has been taken to establish the thesis that the contents of scientific theories and beliefs have social causes, in contradistinction to psychological ones. The causal claim concerns such things as "connections between the gross social structure of groups and the general form of the cosmologies to which they have subscribed" (Bloor 1976, p. 3). That is, the very cognitive content of the beliefs is claimed to be causally connected with immediate, local aspects of the social milieu. Of this general thesis, Bloor and Shapin (1979) were evidently unable to believe that anyone might question the causal claims of the Strong Program except on the assumption that they must be unfamiliar with the extensive literature of the case studies. However, in a precise parallel with Durkheim and Mauss (1903) to be noted presently, the claims of social determination of beliefs are all the more extraordinary in view of the failure of these case studies to support them. Critics have challenged precisely the bearing of these studies on the causal claims, and so, repeatedly citing the burgeoning literature is to entirely miss the point.

Of course, scientific discoveries have always necessarily arisen in some social milieu or other, but this is merely a truism holding equally for most human activity not thought to have been actually caused in this way by social factors. However, to the extent that social factors are indeed ubiquitous, establishing a causal connection requires more than merely characterizing in detail the social milieu which must have existed. These more stringent demands have not been met anywhere in the voluminous case studies in the SSK literature. Thus, although Shapin has acknowledged that "the task is the refinement and clarification of the ways in which scientific knowledge is to be referred to the various contextual factors and interests which produce it," and that "we need to ascertain the exact nature of the links between accounts of natural reality and the social order," nevertheless, his much-cited case study of phrenology offers only a variety of anthropological approaches leading at best to a postulation of "homologies" between society and theories which may serve as "expressive symbolism" or perhaps function to further social interests in their "context of use."

This falls far short of demonstrating the strong claims of social determination which abound in the rhetoric of programmatic statements and their "social epistemology." Thus, it is a truism to assert, as Shapin does, merely that "Culture [taken to include science] is developed and evaluated in particular historical situations" (Shapin 1979, p. 42). Shapin undertakes to refute the accusations of empirical sterility by a lengthy recounting of the "considerable empirical achievements" of the sociology of scientific knowledge (Shapin 1979, p. 65). But he is simply begging the question with his advice that "one can either debate the possibility of the sociology of scientific knowledge or one can do it" (Shapin 1982, p. 158).

31.2.5 When Is a Cigar Just a Cigar?

The claimed contingent, historical determination of scientific theories by local social context entails that the substantive content of theories would have been different had the milieu been different. We are inevitably led to ask: Would Isaac Newton have enunciated an inverse *cube* law of gravitation had the society been different? The model of such empirical studies was Forman's (1971) much-cited work which attributes the development of quantum physics to the prevailing milieu in Weimar Germany. However, in the same vein, we might inquire: Did Kurt Gödel's Incompleteness Theorem arise from some lacunae in the Viennese social order of 1930? This admittedly facetious example merely invokes the same suggestive metaphorical connections adduced by social constructivist case studies.

There is, at best, a kind of affinity claimed between the social context and the contents of the theory in question. Thus, Shapin cites "homologies between society and nature" and sees theories as "expressive symbolism" which can be exploited to serve social interests. Given the tenuous nature of such "homologies" between theories and the *zeitgeist*, the distinction between parody and serious claims is difficult to discern. Shapin's *recherché* homologies between theory content and social context recall the Freudian interpretation of dreams, which involved a similar decoding of an allegedly symbolic connection. Likewise, sociology pretends to disclose the hidden meaning underlying our scientific theories. We may have imagined that nineteenth-century theories of phrenology were about the brain, but they were really "expressing a social experience" and were about the "differentiation and specialization [in the social order] perceived by the bourgeois groups" (Shapin 1979, p. 57). Gödel's Incompleteness Theorem, too, undoubtedly expresses a collective longing for wholeness and fulfillment among the Viennese intelligentsia. However, in the spirit of Freud's famous remark, one is tempted to ask: When is a cigar just a cigar?

31.2.6 The Social Construction of Social Constructivism

It is instructive to look at an authoritative and sympathetic statement of social constructivism in a book whose coauthors include two of its founders—*Scientific Knowledge: A Sociological Analysis* by Barnes and colleagues (1996). These authors are uniquely well qualified to offer the book to anyone "seeking a text in the sociology of scientific knowledge." However, borrowing earlier words of one of its authors, this sociological enterprise appears to "contrive to keep some things well hidden" (Bloor 1976, p. ix). A study of the index is revealing. Georg Cantor, infinite cardinal numbers, and the continuum hypothesis get several entries whereas social constructivism and the Strong Program get none at all. In view of the Strong Program being proclaimed with great fanfare as the radical new approach revolutionizing the study of science and epistemology, its omission from the index is revealing. The Duhem–Quine thesis, mentioned *en passant* in an obscure footnote, gets no index entry either, though the book is, in fact, an extended essay on the alleged consequences of this philosophical doctrine. Other omissions from the index are equally curious. In view of the decisive, foundational status of the diametrical opposition between the rationalist "teleological" account and that of the Strong Program, it is striking that this issue, too, has disappeared without trace. This rewriting of history makes it impossible to understand both the social constructivist doctrines themselves and the scandal they have generated (see Slezak 1997).

31.2.7 Relativism

Despite characterizing their book as focused on "basic foundations," Barnes and colleagues (1996) explain that it "gives little prominence" to such issues as relativism, inter alia. Indeed, a prefatory mention of relativism is the only one in the book. However, relativism has been the central, distinctive theoretical doctrine of social constructivism and the source of most disputes. Neglecting to discuss it is somewhat like a text on evolution professing to concentrate on basic foundations and yet choosing to ignore natural selection. The authors' reticence about their own central, and previously explicitly embraced, doctrines is a telling feature of their work (see Barnes and Bloor 1982). Relativism is at the heart of social constructivism because the supposed absence from the constraints of independent "reality" is assumed to warrant appeal to a sociological account of theory acceptance. Relativism, then, is the spurious assumption that there can be nothing more to say about the goodness of our theories if one cannot meaningfully compare them to an independent, inaccessible reality.

However, the question of realism has been the subject of a vast philosophical literature, and both sides of these philosophical arguments accept the rational force of evidence and the usual considerations of explanatory virtue such as comprehensiveness, coherence, and simplicity as grounds for rational theory choice. Social constructivists mistakenly conclude that the inaccessibility of "things in themselves" behind the veil of our theories (whatever this might mean) precludes saying anything sensible about their cognitive virtues.

31.2.8 Theory Choice: Underdetermination of Theory by Evidence

One consideration, above all, has been widely taken to warrant the appeal to sociological factors in the explanation of scientific theory choice. This is an argument which attempts to exploit the underdetermination of theory by evidence—the

Quine–Duhem thesis that there can be no direct inference from observational data to any particular theory, since indefinitely many theories are equally compatible with the same empirical evidence (see Laudan 1990b, p. 6). Therefore, other considerations must be invoked to explain the preference of scientists for one theory over others which are equally consistent with the observational or experimental data. However, a non sequitur from this thesis has become one of the foundational tenets of the social constructivist enterprise. Thus, when distilled to its essence, the entire case underlying Bloor's (1976) manifesto is a spurious inference from underdetermination to social construction.

However, underdetermination is completely neutral among the various alternative resources which might be invoked to explain theory choice beyond conformity with the evidence. Clearly, it has to be shown independently why it might be social factors rather than some others (say, astrological or theological) which are the operative ones in determining theory choice. Boorse (1975) has pointed out that the underdetermination of theories by all possible observational evidence does not make them indistinguishable on other criteria such as simplicity, fecundity, coherence, comprehensiveness, and explanatory power. These are, of course, the kinds of rational considerations typically invoked by the rationalist or teleological account of the growth of scientific knowledge.

Part of the problem may have arisen from an excessively literal construal of theory choice which cannot be considered an actual selection among equivalent available alternatives. Historians, above all, should recognize that the problem in science is typically to find even a single theory which is consistent with the observations. Accordingly, what is termed "choice" is more appropriately described as the psychology of scientific invention or discovery—the subject of a burgeoning research literature (see Langley et al. 1987; Tweney et al. 1981; Gorman 1992; Giere 1992; Slezak 1989).

31.2.9 Consensus as Conventional

Social constructivism rests on this idea that alternative "choices" are equally "good," for theories are adopted by convention—a view that opens the way to sociological relativism. Barnes et al. (1996, p. 154) assert, "Conventions could always be otherwise" suggesting that knowledge might have been negotiated differently had the local interpretative milieu been different and, thereby, inviting the facetious question about Newton's inverse cube law. Indeed, undaunted, the authors embrace precisely such a paradoxical idea even in the case of arithmetical laws (Barnes et al. 1996, p. 184). According to their own account, given the underdetermination of theory by evidence, sociologists must be committed to the possibility of a consensus settling on a vast range of possible laws via the contingent "collective accomplishment" of "fact production" by "local cultural traditions." They suggest that the consensus on "2+2=4" is due merely to "pragmatic reasons connected with the organization of collective action" and the fact that "it is probably easier to organize" than a different convention such as "2+2=5."

31.2.10 Revisiting Durkheim and Mauss: Recoiling in Dismay

These central ideas of social constructivism have a notable pedigree. Emile Durkheim and Marcel Mauss (1903) in their work *Primitive Classification* claimed that the cosmologies of groups such as the Zuñi reflected precise features of their social structure. In his paper "Revisiting Durkheim and Mauss," Bloor (1982, p. 267) invokes them in support of "one of the central propositions of the sociology of knowledge"—namely, their view that "the classification of things reproduces the classification of men." Bloor recommends that Durkheim and Mauss should be rehabilitated after having been consigned to the history books since their work is important for "showing not merely how society influences knowledge, but how it is constitutive of it" (Bloor 1982, p. 297).

It is understandable, of course, that Bloor should commend the virtues of Durkheim and Mauss, for they offer essentially the same metaphorical links between concepts and contexts which have been the stock-in-trade of the sociology of science. However, the Strong Program emulates *Primitive Classification* to the extent of exactly reproducing its severe shortcomings. Thus, a rather different picture emerges if one takes Bloor's invitation seriously to revisit Durkheim's work in the edition cited by him—including the introduction by Rodney Needham. Needham makes trenchant criticisms of Durkheim and Mauss, which are identical with those which have subsequently been leveled against Bloor's Strong Program.

Needham draws attention to Durkheim's claim which Bloor characterizes without demurral as a "bold unifying principle" but which Needham describes as an unwarranted, abrupt inference and logical error which flaws the entire work. On the alleged parallelism between primitive societies and their concepts, Needham writes:

> Now society is alleged to be the model on which classification is based, yet in society after society examined no formal correspondence can be shown to exist. Different forms of classification are found with identical types of social organization, and similar forms with different types of society. … There is very little sign of the constant correspondence of symbolic classification with social order which the argument leads one to expect, and which indeed the argument is intended to explain (Durkheim and Mauss 1903, p. xvi).

Needham notes further that with respect to one of their claims, their "evidences on this point lend their argument no support whatever" and on another claim "nowhere in the course of their argument do the authors report the slightest empirical evidence, from any society of any form, which might justify their statement" (1903, p. xxii). Needham suggests "Durkheim and Mauss's entire venture to have been misconceived" (1903, p. xxvi). In view of the more recent airing of identical concerns, the following remarks are worth quoting in full:

> Yet all such particular objections of logic and method fade in significance before two criticisms which apply generally to the entire argument. One is that there is no logical necessity to postulate a causal connection between society and symbolic classification, and in the absence of factual indications to this effect there are no grounds for attempting to do so. … If we allow ourselves to be guided by the facts themselves, i.e. by the correspondences, we have to conclude that there are no empirical grounds for a causal explanation. In no single case is there any compulsion to believe that society is the cause or even the model of the

> classification; and it is only the strength of their preoccupation with cause that leads Durkheim and Mauss to cast their argument and present the facts as though this were the case (1903, pp. xxiv–xxv).

Although not mentioned by Bloor, these remarks take on special significance in light of the fact that identical claims of the Strong Program have been repeatedly asserted and repeatedly challenged. Needham draws attention to the extensive evidence which actually suggests a conclusion exactly the reverse of that which Durkheim and Mauss suppose. "That is, forms of classification and modes of symbolic thought display very many more similarities than do the societies in which they are found" (1903, p. xxvi). Needham's sober judgment is:

> We have to conclude that Durkheim and Mauss's argument is logically fallacious, and that it is methodologically unsound. There are grave reasons, indeed, to deny it any validity whatever (1903, p. xxix).

Bloor's enthusiasm for reviving the thesis of Durkheim and Mauss is difficult to reconcile with Needham's judgment, "It is difficult not to recoil in dismay" from their "unevidenced and unreasoned" explanations for the complexities of social and symbolic classification (1903, p. xxiii).

31.2.11 Impartiality

Robert Merton, like Karl Mannheim, argued that theories judged to be correct and founded on rational considerations are not in need of sociological explanation in the way that false and irrational theories are. In this sense, traditional conceptions relegated sociological accounts to the residue of false and irrational beliefs. Bloor's revival of the Durkheimian view was explicitly rescuing sociology from this ignominious role by asserting the appropriateness of sociological explanations for all of science regardless of evaluative judgments such as truth and falsity, rationality and irrationality, and success or failure. Our own cosmology and science in general, like those of the Zuñi, were to be shown to be in their entirety reflections of the social milieu.

Bloor's complaint is directed at asymmetrical approaches such as Lakatos's "rational reconstruction" of episodes in the history of science which sought to explain correct scientific theories as products of reasoned thought and, therefore, not requiring resort to sociological explanations. Bloor regards this approach as having the effect of rendering science "safe from the indignity of empirical explanation" altogether (Bloor 1976, p. 7), but for Lakatos, only sociology was to be excluded from accounts of successful science since reasons are a species of explanation themselves. Analogously, veridical perception does not need explanation in the same way as misperception or illusion. We do not ordinarily seek explanatory causes in the case of normal veridical perception, not because we assume that there is no scientific explanation, but because we assume it to be of a certain general sort. Thus, we seek the cause of perceptual failure (such as the influence of alcohol or disease). In the same way, we do not seek to explain why the train stays on the tracks but only why it fails to do so. Again, this asymmetry does not mean that we believe there is no cause or no explanation for the train staying on the tracks. However, this is the view which Bloor (1976, p. 7) imputes to rationalist philosophers such as Lakatos. In his *Knowledge and Social Imagery*, Bloor characterized the "autonomy of science" view he is opposing:

> One important set of objections to the sociology of knowledge derives from the conviction that some beliefs do not stand in need of any explanation, or do not stand in need of a causal explanation. This feeling is particularly strong when the beliefs in question are taken to be true, rational, scientific or objective (1976, p. 5).

Elsewhere, Bloor characterizes the "rationalistic" view that he opposes as "the claim that nothing makes people do things that are correct but something does make, or cause, them to go wrong" and that in the case of true beliefs, "causes do not need to be invoked" (1976, p. 6). Bloor intends to make an absolute distinction between the "teleological" or "rationalist" view which inclines its proponents to "reject causality" (1976, p. 10), on the one hand, and "the causal view," that is, the sociological approach of the Strong Program. On Bloor's own account, the viability of the Strong Program rests on the tenability of this diametrical opposition and, in particular, the falsity of the "teleological model." There could be no more crucial issue for the constructivist program.

Laudan (1981, p. 178) has characterized Bloor's acausal attribution to philosophers as an absurd view which cannot plausibly be attributed to any philosopher at all. In particular, the approach of Lakatos does not deny the existence of causes in cases of rationally held beliefs, but only assumes that reasons are themselves a species of cause (see Phillips 1997b, p. 100). However, Bloor (1981) responded to Laudan by denying these quite explicit earlier intentions. Bloor's discomfort was understandable, since the entire edifice of the Strong Program rests on this claimed opposition. Indeed, in the second edition of his classic book, in the crucial section on the "Autonomy of Knowledge" dealing with the problem of causation, we discover judicious changes to the original text whose rationale is clearly to avoid the criticisms made by Laudan (see Slezak 1991a).

These alterations are impossible to reconcile with Bloor's prefatorial assertion that "attacks by critics have not convinced me of the need to give ground on any matter of substance" and, therefore, "I have resisted the temptation to alter the original presentation of the case for the sociology of knowledge" apart from minor spelling and stylistic changes (Bloor 1991, p. ix). Despite their significance and implications for the entire sociological Strong Program, the exposé of these alterations (Slezak 1994c) has received little attention in the subsequent literature. Bloor had declared forthrightly, "There is no doubt that if the teleological model is true then the strong programme [sic] is false. The teleological and causal models, then, represent programmatic alternatives which quite exclude one another" (Bloor 1976, p. 9).

31.2.12 Social Constructivism as Born-Again Behaviorism

If the “rationalist, teleological, autonomy” view is not the acausal, anti-empirical straw man that Bloor ascribed to philosophers, then its merits need to be confronted seriously. This means acknowledging the full weight of considerations from cognitive science. This, in turn, means rejecting the hostility to internal, mental, or psychological accounts of rational belief which was a central plank of the Strong Program and other varieties of social constructivism.

The purported causal connection between ideas and social context is actually a version of stimulus-control theory akin to that of Skinnerian behaviorism, and not surprisingly, in his later work, Bloor (1983) explicitly endorses such notorious theories. In characterizing opposing rationalist or teleological views, and quoting Ludwig Wittgenstein, Bloor (1983, p. 6) refers to explanations which postulate mental states as infected by the “disease” of “psychologism.” Bloor’s frontal assault on the explanatory force of mental states is an intrinsic part of the defense of the alternative sociological approach to explaining science, but this bold stance left his program vulnerable to a case on the other side whose strength he had grievously underestimated. For example, anachronistically, Bloor’s program depends on rejecting the reality of mental states such as images.

However, this position is 30 years and a major scientific revolution too late. Thus, Bloor (1983, p. 191) has dismissed Noam Chomsky’s review of B. F. Skinner’s *Verbal Behavior* with a passing footnote and a reference to it as the “fashionable” and “standard” criticism of behaviorism. But this reveals a failure to comprehend its significance. One might have expected some indication of the weaknesses of the review and why this merely “fashionable” criticism is to be ignored—particularly since Skinner himself never replied to it. In fact, the Chomsky review is generally regarded as having precipitated the downfall of the entire tradition of behaviorism in psychology.

Bloor’s handwaving is rather more misleading than these comments suggest. Chomsky’s ideas foreshadowed in this review became the foundations of the dramatic developments of the so-called Cognitive Revolution (see Gardner 1987). Bloor’s failure to indicate the magnitude and import of these developments is comparable to defending Creationism today by dismissing the *Origin of Species* as merely “fashionable” and failing to let one’s readers know anything of modern biology founded on Darwin’s theory.[6]

31.2.13 Newton’s **Principia** *as Conditioned Response*

Since behaviorism is a doctrine concerning psychology, it is at first sight surprising that it has been recruited to the cause of social constructivism. However, behaviorism serves Bloor as an ally, since it denies the explanatory role of internal mental

---

[6] For further discussion, see Papayannakos (2008).

states and is thereby in diametrical opposition to the rationalist or teleological point of view that the Strong Program is also battling. If scientific beliefs are to be construed as the causal effects of an external stimulus, they are precisely analogous to Skinnerian "respondents" or "operants" and, therefore, science is the result of conditioning. In short, the deep insight of social constructivism is that Isaac Newton's *Principia* is to be explained just like a rat's bar-pressing in response to food pellets.

Bloor's recent protest that his views are entirely consistent with cognitive science cannot be taken seriously and can be asserted at all only because Bloor (1991) now pretends that the sociological thesis at stake is merely whether or not there are social aspects to science. This is significantly different from the claim that knowledge is entirely socially constructed and constituted. This new weak and uncontroversial thesis is not the original doctrine he propounded, whose inconsistency with cognitive science was evident from the accompanying assault on rationalism and the postulation of mental states. The truism that there are social dimensions to science would not have generated the opposition and controversy evoked by the Strong Program. Significantly, Bloor's sociological colleagues have reacted differently: their vehement attacks on cognitive science and artificial intelligence have been both telling and more ingenuous. Their strenuous attempts to discredit the claims of cognitive science have given tacit acknowledgment to the threat these pose to the central sociological doctrines (Slezak 1989). Indeed, Collins (1990), among others, has been perfectly explicit on this point, seeing the claims of artificial intelligence as a crucial test case for the sociology of scientific knowledge (Slezak 1991b).

31.2.14 Revolt Against Reason

Social constructivism is essentially the doctrine characterized in an earlier generation by Karl Popper (1966) as the "revolt against reason"—a rejection of certain ideals of truth and rationality which, however difficult to explicate, are nonetheless central to the Western heritage since the Milesian Pre-Socratics. Popper saw the same tendencies in Hegel which he bitterly denounced as "this despicable perversion of everything that is decent." There can be little doubt about the close affinities between Hegel's doctrines and those of social constructivism: Popper (1966, p. 49) observes that for Hegel, "History is our judge. Since History and Providence have brought the existing powers into being, their might must be right." The parallel is seen in their essentially similar answers to Popper's fundamental question, "who is to judge what is, and what is not, objective truth?" He reports Hegel's reply, "The state has, in general…to make up its own mind concerning what is to be considered as objective truth," and adds, "With this reply, freedom of thought, and the claims of science to set its own standards, give way, finally to their opposites" (1966, p. 43).

Hegel's doctrine expressed in terms of the "state" is essentially the idea that political success is ipso facto the criterion of truth. As we will see presently, this idea is resuscitated by Latour and Woolgar, Pinch and Collins, and the entire enterprise of contemporary social constructivism. This is a historical relativism according to which truth is merely political and dependent on the *zeitgeist* or spirit of the age. It is a view which Popper (1966, p. 308) charges with helping to destroy the tradition of respecting the truth, and his discussion of Hegel's "bombastic and mystifying cant" is striking in its aptness to recent sociology of science and is echoed by Gross and Levitt, Laudan and Stove, and among others. Popper warns against the "magic of high-sounding words" and the "power of jargon" to be found in doctrines which are

> … full of logical mistakes and of tricks, presented with pretentious impressiveness. This undermined and eventually lowered the traditional standards of intellectual responsibility and honesty. It also contributed to the rise of totalitarian philosophizing and, even more serious, to the lack of any determined intellectual resistance to it (Popper 1966, p. 395).

31.2.15 Laboratory Life *Under the Microscope*

Perhaps the most obvious cause for such concern is another celebrated, foundational classic of social constructivism, *Laboratory Life* by Latour and Woolgar (1979). This work is self-consciously subversive, rejecting the rules of logic and rationality as a merely "coercive orthodoxy" (Woolgar 1988). It has the avowed goal of deflating the pretensions of science both in its knowledge claims and in its possession of a special method. Among its iconoclastic goals, the book professes to "penetrate the mystique" (Latour and Woolgar 1979, p. 18), dissolve the appearances, and reveal the hidden realities of science-in-the-making at the laboratory workbench. This study purports to give an exposé of the "internal workings of scientific activity" (Latour and Woolgar 1979, p. 17).

Discovering puzzling questions concerning science, Latour and Woolgar conclude that all of science is merely the "construction of fictions" (1979, p. 284). Latour explains the insights emerging from the new discipline:

> Now that field studies of laboratory practice are starting to pour in, we are beginning to have a better picture of what scientists do inside the walls of these strange places called "laboratories." … The result, to summarize it in one sentence, was that nothing extraordinary and nothing "scientific" was happening inside the sacred walls of these temples (Latour 1983, p. 141).
>
> … The moment sociologists walked into laboratories and started checking all these theories about the strength of science, they just disappeared. Nothing special, nothing extraordinary, in fact nothing of any cognitive quality was occurring there (Latour 1983, p. 160).

Needless to say, if warranted, the implications of such insights must be revolutionary, not least for science education. Indeed, the foregoing remarks have been approvingly quoted in a teachers' journal recommending a radical new vision of "the reality of the scientific process" (Gough 1993). Science education is presumably only socialization into power, persuasion, and propaganda. Rather than learning as a cognitive process involving reasoning, logic, and understanding, education involves merely the observance of arbitrary practices and political interest. Although Latour and Woolgar do not explicitly address the questions of most direct interest to educators as such, their characterization of science clearly suggests the appropriate role of the teacher:

> Each text, laboratory, author and discipline strives to establish a world in which its own interpretation is made more likely by virtue of the increasing number of people from whom it extracts compliance (Latour and Woolgar 1986, p. 285).

On this conception, the function of science teacher is extraction of compliance, more like camp commandant than teacher.

31.2.16 Constructing the World

As a façon de parler, the thesis of "constructing facts" permits a sensible reading according to which a theory or description is settled upon and in a certain sense perhaps even "socially negotiated." However, one can also choose to construe such truisms as something more paradoxical—namely, that objects and substances themselves did not have an independent existence and were socially constructed. In like manner, one might say that Copernicus "removed the earth from the center of the universe," but intending this literally would be an attempt at humor or evidence of derangement. Nevertheless, it is just this sort of claim for which the work of Latour and Woolgar has been acclaimed as a defining text in the genre of ethnomethodology of science.

31.2.17 Witchcraft, Oracles, and Magic Among the Academics

On the face of it, the authors' own description of their project in *Laboratory Life* reads like a parody. Upon entering the Salk Institute for a 2-year study, "Professor Latour's knowledge of science was non-existent; his mastery of English was very poor; and he was completely unaware of the existence of the social studies of science" (1986, p. 273). It is from this auspicious beginning that the "revolutionary" insights into science were to emerge.

Of course, these apparent liabilities are portrayed by Latour and Woolgar as a unique advantage, since "he was thus in the classic position of the ethnographer sent to a completely foreign environment" (1986, p. 273). However, the idea that the inability to understand one's human subjects is a positive methodological virtue is surely a bizarre conception. For Latour and Woolgar, however, it is intimately connected with their doctrine of "inscriptions." The meaninglessness of the "traces, spots, points," and other recordings being made by workers in the laboratory is a direct consequence of Latour's admitted scientific illiteracy. Predictably, all these symbols are indiscriminable to an observer who is completely ignorant, and they must, therefore, be placed in the category of unintelligible markings or "inscriptions." Avoiding the possibility of understanding their subjects' behavior is justified on the grounds that just as the anthropologist does not wish to accept the witch doctor's own explanations, so one should remain uncommitted to the scientists' rationalizations too. However, this attitude follows from the simple failure to appreciate the difference between *understanding* the native and *believing* him.

31.2.18 Persuasion by Literary Inscription and Achieving Objects by Modalities

It is from a point of view of ignorance and incomprehension that Latour comes to rely on a "simple grammatical technique" in order to discern the true significance of the papers accumulating in the laboratory in which he was doing the fieldwork. Undeniably, this method has great merit as an alternative to undertaking many years of undergraduate study and postgraduate work as preparation for his fieldwork. On this grammatical basis, then, Latour and Woolgar obtain their insight: "Activity in the laboratory had the effect of transforming statements from one type to another" (1986, p. 81). Specifically, the rationale of the laboratory activities was the linguistic exercise of transforming statements in various ways in order to enhance their "facticity."

Thus, we see how Latour and Woolgar arrive at their celebrated social constructivist conclusions. They maintain that "a laboratory is constantly performing operations on statements," (1986, p. 86) and it is through this process that "a fact has then been constituted" (1987, p. 87) by social negotiation and construction. In short, the laboratory must be understood "as the organization of persuasion through literary inscription" (1986, p. 88). These are the grounds on which we must understand their claims that substances studied in the laboratory "did not exist" prior to operations on statements (1986, p. 110, 121). "An object can be said to exist solely in terms of the difference between two inscriptions" (1986, p. 127).

31.2.19 Poison Oracles and Other Laboratory Experiments

From the meaninglessness of the "inscriptions" and his revelation that "the 'scientificity' of science has disappeared" (Latour 1983, p. 142), Latour is led inexorably to a "naive but nagging question"—namely, "if nothing scientific is happening in laboratories, why are there laboratories to begin with and why, strangely enough, is the society surrounding them paying for these places where nothing special is produced" (Latour 1983, p. 141)? This is undoubtedly a deep mystery if one systematically refuses to understand the meaningfulness of the "inscriptions" on these papers.

On the analogy of the "anthropologist's refusal to bow before the knowledge of a primitive sorcerer" (1986, p. 29), Latour and Woolgar refuse to accept the authority of our best science, saying, "We take the apparent superiority of the members of our laboratory in technical matters to be insignificant, in the sense that we do not regard prior cognition … as a necessary prerequisite for understanding scientists' work" (1986, p. 29). The affectation that Latour was like Evans-Pritchard among the Azande is "anthropological strangeness" in a rather different sense of the term: No anthropologist was ever so strange. Given his method, predictably, Latour finds the activities in the laboratory completely incomprehensible. Undaunted, and unwilling to allow this to become a liability, it becomes, in fact, the deep insight of *Laboratory Life.* The behavior of the scientists not only appears meaningless, it is meaningless. In their conclusion, Latour and Woolgar reveal that "[a] laboratory is constantly performing operations on statements" (1986, p. 86) and the activities of the laboratory consist in manufacturing "traces, spots, and points" with their "inscription devices." The production of papers with meaningless marks is taken to be the main objective of the participants in essentially the same way that the production of manufactured goods is the goal of any industrial process.

31.2.20 "Derridadaism": Readers as Writers of the Text

Concern about the perversity of this work arises from the fact that in the new edition of their book, Latour and Woolgar (1986) tell us that laboratory studies such as their own should, after all, not be understood as providing a closer look at the actual production of science at the workbench, as everyone had thought. This view would be "both arrogant and misleading" (1986, p. 282) and would presume they had some "privileged access to the 'real truth' about science" which emerged from a more detailed observation of the technical practices. Instead, Latour and Woolgar explain that their work "recognizes itself as the construction of fictions about fiction constructions" (1986, p. 282). This is the textualism of Jacques Derrida combined with a much-vaunted "reflexivity." They continue, "all texts are stories. This applies as much to the facts of our scientists as to the fictions 'through which' we display their work." Their own work, then, just like all of science, has no determinate meaning since "[i]t is the reader who writes the text" (1986, p. 273).

Here, we see a notorious deconstructionist affectation which conveniently serves to protect Latour and Woolgar against any conceivable criticism. The contrast with the work of Bloor is interesting: Where Bloor professes to adhere to the usual principles of scientific inquiry, Latour and Woolgar engage in a game David Lehman (1991) has aptly called "Derridadaism." They manage to evade criticism only by adopting deconstructionist double-talk and affecting a posture of nihilistic indifference to the ultimate cogency of their own thesis. In keeping with the principle of reflexivity, they embrace the notion that their own text (like the science they describe) has no "real meaning," being "an illusory, or at least, infinitely renegotiable concept" (Latour and Woolgar 1986, p. 273).

Reflecting on the controversies surrounding their work, Latour and Woolgar observe that defenders and critics alike have been duped into engaging in this futile "spectacle" in which they have debated the presumed intentions of the authors.

This “spectacle” is, of course, just the traditional exercise of scholarly criticism. Latour and Woolgar now reveal that the “real” meaning of a text must be recognized as illusory and indeterminate. Questions of what the authors intended or what is reported to have happened “are now very much up to the reader.”

This Rorschach inkblot view of their own work is undoubtedly correct in one sense, if only because *Laboratory Life* is in many respects completely incoherent and unintelligible. For example, some of the diagrams offered as explanatory schemas are impossible to decipher. Above all, it is sobering to consider how science teaching might be conducted in accordance with this model of scholarship. Perhaps an indication can be seen in the notorious constructivist claim of Sandra Harding (1986) that Isaac Newton’s *Principia* is a “rape manual.”

31.2.21 Balance of Forces

Though the implications of social constructivism are not drawn out by the authors, these are not difficult to discern. Thus, once Latour and Woolgar reject “the intrinsic existence of accurate and fictitious accounts per se,” the only remaining criterion for judgment is judgment itself. They say “the degree of accuracy (or fiction) of an account depends on what is subsequently made of the story, not on the story itself” (1986, p. 284). There are no grounds for judging the merits of any claim besides the “modalizing and demodalizing of statements,” a purely political question of persuasion, propaganda, and power.

Thus, they suggest that the very idea of “plausibility” of any work, including their own, is not a rational, intellectual, or cognitive question, but simply a matter of political redefinition of the field and other such transformations involving shift in the “balance of forces.” In particular, the current implausibility of their own theory is only due to its relative political disadvantages rather than the lack of any intellectual merits. Apart from being a self-serving justification of any nonsense at all, one could hardly find a more open endorsement of the doctrine that “might is right.” The very distinction between education and indoctrination becomes impossible to draw.

31.2.22 Education: Truth as Power

The bearing of these doctrines on educational questions is starkly brought out in Chomsky’s remarks:

> It is the responsibility of intellectuals to speak the truth and to expose lies. This, at least, may seem enough of a truism to pass without comment. Not so, however. For the modern intellectual, it is not at all obvious (Chomsky 1969, p. 257).

Chomsky quotes Martin Heidegger in a pro-Hitler declaration, echoing social constructivist ideas that “truth is the revelation of that which makes a people certain, clear and strong in its action and knowledge.” Chomsky remarks ironically that for

Heidegger, it seems that it is only this kind of "truth" that one has a responsibility to speak, that is, the "truth" which comes from power. In the same vein, we have seen Latour and Woolgar assert that the success of any theory is entirely a matter of not persuasion but politics and power extracting compliance. On this theory, a repressive totalitarian regime must count as a model of scientific success.

31.2.23 Mertonian Norms: The Ethos of Science

On such a theory, it is impossible to distinguish fairness from fraud in science since, after all, both are ways of constructing fiction. In the absence of the usual distinctions, the scientist who fraudulently manufactures his evidence cannot be meaningfully distinguished from the honest researcher whose data are also "constructed," albeit in different ways. The problem arises from the social constructivists' rejection of the famous Mertonian norms of universalism, communism, disinterestedness, and organized skepticism which constitute the "ethos of science" (Merton 1942). Merton described these as institutional imperatives, being "moral as well as technical prescriptions," that is, "that affectively toned complex of values and norms which is held to be binding" on the scientist. As Merton observes, these institutional values are transmitted by precept and example, presumably in the course of the scientist's education. It is difficult to see how someone committed to the social constructivist view can either teach or conduct science according to the usual rules in which truth, honesty, and other intellectual and ethical measures of worth are taken seriously.

31.2.24 Facticity and Maintaining One's Position

In articulating the same political view of scientific claims, social constructivist authors stop short of openly encouraging cheating and other forms of dishonesty in science, but there can be no mistake about what their theory entails. Thus, when examining a dispute concerning the claims of parapsychology or astrology, Pinch and Collins (1984) draw attention to symmetries in the attempts of opponents to maintain their commitments—in one case, to orthodox science and, in the other, to the paranormal. However, from the standpoint of scrupulous sociological "neutrality" or "impartiality" regarding the intellectual merits of the case on each side, there can be no way to discriminate the relative merits of either the arguments or the evidence itself.

In the case study offered by Pinch and Collins, both sides make questionable attempts to protect their favored theory against contrary evidence and, indeed, the scientists appear to have been less than completely forthright about some disconfirming evidence. Pinch and Collins wish to generalize from this to a thesis about science as a whole by construing it as a typical case, that is, as evidence of the way in which public scrutiny removes the mystique of science and exposes its socially constructed, negotiated character. Such exposé serves to "dissolve the facticity of the claims."

Pinch and Collins are unwilling to see such episodes as anything other than the way science always operates—not because all scientists are dishonest, but because the very distinction relies on being able to discriminate fact from fiction. When the scientists finally admit their error and revise their earlier stance in the light of falsifying evidence, they are ridiculed by Pinch and Collins for their grandiose, mythical pretensions and for appearing to adopt "a mantle of almost Olympian magnanimity" (Pinch and Collins, 536). The scientists are reproached for failing to "re-appraise their understanding of scientific method" and to learn about its "active" character, that is, about the way in which "facts, previously established by their presentation in the formal literature [sic], can be deconstructed" (1984, p. 538) by public scrutiny of the informal, behind-the-scene reality of science.

Remarkably, however, Pinch and Collins suggest that the right lesson about science was that "provided they had been prepared to endorse the canonical model in public while operating in a rather different way in private, they could have maintained their position" (1984, p. 539). In other words, if they had been even more dishonest, they would have been right—in the only sense of "right" possible, that is, they would have "maintained their position." The status or "facticity" of a claim is just a matter of how the claim is publicly presented, and the literature can either construct or "dissolve the facticity of the claims" (1984, p. 523). If we drop all this jargon, their point is simply that truth is what you can get away with.

31.2.25 Altering the Grounds of Consensus: Affirmative Action?

In practice, through the feigned suspension of judgment, social constructivism has led to explicit advocacy of discredited or disreputable pseudoscience. Pinch (1993) and Ashmore (1993) go so far as to defend the supposed "merits" of unorthodox and rejected theories on the grounds of equity. Not least, this policy is evidently taken to include the case of fraud since this "is to be seen as an attributed category, something made in a particular context which may become unmade later" (Pinch 1993, p. 368). Ashmore proposes a radical skepticism concerning the exposé of notorious cases of misguided science such as that of Blondlot's N-rays. Amid the usual jargon-laden pseudotechnicality, such an approach amounts to actually promoting the alleged scientific merits or deserts of such discredited cases. Thus, Pinch writes of "making plausible the rejected view" (1993, p. 371) and Ashmore is perfectly explicit: "To put it very starkly, I am looking for justice! … in a rhetorically self-conscious effort to alter the grounds of consensus" (Ashmore 1993, p. 71). Again, the educational implications for the curriculum should hardly need drawing out. The "impartiality" defended by radical social constructivism has come to mean something like affirmative action for bullshit.[7]

---

[7] This may be regarded as a technical philosophical term since Frankfurt's (2005) celebrated article. However, my use of the term does not fit Frankfurt's taxonomy.

31.3 Conclusion

The two main varieties of constructivism considered here have different, but dramatic, consequences for science education. The psychological or "radical" constructivism of von Glasersfeld has had a direct and wide influence on educational theory and practice and makes extravagant claims to overturn the entire tradition of Western epistemology and pedagogical theory. However, when examined critically, radical constructivism appears to offer only commonplaces and platitudes.

By contrast, there could be no more fundamental challenge to science education than the one posed by the sociology of scientific knowledge, since social constructivism purports to overthrow conceptions of rationality, truth, and evidence to be replaced by fashion, negotiation, and consensus. On this view, science is a social institution just like any other. According to social constructivism, there can be no difference between true and false, fact and fiction, fair and fraudulent. On this account, the greatest achievements of the creative human intellect are merely accidents of social context. Isaac Newton was just lucky to be in the right place at the right time.

Peter Slezak is Associate Professor in Philosophy at the University of New South Wales. His B.A. was from University of New South Wales, and his M.Phil. and Ph.D. in Philosophy from Columbia University, New York. Dr. Slezak is Series Editor for Elsevier's "Perspectives on Cognitive Science" and on the editorial board of several leading journals. Dr. Slezak's teaching areas include philosophy of science, philosophy of religion, Galileo, and philosophy of mind and cognitive science. His research publications are in the areas of and philosophy of mind and philosophy of language and cognitive science with special interests in problems of mental representation and the work of René Descartes. He has also published widely on science education and the sociology of science as a combatant in the "Science Wars."

Chapter 32
Postmodernism and Science Education: An Appraisal

Jim Mackenzie, Ron Good, and James Robert Brown

32.1 Introduction

Though not easy to define, postmodernism has elicited strong reaction, both laudatory and critical. Some see it as liberating us from the tyranny of science, while others see it as a new form of insanity. It has kinship with some feminist and social constructivist approaches to science, though the overlap is limited. This three-part article will attempt to outline and evaluate some of the main ideas.

Postmodernism in different forms has had, inevitably, an impact on education and specifically science education. A number of countries have explicitly stated that their national science curricula are based on postmodern understanding of science and human knowledge claims. Constructivism, which has been a most influential force in science and mathematics education, is one manifestation of the educational reach of postmodernism. A great deal of research and curriculum construction in multicultural education is predicated on postmodernist epistemological assumptions.

This chapter will first document and give a sense of the impact of postmodernism in science education curriculum and research, then delineate and give some evaluation of the rise of postmodernist positions in philosophy and philosophy of science, and finally return to appraise some of the chief postmodernist arguments and claims in science education. The separate contributions by Good, Brown and Mackenzie have been interwoven to some extent to minimise overlap in their discussion. It will

be readily appreciated in a complex and controversial topic such as this that the authors will stress different features and not be in full agreement on every detail. Their respective contributions are indicated by initials in the text.

32.2 Part One [R.G.]

32.2.1 Postmodernism in Science Education

In November 1992, the US National Research Council published *National Science Education Standards: A Sampler* and on page A-2 was this statement: 'The National Science Education Standards are based on the postmodern [PM] view of the nature of science'.

For our purposes in this chapter, we will use this statement to mark the beginning of the recognition of PM as an underlying force in the US effort to reform science education. As soon as this statement became known to scientists and others familiar with the history and nature of PM, it was opposed and omitted from later versions of the *Standards*. Among the public statements of opposition, there are two that appeared as editorials in professional journals and each is summarised here. The first, entitled 'The Slippery Slopes of Postmodernism', appeared in the May 1993 issue of *The Journal of Research in Science Teaching* and the following two statements (p. 427) are representative of the overall editorial:

> To question the *objectivity* of observation or the *truth* of scientific knowledge, one does not need to travel to the wispy world of postmodernism. Logical positivism and postmodernism are at the extremes of a long continuum of positions taken by scholars of the nature of science. It is not necessary to carry along the unwanted baggage of either logical positivism or postmodernism to place oneself, as did the authors of *Science for All Americans*, in a more *scientifically* defensible position.
>
> Science education research, like the science education standards being developed by the National Research Council, should be well-grounded on defensible assumptions about the nature of science. The postmodernism of Feyerabend, Foucault, and their followers offers very little insight about the nature of biology and chemistry and physics and so on, that can help in the reform of science education.

Following this editorial, an editorial entitled 'Postmodernism' appeared in the July 9, 1993, issue of *Science*, the journal of the American Association for the Advancement of Science (AAAS). *Science* editor Richard Nicholson begins by questioning whether there is a growing anti-science attitude, providing examples of recent criticisms. He then goes on to ask:

> Are these [criticisms] just isolated events or is something more going on? Harvard's Gerald Holton recently addressed this question from the historian's perspective in a Sigma Xi speech. Holton says "the discussion about science and values has been shifting in remarkable ways" and in this he sees a trend. The trend even has a name: The Postmodern Movement. It is decidedly anti-science. Holton acknowledges that today this movement represents "a minority view." However, he goes on to warn, "but a view held in prominent circles, among persons who can indeed influence the direction of a cultural shift.

An early systematic contribution of postmodernist thinking to education was William Doll's book *A Post-Modern Perspective on Curriculum* (Doll 1993). As a curriculum theorist known for his postmodern perspective, Doll reaches into science and mathematics to the uncertainty theory of Heisenberg, the incompleteness proof of Godel, and especially the chaos theory of Prigogine to craft his vision of a postmodern world. In a separate chapter on 'Prigogine and Chaotic Order', Doll uses a variety of examples, from chaotic pendula to chaotic change in gypsy moth populations to entropy interpretations that supposedly show how evolution can achieve 'perfectibility and perfection of humankind' (p. 100) in his attempt to envision a new postmodern world. According to Doll the paradigm he sees emerging from the insights of chaos theory 'requires of us nothing less than a brand new start in the description of nature—a start which will affect our metaphysics as well as our physics, our cosmology as well as our logic' (pp. 90–91).

In his 1993 book *Science and Anti-Science*, Holton discusses the anti-science phenomenon in detail in the last chapter and some of that discussion is used to focus attention on what he calls the single most malignant part: 'the type of pseudo-scientific nonsense that manages to pass itself off as an *alternative science*, *and does so in the service of political ambition*' (p. 147). He goes on to describe the relatively poor level of scientific literacy in the USA and warns of the dangers to democracy of a poorly informed public, especially in the sciences:

> Today there exist a number of different groups which from their various perspectives oppose what they conceive of as the hegemony of science-as-done-today in our culture. These groups do not form a coherent movement, and indeed have little interest in one another; some focus on the epistemological claims of science, others on its effects via technology, others still long for a romanticized pre-modern version of science. But what they do have in common is that each, in its own way, advocates nothing less than the end of science as we know it. That is what makes these disparate assemblages operationally members of a loose consortium. (p. 153)

In science education, Holton's postmodernist *loose consortium* consists of radical constructivism, queerism, variants of multiculturalism, some versions of feminism and more recently 'cultural studies of science education' (CSSE). They all share a family resemblance of postmodern ontology, epistemology, psychology and social theory. The following four claims are representative of the convictions of this consortium and indicate what is being contested in the 'science education wars'.

Claim One:

> We have to learn how to de-privilege science in education and to free our children from the *regime of truth* that prevents them from learning to apply the current cornucopia of simultaneous but different forms of human knowledge with the aim to solve the problems they encounter today and tomorrow (Van Eijck and Roth 2007, p. 944).

This first statement was published in *Science Education,* a well-established, highly regarded professional journal.

Claim Two:

> In the field of science education, the current views of scientific language and scientific literacy are based on an epistemology that begins the [sic] presupposition of the identity of a thing with itself – both the phenomenon of representation (inscription) and the figure of

> the scientist as rational thinker and actor are premised on this identity. However, recent philosophical scholarship generally and the French philosophers of difference particularly – including Gilles Deleuze, Jacques Derrida, Didier Franck, Jean-Luc Nancy, and Paul Ricœur – take a very different perspective on the question of language. This perspective emphasizes the opposite, that is, the non-self-identity of a thing or person with it or him/herself, which is a conception more compatible with our experiential reality. This perspective also allows us to better theorize the learning of science and scientific literacy in the indeterminate manner in which it is actually experienced and observed (Roth et al 2008, p. 153).

Claim Three:

> Even more hidden and therefore more difficult to recover is the epistemological ground that presupposes equality (e.g., of gender) and sameness (identity of, for example, A and A in the equation A=A) rather than recognizing the inherent plural singularity of each human being. …
>
> If, on the other hand, we begin with the ontological assumption of difference that exists in and for itself, that is, with the recognition that A A (e.g., because different ink drops attached to different paper particles at a different moment in time), then all sameness and identity is the result of work that not only sets two things, concepts, or processes equal but also deletes the inherent and unavoidable differences that do in fact exist. This assumption is an insidious part of the phallogocentric epistemology undergirding science as the method of decomposing unitary systems into sets of variables, which never can be more than external, one-sided expressions of a superordinate unit (Roth and Tobin 2007, pp. 99–100).

The second and third statements were published in a book series *New Directions in Mathematics and Science Education*.

Inasmuch as the third claim can be understood, it lays out what is at stake if postmodernism becomes further established in the science education community. The very achievements of Galileo and Newton depend on studying wholes (falling bodies and planetary motion) by dissolving them into parts (horizontal and vertical motions on an inclined plane and the moon-earth-sun orbits as a 3-body that neglected the effects of other planets, not a multi-body problem as it actually was). Without abstraction and idealisation, science goes nowhere, likewise of course for social science. The latter advances and discovers some things by dividing populations into classes and ascertaining average class weights, health, longevity, etc. and then looking for causal factors in a controlled manner. That no one embodies the 'average weight' does not mean that the construct is mythical and of no use in promotion of public health. In most scientific investigations, the whole cannot be grasped in toto, only in parts. The apple remains red, juicy and attractive even if physicists studying its rate of fall ignore all of this and even if economists likewise abstract from these real features and study the apple's exchange value in a given economic context. In none of this is the reality of the whole apple denied.[1]

This should be a basic lesson learned in science classes, not the reverse lesson that the above authors want students to learn, namely, that such method is 'insidious' and 'phallogocentric'. A historically and philosophically literate science teacher can assist students to grasp just how science captures, and does not capture, the real, subjective, lived world—the 'life world' as it is called by phenomenologists.

---

[1] On this important topic, see at least Harré (1989), McMullin (1985) and Nowak (1980).

An HPS-illiterate teacher, or science educator, leaves students with the unhappy choice between disowning their own world as a fantasy and rejecting the world of science as a fantasy, with, sadly, many doing the latter. Aldous Huxley, at the end of World War Two, commented on this matter saying:

> The scientific picture of the world is inadequate, for the simple reason that science does not even profess to deal with experience as a whole, but only with certain aspects of it in certain contexts. All of this is quite clearly understood by the more philosophically minded men of science (Huxley 1947, p. 28).

Claim Four:

> This centripetal tendency of science—a hegemonic, homogenizing force—is well described in the 'pasteurization' of France: Louis Pasteur's science works only when stables in the countryside are made to resemble laboratories, where re-presentations of nature come to be the same irrespective of time and space (Latour 1984); these re-presentations constitute, in Bakhtinian terms, a particular form of chronotope (time-space) (van Eijck and Roth 2011, p. 825).

> Novelization therefore models a process of cultural change toward democracy. In fighting 'for the renovation of an antiquated … language,' novelization is in the interest of those who are located 'outside the centralizing and unifying influence of … the ideological norm established by the dominant literary language.' Novelization constitutes a process of continuous 'linguistic stratification and differentiation' (Bakhtin 1981, p. 67) toward heteroglossia, a process that others much later have referred to as the 'multiplication of meaning' that comes about as the same and different means of expression are produced and stratified (Lat. *Stratum*, spread, layer) one on top of the other (e.g., Lemke 1998) (ibid, pp. 831–2).

> We propose abandoning the dominant notion of science curricula as inculcating the canonical scientific discourse of yesteryear, since this notion comes with its maintenance of a unitary language and hence cultural centralization that does not allow for valuing and keeping cultural diversity in science education (ibid, 840).

This article—'Cultural Diversity in Science Education Through "Novelization": Against the Epicization of Science and Cultural Centralization'—was published in the *Journal of Research in Science Teaching* which is considered by many to be the top professional journal of research devoted to science education and is the official journal of the world's largest science education research organisation (NARST).

After repeatedly warning that traditional science and science education are 'epics' that must be changed through 'novelisation' to ensure the future of multiculturalism and democracy, van Ejick and Roth warn against becoming too successful because that will 'institute the epicisation of novelisation'. In their words:

> We conclude this text with a word of caution. If novelization were to be the name of a form of science education that we aim at and eventually achieve, a new canonical form, then we would have done nothing other than institute the epicization of novelization (p. 843).

It is not difficult to see why one might dismiss this 'epic' project, and more generally, the CSSE project represented in the foregoing four claims, with words like 'a stupid and discreditable business', as Stove (1991) did when summarising the SSK project; 'Fashionable nonsense', the phrase used by Sokal and Bricmont in the title of their 1998 book that describes the postmodern agenda in SSK; or simply as pieces of execrable and inexcusably bad writing designed not to communicate but to obfuscate.

The postmodern movement in science education created its academic home in 2006 with publication of the journal *Cultural Studies of Science Education* with Kenneth Tobin and Wolff-Michael Roth as founding editors. Their aspirations for the journal were expressed as:

> In many ways, this new journal departs from the trodden paths in our discipline. CSSE is unique in focusing on the publication of scholarly articles that employ social and cultural perspectives as foundations for research and other scholarly activities in science education and studies of science. The journal encourages empirical and non-empirical research that explores science and science education as forms of culture, enacted in a variety of fields that are formally and informally constituted. ….We anticipate that the forms of dissemination will make visible the non-linearity of doing research and the recursive nature of delineating problems, deploying theoretical frameworks, constructing data, and adopting dynamic approaches to methodology, design, analysis, interpretation, and writing (Tobin and Roth 2006, p. 1).

What 'dynamic approaches' to methodology, design, analysis and interpretation might mean is left unstated, but the passage itself exhibits what a postmodern 'dynamical' approach to writing might be and why it should be avoided. George Orwell long ago warned of what happens in societies and cultures when such obfuscatory writing goes unchecked and becomes normalised (Orwell 1945).

It is difficult to measure the impact of the many CSSE books and articles in professional journals on the actual science curriculum and instruction in our schools; but the professional recognition given to its proponents is significant (see Chap. 39). The wider cultural and philosophical background that gave rise to postmodern enthusiasm in science education will be outlined in the following sections.

32.3 Part Two [J.M.]

32.3.1 What Is Postmodernism?

The term 'postmodern' was imported into discussions of knowledge (from architecture) by Jean-François Lyotard in *The Post Modern Condition* (1979, tr. 1984) and signified, if nothing else, a suspicion of, and scepticism about, grand narratives or universal claims. In practice, this extended to an opposition to rationality, a rejection of the notion of objective truth and an enthusiastic endorsement of localism (see Brown 2001, p. 76). The opposition to rationality took the form of supposing that scientists' behaviour served only their own social interests and discounting any suggestion that it was related to scientific evidence. In taking this position, the investigator is claiming to know what the scientists' interests are and attributing to those interests efficacy as causes. This is exactly the kind of knowledge of the topic under investigation that they denied scientists could have.[2] The rejection of objective truth

---

[2] Harry Collins and Steven Yearley argued: 'Natural scientists, working at the bench, should be naïve realists—that is what will get the work done. Sociologists, historians, scientists away from the bench, and the rest of the general public should be social realists. Social realists must experience

recalled the grand tradition of scepticism and its traditional tropes, which goes back to Sextus Empiricus in around the year 200 CE.

> Those who claim for themselves to judge the truth are bound to possess a criterion of truth. This criterion, then, either is without a judge's approval or has been approved. But if it is without approval, whence comes it that it is truth worthy? For no matter of dispute is to be trusted without judging. And, if it has been approved, that which approves it, in turn, either has been approved or has not been approved, and so on *ad infinitum* (Sextus Empiricus, *Adv. Log.* I 340 = 1935, p. 179).

But Lyotard and others formulation was more than usually conceptually muddled. The localism was adopted as a measure to combat totalising theory which was blamed for the wars and violence of the nineteenth and twentieth centuries. 'We have paid a high price for the nostalgia of the whole and the one …', said Lyotard (1983, p. 46), characteristically exaggerating just how consequential the role of those like himself had been. How academic papers in the humanities and social sciences had made any significant contribution to promoting wars and violence was left unexplained.

32.3.2 Thomas Kuhn and the Origins of Social Constructivism

Science is a social construction. It is an account of the world that has been, and is still being, put together by people. Many would regard this as so obvious as to be hardly worth saying. Nevertheless, over the past thirty or forty years, it has become the slogan of some science educators. They clearly think that it is somehow an important thing to say, one which is contrary to accepted ideas. Keith Tobin proclaimed: 'In 1997 I took a bold step in pronouncing that learning involved cultural production' (2010, p. 23). (It is difficult to think of any pronouncement which would have been less bold.) From their slogan the science educators draw a number of substantive conclusions about science education, such as an emphasis on the social aspects of how children learn science, and advise teachers also to concentrate on these aspects of what they do in the classroom. We need to ask how an idea which would hitherto have been regarded as banal could have come to seem so controversial and significant.

The stage for the conventional landscape in philosophy of science in the twenty-first century was set by a conference on July 13, 1965, at the then Bedford College of the University of London organised by Imre Lakatos. This conference was intended to oppose two thinkers. One was Karl Popper, an Austrian educated philosopher of science, whose seminal book *The Logic of Scientific Revolutions*, though published in German in 1934, had only been available in English since 1959. Popper was more widely known in the English-speaking world for his works on political

---

the social world in a naïve way, as the day to day foundation of reality (as natural scientists naively experience the natural world). That is the way to understand the relationship between science and the rest of our cultural activities' (Collins and Yearley 1992, p. 308).

philosophy, *The Poverty of Historicism*, published in three parts in the journal *Economica* in 1944–1945 and in book form only in 1957, and *The Open Society and its Enemies*, first edition 1945. The other was Thomas Kuhn, a Harvard historian of science, whose book *The Structure of Scientific Revolutions* was published in 1962. In organising the debate, Lakatos may have hoped that the debate would cast Popper and Kuhn as the opposing poles, allowing his own position to come through the middle as a less extreme compromise, embodying the strengths of each side. Also present was Paul K. Feyerabend, a former student of Popper, a former colleague of Kuhn at the University of California Berkeley and commentator on drafts of Kuhn's book and a correspondent of Lakatos himself.

But what were the two sides? In conventional accounts of philosophy of science today, they are generally represented with Popper as standing for a narrowly conceived prescriptive view of science, modelled on physics, and as rejecting almost everything apart from physics as insufficiently scientific to merit the name and with Kuhn as a radical, open-minded thinker, firmly based on a sound understanding of the history of the sciences and accepting a wide range of disciplines. That, after all, is how things would surely develop, from narrow to broad, from rigid to flexible and from prescriptive to empirical, and that is how those who compose textbooks most easily organise things. The temptation was perhaps exacerbated by the ages of the principals and the climate of the times: Popper was on the verge of retirement and Kuhn was some 20 years younger, and the social and intellectual turmoil of the 60s was beginning.

Nevertheless, this conventional picture has things almost exactly the wrong way round. Popper had indeed studied physics and used it as an example, and he did draw careful lines of demarcation among theories between those he would accept as scientific and those which were not, framed in terms of falsification by observation. He did not, unlike the positivists of the Vienna Circle, reject what was not scientific as meaningless nonsense: mathematics, history and ethics were all important and reputable disciplines, even though they did not count as science by his criterion. His criterion did, however, exclude from among the sciences not only such soft targets as astrology but the psychoanalysis of Freud and the dialectical materialism of the followers of Marx (Marx's own version may have been scientific, but if so it had already been falsified). Popper rejected traditional ideas of science having to have secure foundations. He was very aware of the need for a social structure to enable scientists to compare, test and above all criticise ideas—science for Popper could not be a merely personal or subjective activity.

Kuhn had begun his academic career as a physicist, and one of the motives behind his work was a desire to explain, or at least to characterise, the difference separating the natural sciences like physics, where practitioners largely agree about what is good work and what is not, from history and other areas in the social sciences, where the very criteria for evaluation are contested. Kuhn proposed as the distinguishing mark of a science that a scientific community shared what he called a *paradigm*, by which he meant an exemplar that serves as a model for future research. To be more specific would be risky: Margaret Masterman (1970) enumerated more than twenty different meanings of the term ‘paradigm’ in Kuhn’s 1962 book. In non-sciences such as history or the study of society, there was no paradigm, and therefore no agreement about what constituted acceptable research. In a science governed by a paradigm, research was merely the working out of puzzles within the universe of the paradigm.

Like the positivists of the Vienna Circle, Kuhn required that science have a solid foundation, but whereas they had sought a foundation in eternally true principles of logic, for Kuhn the foundation lay in the historically situated social practices of interpretation and understanding of a professional community. Since these were not eternal, they were subject to change. For Kuhn, this occurred when ‘normal science’ broke down, increasing numbers of puzzles resisted solution, anomalies multiplied and the community began to be eroded by feelings of anxiety and insecurity. Half-formed ideas about how to proceed would be produced and developed and compared with one another. For a Popperian, this was how a science should be at any time; for Kuhn, it was a suspension of science, a reversion to pre-scientific confusion and a crisis. Popper would hope that the crisis might be resolved, if at all, by members of the scientific community becoming rationally convinced by evidence and arguments that at least some of the competing views should be abandoned and perhaps that all but one should be. Kuhn (1962, p. 150) cited the reminiscences of Max Planck, who in his *Autobiography* (1950, pp. 33–4) had said that a new scientific theory succeeds not by convincing its opponents but by the opponents dying and a new generation familiar with the theory growing up. Though he immediately (p. 151) insisted that scientists were sometimes persuaded by arguments and that on occasion a scientific community would change its mind in advance of biological succession of the next generation, Kuhn’s underlying account of the adoption of a new paradigm is by comparison to the phenomenon of religious conversion.

Initially Kuhn’s work was faced with severe criticisms, ranging from positivists and Popperians to more straightforward historians of science, let alone those worried by its ambiguities and inconsistencies. And of course Kuhn has retracted and qualified many of his claims and has regretted writing ‘the purple passages’ (Kuhn 1991/2000; 1993). But over the last twenty years, a new generation has grown up in the relevant disciplines who take Kuhn unproblematically as the paradigm for the study of science, and who are quite unaware of the original, and often still unanswered, criticisms. The uncritical embrace of Kuhn is especially apparent in the science education community (Matthews 2004).

32.3.3 The Possibility of Objective Truth

A major rhetorical weapon of sceptical positions is to sow doubt about the concept of objective truth. Objectivity presupposes the ability to distinguish the significance a remark has from the perspective of the person to whom it is attributed from its significance from the perspective of the one doing the attributing. As Donald Davidson pointed out, this becomes especially clear when a thought is attributed to a non-verbal creature. ‘The dog, we say, knows that its master is home. But does it know that Mr. Smith (who is his master), or that the president of the bank (who is that same master), is at home?’ (1984, p. 163). Brandom elucidates, ‘The dog knows *of* the president of the bank that he is home, he just does not know *that* the president is home. … [O]ne wants to appeal to the belief that his master is home to explain why the dog is so happy, and to its being a belief *of* the president of the bank (whether the dog knows this or not) in order to explain why one result of the dog’s happiness is that he slobbers on the president of the bank’ (1994, p. 710, n. 95). The same claim is specified differently depending on whether we consider its inferential antecedents and consequences in the context of what is admitted by the attributer or by the one to whom the claim is attributed.

It is this notion of objective truth conditions that makes explicit the possibility of mistaken belief, and so of the difference between what is merely held to be true (believed) and what is correctly held to be true. But objectivity is undermined if the objective correctness of a claim is taken to be what is endorsed by a privileged point of view, such as that of ‘we’, or of the community as a whole. That privileging would leave no possibility for the chosen point of view to be itself mistaken. For objectivity to be possible, no point of view can be globally privileged. Objectivity consists in a perspectival form, rather than any possibility of a non-perspectival content. ‘What is shared by all discursive perspectives is *that* there is a difference between what is objectively correct in the way of concept application and what is merely taken to be so, not *what* it is—the structure, not the content’ (Brandom 1994, p. 600).

This structure is symmetrical. Person A distinguishes between what is to be treated as specifying the objective content and what A regards as specifying the attributee B’s subjective attitude. B does so too but the other way round. This symmetry is what prevents any one perspective from being privileged over all others. ‘Sorting out who should be counted as correct, whose claims and applications of concepts should be treated as authoritative, is a messy retail business of assessing the comparative authority of competing evidential and inferential claims’ (p. 601). A lack of understanding of this perspectival structure leads students of scientists’ behaviour to focus only on what is agreed between them and to neglect of what it is that the scientists are agreeing or failing to agree about: to fail to take account of the *objects* of their discussion, its *object-ivity*.

> From the perspective of our students we might ask, ‘Why should there be so much investment in teaching and learning science?’ Maybe then we will be able to address conceptual change more adequately and for clearer and more significant purposes (Reis 2010, p. 239).

Our investment in science education may be opaque from the perspective of a schoolchild, but it is hardly from that of anybody else. Scientific knowledge is spread through our economy, our health system and our agriculture. Without a solid core of scientifically educated technicians, we could not keep our populations safe from diseases, adequately fed and gainfully employed.

32.3.4 Western and Indigenous Science

Nowadays we routinely hear about 'Western science', whereby 'West' is meant Western Europe and those regions elsewhere predominantly settled by descendants of people from Western Europe. The notion of science as being a cultural product of these people rather than others may have had some validity in the nineteenth century, and indeed even into the 1940s.[3] Science as known today can be, and in Western countries usually is, traced back to ideas largely formulated in Western Europe in the seventeenth century (though see Needham et al. 1954–2004), but it has long ago outgrown that locale and many of the ideas of that time have been superseded or incorporated into subsequent developments. To refer to today's science as Western is to overemphasise its origins and mislead in somewhat the same way as one would by describing modern Christianity as a Middle Eastern religion or the potato as a Peruvian vegetable. The terminology 'Western Science' substantially misrepresents the social context in which science has been done over the last 60 years or so.

The need for this term is of course to draw a contrast: One talks about 'Western' science to contrast it with the sciences of indigenous cultures. In this vein, two advocates of indigenous science have recently written:

> In most countries of the world, a culturally specific (Western) form of science has masqueraded as universal, true and irrefutable. With the introduction of the first national Australian curriculum, Western science and its epistemological base have been challenged by formal expectations that Australian Aboriginal and Torres Strait Islander knowledges be included in formal school science programmes (Baynes and Austin 2012, p. 60).[4]

There is a familiar and pointless debate as to whether indigenous cultures can be said to have sciences. Manifestly every human community has some knowledge of the world in which it lives and how things in that world interact—which plants are poisonous, for example—though that knowledge may not be seen by that community as forming a unified system but as being parts of the lore of hunters, of healers and of midwives. So in that sense every society has its own science. Manifestly no pre-industrial society has had the sort of organised knowledge-sector on which economies like Japan, China, India, Brazil and Russia (as well as Europe and North America) rely in the twenty-first century. In that sense no early society had science. But no cultures, including indigenous ones, are static, and people raised in them often adopt ideas and practices from elsewhere. Science has of course adopted and adapted much knowledge from pre-industrial cultures, and continues to do so. Many people with an indigenous background have become scientists.

---

[3] The Nobel Prize for Physics was first awarded outside the 'West' so defined in 1930, to ChandrasekharaVenkata Raman of Calcutta University for his discovery that when light traverses a transparent material, some of the light that is deflected changes in wavelength, a phenomenon now called *Raman scattering*.

[4] Baynes and Austin's use of the word *irrefutable* suggests that their understanding of Karl Popper's contributions to philosophy of science is not very deep. Popper famously maintained that the very defining feature of scientific claims is their refutability (see following section). Such disregard if not ignorance of important philosophical and historical matters is characteristic of the PM 'loose consortium' in science education.

Surprisingly, the dogma that science is a cultural product of, and therefore confined to, Western societies is not opened to empirical test. When an attempt is made to do so, the inconvenient conclusion is often that Western and indigenous sciences agree to an extraordinary extent. Ernst Mayr wrote:

> Forty years ago, I lived all alone with a tribe of Papuans in the mountains of New Guinea. These superb woodsmen had 136 names for the 137 species of birds I distinguished (confusing only two nondescript species of warblers). That … Stone Age man recognises the same entities of nature as Western university-trained scientists refutes rather decisively the claim that species are nothing but a product of the human imagination (Mayr 1963, p. 17, quoted Gould 1980, p. 173).

Subsequent investigations have provided further examples of indigenous taxonomies matching those of Western science.[5] One taxonomy which does diverge from the scientific is the taxonomy embodied in vernacular English. For example, the western class ‘panda’ is confused: cladistically, giant pandas are bears, but red pandas are a separate family more closely related to racoons (Flynn et al. 2005, p. 325a; O’Brien et al. 1985; O’Brien 1987). Charles Sibley and John Ahlquist showed that Australian birds evolved from a crow-like ancestor and that their similarity to various European birds whose names they were given (e.g., warblers and robins) is a matter of evolutionary convergence. Jack Pettigrew has argued (1986) that flying foxes are more closely related to primates than to the microbats. If compared to modern cladistics, the English language with its pandas, robins and bats might fare much less well than many indigenous taxonomies.

A very obvious fact about the sociology of different cultures is that some cultural products have wide appeal, and others remain confined to their original homes. The dramas of Shakespeare, for example, seem to work well in other languages and other dramatic traditions, notably those of speakers of German and Russian, whereas the dramas of Racine have had much less success outside their native French habitat. The music of societies from Africa, including those of Africans transported to the Western hemisphere, has wide appeal those of China and Japan seem not to. The students of the social aspects of science, however, have not investigated this aspect of science’s influence.

32.4 Part Three [J.R.B.]

32.4.1 Postmodernism and Philosophy of Science

Let’s begin with something like *the standard view of science*, which we can roughly express like this: *There is a way things are and scientists try to figure it out; they*

---

[5] See, for example, Berlin et al. (1974), Boster and D’Andrade (1989), Diamond (1966), Hunn (1976), Majnep and Bulmer (1977). Though contrast, for example, Björnsen Gurung (2003).

have a variety of (fallible) techniques for doing so and thus far have been quite successful. If pressed for details, we might include the following[6]:

1. There is a world in which there are objects, processes and properties which are independent of us and our beliefs about them. Any statement we make about them is true or is false (or at least approximately so). Of course, we may never know which.
2. The *aim* of science is to give true descriptions of reality. Science can have other aims as well (usually associated with technology), but truth is the chief aim of pure science.
3. We have a variety of tools and techniques (observation, logic, statistical inference, etc.) for learning how things are. These methods have developed from earlier methods and very likely will themselves be developed further.
4. Such methods are fallible; they may lead us astray. Nevertheless, science has made remarkable progress so far. It is reasonable to continue to use these methods in the belief that they are the most reliable source of information about nature.
5. There are no alternatives to this. For instance, the Bible does not give us reliable information about human origins; astrology and precognition do not give us reliable information about our futures and so on.
6. The progress of science is tied to these principles. Social factors can and do influence science, but the main course of its development is based on the recognised methods of evaluation.

Postmoderns and social constructivists generally would consider these points delusional. And yet, this cluster of views is what we all more or less start out with and is what most working scientists believe (though the fifth point might be controversial for some). It is, in short, common sense realism. But, as we know only too well, common sense is sometimes wrong. It is seriously challenged by a number of people active in science studies. Even some who would reject any form of postmodernism will reject parts of the standard picture as sketched here. For instance, various antirealists (including instrumentalists, verificationists and pragmatists) would all reject the idea that science aims at truth that exists independently from us. An instrumentalist such as Duhem claims that a scientific theory aims at ‘saving the phenomena’, that is, getting all the observational claims right but is indifferent to the truth of the theory itself. We might not be able to tell whether the earth rotates or is stationary, while everything else goes around it. What matters, instrumentalists claim, is that we correctly predict the angle at which we see Mars at any specified time. When two theories make the same predictions, we choose to adopt one of them on the basis of convenience—truth (which is inaccessible) has nothing to do with it.

Karl Popper, famous for asserting falsifiability as the defining criterion of scientific theory, would also be critical of aspects of the standard picture but for a different reason. He thought the aim of science is indeed truth, but he didn’t think we could have good inductive evidence for the truth of any theory. Instead, the method of science should be conjectures and refutations. We make a guess, then we try to

---

[6] This section draws heavily on Brown (2001).

find counterexamples. When we refute our theory, we then make a new conjecture and so the process goes.

Though Duhem and Popper challenge some aspects of the standard picture of science, they do not quarrel with those features that are most central, namely, the idea that reason and observation play a dominant role in theory evaluation. The postmodern challenge is really quite different. The very idea of scientific reason and objectivity is at issue. Consequently, when we talk about the standard picture of science, we will include Duhem and Popper and almost every other major philosopher of science as embracing that picture. Of course, they differ significantly in detail, but they all hold that reason and observation are at least in principle objective and play a dominant role in science. When we talk about the standard view of science, we mean to include most prominent philosophers of science as upholding some version of it. This would include Whewell, Mill, Mach, Poincaré, Pierce, Duhem, Russell, Carnap, Neurath, Popper, Quine, Lakatos, Putnam, van Fraassen and a great many others. Kuhn and Feyerabend might also be included but are somewhat problematic. Interestingly, they are often seen as postmoderns.

With this outline of the standard view of science in mind, we can better understand the challenge posed by postmoderns and other social constructivists. Let's start by asking: Who's involved? Why should we care? What are the main battle lines?

32.4.2 Antecedents to Postmodernism

In some ways the fight is quite old. The much-cited second-century CE views of Sextus Empiricus and his rejection of the possibility of objectivity have been mentioned above. Two and a half thousand years ago, Protagoras championed a kind of relativism when he said 'Man is the measure of all things'. Plato took up the challenge and fought for objective knowledge. The Enlightenment with its emphasis on progress through rationality was no sooner established in the eighteenth century, then early in the nineteenth it faced the Romantic rebellion which stressed feeling over intellect and emotion over rational inference. Much debate in this century has been stimulated by Karl Marx, though sometimes his writings pull in opposite directions. Marx sounds distinctly like a social constructivist when he famously declared: 'The mode of production of material life conditions the general process of social political and intellectual life. It is not the consciousness of men that determines their existence, but their social existence that determines their consciousness' (1859, 20f.). Yet Marx also thought that objective knowledge is possible; the constructive sentiment gives way to a sensible though subtle form of realism:

> With the change of economic foundation the entire immense superstructure is more or less rapidly transformed. In considering such transformations the distinction should always be made between the material transformations of the economic conditions or production which can be determined with the precision of natural science, and the legal, political, religious, aesthetic or philosophic — in short, ideological — forms in which men become conscious of this conflict and fight it out (*ibid.*, 21).

32.4.3 The Strong Programme in Sociology of Knowledge

Current social constructivism has plenty of antecedents, but it is also reasonable to think of it as mainly a product of the recent past (see Chap. 31). In the mid-1970s David Bloor (in Edinburgh) announced the *strong programme* in the sociology of knowledge. Why *strong*? It's in opposition to *weak* sociology of science, any account which focuses on institutions and various other social features of science but takes for granted that the *content* of science has nothing to do with sociology. By contrast, Bloor asserts that the very content of scientific theories is also to be understood in terms of social factors.

This is a point that must be stressed, since a great deal of sociology of science is quite compatible with the epistemology of scientific orthodoxy while at the same time is potentially embarrassing to the orthodox. So-called weak sociology, for example, can ask: Why are there so few women physicists?, Why do they feel they must sacrifice career or children, and can't (unlike their male colleagues) have both? However, weak sociology of science does not ask questions such as: Why do women believe that the trajectory of a cannon ball is a parabola? The answer to such a question is 'the evidence' and it has nothing to do with their sex, nor with any other sociological factor. Bloor's *strong programme* will have none of this hands-off attitude. He, too, will ask the background questions, of course. But as likely as not, he will relate those factors to the very content of the theory at hand. More on his views below.

There are many others who are like-minded. Shortly after Bloor started to make his mark in science studies, Bruno Latour (a French philosopher and anthropologist) adopted the role of an 'anthropologist in the lab'. With Steve Woolgar he wrote up his experiences of an exotic tribe—a team of California biochemists—explaining their behaviour in social, political and economic terms. Meanwhile in France, Michel Foucault was claiming that *knowledge = power*, not in the sense that by having knowledge one has power (a sense made famous by Bacon), but in the very different sense that having political power allows one to say what knowledge is and is not.

32.4.4 The Sociology of Scientific Knowledge (SSK)

David Bloor's now classic book, *Knowledge and Social Imagery* (Bloor 1976/1991), is perhaps the single most important and influential work in the current social constructivist literature. It contains the manifesto of the *Edinburgh School* known as 'the strong programme'. What (to repeat my earlier question) might the *weak* programme be? To elaborate on my former answer, before Bloor and his like-minded colleagues got to work, *traditional* sociology of scientific knowledge focussed on various issues surrounding science, such as institutions (Who funds them? Why did this one flourish and that one collapse?), scientists (What social class do they come from? Why are there so few women?), relations to governments and corporations

(What impact did the cold war have on science funding? How is the biotech industry influencing research?) and choices of research topics (Why did Galileo take an interest in projectile motion?). But traditional sociology of science would *not* try to account for the *content* of any scientific theory. This, according to Bloor, is what makes the traditional approach 'weak'.

Robert Merton and his school is Bloor's target. Merton's sociology of science does not challenge, but rather complements traditional history and philosophy. Merton, for example, would be happy to account for the growth of science in seventeenth-century England by linking it to Puritanism, as he did in his famous study (1970). But not for a moment would he think it appropriate to give a sociological explanation of why Newton's theory of universal gravitation was widely accepted. Merton formulated a rule of thumb that has come to be known as the *A-rationality Principle*: If a rational explanation for a scientific belief is available, that explanation should be accepted; we should only turn to non-rational, sociological or psychological explanations when rational accounts are unavailable.[7] This is part of the *weak* approach that Bloor explicitly opposes. He insists upon a uniform strategy in dealing with science, one that is utterly thoroughgoing and which penetrates into the very content of scientific theories—in short, he wants a *strong* programme.

Bloor's motivation is his naturalism and his attachment to science. The idea of naturalism is also popular among philosophers, especially philosophers of science, who hold a variety of versions. The general principle is this: The natural world is all there is; there are no special methods of investigating things except the fallible methods of empirical science; norms (whether they be the norms of morality or the norms of scientific method) must be explained away or reduced to the concepts and categories of ordinary science; they must be understood in terms of the natural world.

Naturalism has great appeal, and many would cheer him on, if Bloor said: we want to know about the atom? Study it scientifically! Want to know about disease? Study it scientifically! Want to know about religion? Study it scientifically! Want to know about human society? Study it scientifically! We seem to be tripping right along, and now that we're on a roll, why hesitate? It's hard to resist continuing in the same way: Want to know about science? Study it scientifically! That's what Bloor urges, and it's difficult to object. But what's involved in a scientific study of science itself? Bloor's answer is the four tenets of the strong programme. If you want to adhere to a scientific understanding of science, Bloor claims, then these are the main principles with which your account must comply (See Bloor 1991, p. 7).

Causality: A proper account of science would be causal, that is, concerned with the conditions that bring about belief or states of knowledge.

Impartiality: It would be impartial with respect to truth and falsity, rationality or irrationality and success or failure. Both sides of these dichotomies will require explanation.

---

[7] (Merton (1968, p. 516); the principle is also embraced and discussed at length by Laudan (1977, p. 202).

Symmetry: It would be symmetrical in its style of explanation. The same types of cause would explain, say, true and false, [rational and irrational] beliefs.

Reflexivity: It would be reflexive. In principle its patterns of explanation would have to be applicable to sociology itself. Like the requirement of symmetry, this is a response to the need to seek for general explanations. It is an obvious requirement of principle; otherwise sociology would be a standing refutation of its own theories.

Two of these principles seem to be perfectly correct—impartiality and reflexivity. The other two either need serious qualification or are simply wrong. Bloor does not say so, but he seems to assume that reason and evidence are not the sort of things that could be a cause. If we take evidence to be a cause, then there is no objection to the first principle. Let's see what's right about impartiality and reflexivity, which we can do without having to reinterpret them.

Since we're in the business of explaining belief, we're interested in all beliefs, not just the true or rational ones, and not just the false or crazy ones. Optical illusions, for example, are an engaging curiosity and it's nice to have explanations for them. But ordinary veridical perception is also worthy of our intellectual interest. Bloor is not alone in saying this, but he does think the point is underappreciated. The reigning story of how I manage to correctly see a cup on the desk in front of me is a wonderful achievement of physics and physiology research. It involves photons coming from the cup and entering my eye, a signal is sent down the visual pathway into the cortex and so on. Events such as these play a role in explaining how I come to believe that there is a cup on the desk. Whether my perception is veridical or illusory, it needs explaining. The true and the false are in this respect on a par. This is Bloor's impartiality principle. And he's perfectly right to espouse it.

Would anyone think explaining both the true/rational and the false/irrational wasn't the proper thing to do? The impartiality principle hardly seems necessary, yet the A-rationality principle (mentioned above) might be thought to be in conflict. That principle called on giving sociological explanations for beliefs *only* when no rational explanation was available. Actually, there is no conflict between the two principles. Every belief requires explanation, but some will get one type of explanation (say, in terms of social factors), while others will get a different type account (say, in terms of evidence and reason). As we will soon see, this conflicts with Bloor's symmetry principle, but not with impartiality. All sides in this debate can cheerfully embrace the impartiality principle.

What about the principle of reflexivity? Bloor's principle is something that readers immediately pounce on. If all belief is merely the product of various social forces (so this argument goes), then the same can be said of the strong programme itself. There can't be any evidence in support of the strong programme, if Bloor is right, because he has argued that there is no such thing as genuine evidence. Bloor may well believe the strong programme but that (by his own lights) is because it serves his interests.

This sort of self-refutation problem plagues all sorts of views. The sceptic says no belief is justified; thus, the sceptic's own scepticism isn't justified, so we can ignore it. Marx says belief reflects class structure; thus, Marx's own theory merely reflects his social position, so we can ignore it. These kinds of quick rebuttals really won't do, though they are a favourite with beginning philosophy students. It might well be that a particular doctrine is basically right, but any formulation of it runs into problems. It might well be that none of our beliefs is in any way justified, even though *saying so* runs into paradox.

The reflexivity of the sociology of knowledge is a small problem, perhaps none at all. Yes, says Bloor, social factors cause all belief, and yes, social factors even cause the belief that social factors cause all belief. There is certainly no logical problem here. If there is any sort of difficulty, it stems from thinking that if we know a belief is caused by social factors, then our faith in that belief is undermined. So, if we know that belief in the strong programme itself is caused by social factors, then that belief is also undermined. Bloor simply denies this. He staunchly holds that we can simultaneously hold a belief *and* hold that the belief is caused by social factors. Perhaps this is implausible (at least for a wide range of cases); but even if Bloor hasn't answered the self-refuting objection, his reflexivity principle certainly defuses it. Tell him that social factors are making him accept the strong programme and he will smile pleasantly back at you.

The symmetry principle may be the most contentious. It demands the same type of explanation for rational and for irrational beliefs. We can explain your health or your illness in physiological terms. We can explain why a bridge is standing or why it collapsed in terms of its structural properties. These are instances of symmetrical explanations. So, in the same vein we should explain rational and irrational beliefs in the same way. This contradicts the A-rationality principle in that it would demand sociological explanations for all beliefs, not just the irrational ones. An opponent of Bloor could turn this around and demand an explanation in terms of reason for all beliefs, rational and irrational. How could this possibly work? By showing that the agent rationally believes that holding the irrational belief will promote her interests. The symmetry principle looks plausible initially, but on close inspection it crumbles.

SSK rests on two strands. One is the philosophical argument (or should that be anti-philosophical argument) presented by Bloor and others. The other strand is the support it gains from the perceived success of several case studies. These are historical examples where some episode is analysed in sociological terms of 'interest' rather than in terms of reason and evidence, the way a traditional intellectual historian would try to understand the same events. A famous study by Paul Forman well illustrates this.

32.4.5 A Social Constructivist Case Study: Quantum Theory in the Weimar Republic

How do we explain the rise of the quantum theory in the mid-1920s? Paul Forman, in his elaborately titled 'Weimar Culture, Causality and Quantum Theory, 1918–1927: Adaptation by German Physicists and Mathematicians to a Hostile Intellectual Environment', offered a sociological explanation: After the Great War, German scientists lost much of their prestige; Spengler had just published his wildly popular *Decline of the*

West and Spenglerism was everywhere. The spirit of the times was decidedly mystical and anti-mechanistic. The scientists of the Weimar Republic, says Forman, created non-causal, non-deterministic quantum mechanics to appeal to the German public's mystical and anti-mechanistic outlook and thereby to regain their high social standing.

By contrast, a more traditional, 'rational' explanation might look something like this: The old quantum theory of Bohr and Sommerfeld was not a coherent set of physical principles; the new theory of Heisenberg, Born, Schrödinger and others (1925–1927) accounted for a wide range of phenomena including the so-called anomalous Zeeman effect which had been the subject of much perplexity; consequently, scientists who worked in this field were won over by the explanatory successes of the new mechanics and completely accepted it for that reason.

Forman will have none of this. Where others see 'rational' factors, he sees social forces. One need only pay attention to the footnotes of sociological literature in the 1970s and later to see the great importance of Forman's work to the newly emerging style of science studies. To use a Kuhnian expression, it was a new paradigm. The general idea, manifest in Forman's account, is that scientists had social interests and their scientific beliefs are shaped by those interests, not by so-called rational factors. Let's examine Forman's case study in a bit more detail, so that we can clearly see the structure of his argument.

The scientists of the Weimar Republic were living in a hostile intellectual environment, according to Forman. World War I was over and Germany had lost. The public was seriously disillusioned with science and technology. The spirit of the times was mystical and antirational. Indeed there was considerable opposition to science which was seen as mechanical, rationalistic and linked to causality and determinism. Into this hostile intellectual climate came Oswald Spengler's *Decline of the West*, which claimed that physics expressed the 'Faustian' nature of current Western culture. According to Spengler, physics had run its course, exhausting all its possibilities. It stood condemned as a force in opposition to 'creativity', 'life' and 'destiny'. Salvation could only come if science returned to its 'spiritual' home.

Several leading Weimar physicists are cited by Forman stressing the importance of 'spiritual values' and acknowledging the 'mystery of things'. He concludes that the concessions were so numerous and extensive that they constituted a 'capitulation to Spenglerism' (1971, p. 55). And so the general 'crisis of culture' was embraced by the scientists themselves: 'The *possibility* of the crisis of the old quantum theory was dependent upon the physicists' own craving for crises, arising from participation in, and adaptation to, the Weimar intellectual milieu' (1971, p. 62).

Perhaps the most striking feature of quantum mechanics is the widely accepted belief that it abandons strict causality; quantum processes have various probabilities of occurring, but they are not invariably determined to do so. (This is one of the features that Einstein so disliked, claiming that God does not play dice.) Did this new theory which surrendered determinism result from the usual evidential considerations? Not at all, says Forman:

> Suddenly deprived by a change in public values of the approbation and prestige which they had enjoyed before and during Wold War I, the German physicists were impelled to alter their ideology and even the content of their science in order to recover a favorable public

> image. In particular, many resolved that one way or another, they must rid themselves of the albatross of causality (1971, p. 109).
>
> …the movement to dispense with causality expressed less a research program than a proposal to sacrifice physics, indeed the scientific enterprise, to the *Zeitgeist* (1971, p. 113).

Forman's celebrated study became a new model for many historians of science. According to this model, we understand events in the history of science, not in terms of the empirical evidence, not in terms of theoretical innovations, not in terms of conceptual breakthroughs but rather in terms of social factors. A group of scientists in Weimar Germany had a social goal—to regain lost prestige. That's why the old quantum theory was rejected and the new quantum mechanics of Heisenberg, Born and others was adopted.

It's difficult to say why social constructivism has flourished to the extent that it has. One of the reasons is the perceived success of historical case studies such as Forman's. But are they really successful? Lots of historians do think so and lots do not. It's not easy to make a decisive case one way or the other. Certainly, explanations by social factors tend to be more interesting than explanations via dry data and arid inductive inferences. One can read about the events, study the experimental data and laboriously work through the calculations that lead up to the revolution in quantum mechanics in, say, Max Jammer's history of the period (Jammer 1966). Of its kind it's a fine work, but it's also hard going. By contrast, Forman's account is a real page turner with its descriptions of the social atmosphere of post-war Germany, Weimar politics and so on. Social history is often more fun—but that, of course, doesn't mean that it's right.

32.4.6 Feminism and Science

Sandra Harding famously introduced a taxonomy of feminist critiques of science:

1. Feminist empiricism
2. Feminist standpoint theory
3. Feminist postmodernism

She saw feminist philosophers of science as falling into one of these categories. Though something of a simplification, the taxonomy has proved quite useful. The first of these views, *feminist empiricism*, holds that the standard methods of science are fine as they are. Sexist science is the result of not living up to the existing canons of good science. (They often add that the same can be said about racist science.) When looking at nineteenth-century accounts of hysteria or Nazi race science, one cannot help but think that these were appallingly bad researchers who violated every principle of good science.

Feminist standpoint theory comes from Hegel and Marx. A slave has a superior understanding to the slave owner, according to Hegel, because he must understand both his own situation and the owner's. Similarly, for Marx, the worker must understand the boss's view as well as his own. A standpoint is not a mere perspective or point of view. It is an accomplishment requiring a struggle to obtain. For that reason it is a superior understanding of how things are. It is not automatic that women will have a feminist standpoint (unlike a woman's perspective), but if they do achieve it, they will have a better understanding than their male counterparts for whom nothing is to be gained by acquiring an understanding of the position of women. Feminist standpoint theory is a challenge to the standard account of science, but it is important to stress that it remains wedded to the ideal of scientific objectivity. It is just that objectivity is more complex and difficult to obtain than previously thought.

Feminist postmodernism (the third of Harding's categories), as an approach to science, was inspired by a number of feminist postmoderns, such as Judith Butler, Julia Kristeva and Luce Irigaray. It is highly sceptical of general principles and objectivity and takes a very dim view of what is here called the standard view of science. The emphasis is on the local with scant regard for any inconsistencies among different 'local narratives'. It thus embraces a form of relativism. Different societies have their own stories, their own local narratives. An all-embracing or 'total narrative' is dismissed out of hand.

When she proposed the taxonomy, Harding allowed that all three were genuine feminist outlooks, but that she seemed to favour postmodernism. More recently she has pulled away into what she calls 'strong objectivity'. It is generally true that while many feminists have considerable sympathy for postmodernism, the vast majority of feminist philosophers of science do not. In terms of Harding's taxonomy, they adhere to some version of feminist empiricism or standpoint theory, though they may not use these labels.

We can illustrate the more objective feminist approaches with the example of Okruhlik (1994). She begins with two assumptions that are commonly, though not universally, accepted by philosophers of science. One is the distinction between discovery (having new ideas) and justification (putting them to the test). We can ignore the process of discovery, the argument often runs, because the justification process will filter out all the crazy and biased aspects that go into having ideas and only the evidentially supported will survive. Her second assumption is that the process of justification, theory evaluation, is comparative. That is, we do not evaluate a theory merely by testing it against nature. Instead, we test it and its rivals against nature and on that basis we can (objectively) rank order them. We cannot really say a theory is good or bad except with respect to a comparison group. When we say a tennis player is good, we mean she can beat most other tennis players. Imagine that only one tennis player existed. We would have no way of saying she is or isn't a good player; we need the comparison group.

The moral Okruhlik draws from this is rather straightforward. If there is some bias systematically built into the comparison group, it will not be filtered out in the process of justification. What is needed to improve the process of evaluation it to enlarge and diversify the set of rival candidate theories. There are nice illustrations of how this has happened.

There is an important and influential class of theories called 'man-the-hunter' that accounts for human evolution. The general claim is that our ancestors developed language and tool use through the practice of hunting. Male developed tools for hunting and the developed language in order to facilitate cooperative hunting. This even accounts for some aspects of our physiology: large incisors gave way in the evolutionary process to molars, which are better for digestion, because tools replaced the need for teeth that rip apart a prey's throat. There were variations on this general idea and the available evidence would tend to support some of these over others. This was science as usual, rational, objective and so on.

With a growing number of women in anthropology, there arose a different approach to this issue. 'Woman-the-gatherer' theories made a different claim about human evolution. The claim was that our female ancestors are chiefly responsible for our evolution. Tools that were thought to be for hunting were reinterpreted as for food preparation. Language was seen as arising out of sociability. And certain types of facts that had been ignored were investigated. For instance, among contemporary hunter-gatherer communities, it turns out that the female gatherers provide 75% of the family caloric intake.

It does not matter which type to theory is right—perhaps neither is. The philosophical moral is that the quality of the set of rival theories to be evaluated has improved greatly. Okruhlik would not say women researchers are free from bias; rather, they have different biases. But now in the process of comparative evaluation, there is some hope that these biases can be neutralised.

As an approach to understanding science, it is indeed a challenge to the standard view. However, it is more of a modification than a rejection. It requires looking at the scientific community and making sure it is appropriately diverse. This is not a brand of social constructivism, but it does take the society in which science is pursued to be of great importance. This is quite different from the standard account which is largely oblivious to society as long as it does not interfere. Feminist philosophers of science who insist on taking these sorts of social factors into account while still upholding scientific objectivity have probably improved the standard account of science considerably, especially as it applies to the social sciences. Their ranks include Anderson, Harding, Kourany, Longino, Nelson, Okruhlik, Wylie and many others.

There are common misconceptions about feminist critics of science. They are often portrayed as anti-objectivity, anti-science and so on. Of course, some are, but one needs to be, careful when passing judgement. Norette Koertge, a prominent philosopher of science and among the first to write on science education (Koertge 1969), maintains that science needs more unorthodox ideas and a greater plurality of approaches. This is a standard Popperian position which does not in itself constitute an argument for a new epistemology of science. She then sounds the alarm against certain feminists, warning that

> If it really could be shown that patriarchal thinking not only played a crucial role in the Scientific Revolution but is also necessary for carrying out scientific inquiry as we now know it, that would constitute the strongest argument for patriarchy that I can think of (Koertge 1981, p. 354).

And she goes on to say

> I continue to believe that science -- even white, upper-class, male-dominated science -- is one of the most important allies of oppressed people (Koertge 1981, p. 354).

She is quite right, but the problem is that many of those she attacks believe the same thing. Most feminist philosophers of science believe that science can be objective. They are trying to find ways to improve its objectivity, not to expose it as a fraud. Similar sentiments are echoed by many feminists, including Susan Haack (2003) and Cassandra Pinnick (2003, 2005, 2008). Pinnick believes that popular, or postmodernist, feminist philosophy of science is not only unsupportable, but it has done an immense disservice to science and the advancement of women in science. She is right to heavily criticise postmodern approaches, but sometimes she assimilates feminist philosophers who champion objectivity with postmoderns who do not. Pinnick writes

> Viewed by a philosopher of science, there is nothing short of a puzzle as to why, at this date, any group of science educators would invoke so patently flawed a philosophical position as 'epistemologies of feminism', in the hope that women in science will then benefit from a revamped theory of learning that is modelled on or guided by its flawed theoretical notions. It is time that science educators are told, bluntly, the conclusion which philosophers of science have reached after two decades or so of careful, and even hopeful, consideration of feminist standpoint theory. The conclusion, in brief, is that feminist standpoint theory is indefensible (Pinnick 2008, p. 1056).

Expressions such as 'feminist epistemology' cover a variety of views. Helen Longino would advocate doing science as a feminist, by which she means investigating nature with a concern of women's issues. There is no conflict with objectivity here. Thus, a feminist anthropologist might ask new questions about the female gatherers, such as how many calories did they contribute to family intake. They discovered that it is about 75%, which came as a shock to those who thought they had overwhelming evidence for understanding our evolutionary past in terms of man-the-hunter. There is not a hint of different facts of different forms of reasoning for men and women. We might acknowledge different biases that go into theory construction, but those biases can (and we hope will) be overwhelmed by evidence in the long run. Acknowledging this is to promote objectivity.

32.4.7 Postmodern Critics of Science

The foregoing has partially characterised postmodernism but more must be said. Postmodernism stands in opposition to the Enlightenment (which is taken to be the core of modernism). Of course, there is no simple characterisation of the Enlightenment any more than there is of postmodernism, but a rough and ready portrayal might go like this: Enlightenment is a general attitude fostered (on the heels of the Scientific Revolution) in the seventeenth and eighteenth centuries; it aims to replace superstition and authority by critical reason. Divine revelation and Holy Scripture give way to secular science; tradition gives way to progress. Enlightenment advance is of two sorts: scientific and moral. Our scientific beliefs are objectively better than before and are continuing to improve, and our moral and social behaviour is also improving and will continue to do so.

There is another aspect to Modernism which is often linked to the Enlightenment but seems to go well beyond. This is the doctrine that there is one true story of how things are. Jean-François Lyotard, one of the most prominent postmodern commentators, speaks of the ‘incredulity about metanarratives’ (1984). Science for him is just a game with arbitrary rules, and truth is nothing more than what a group of speakers say it is. While most Enlightenment figures that postmoderns attack would happily embrace the view that there is one true story (perhaps with qualifications), so would Aristotle and so would the Mediaevals. In attacking so-called grand narratives or metanarratives, postmoderns are attacking much more than Modernism. Roman Catholicism’s fondness for tradition and authority may stand opposed to the Enlightenment, but it certainly disdains relativism and embraces the one-true-story outlook.

Just as critical reason is seen by postmoderns as a delusion, so are all attempts to generalise or universalise. In place of so-called ‘totalising’ accounts of nature, society and history, ‘local’ accounts are offered. *Localism* or *perspectivalism* is the view that only very limited accounts of nature, or society, (or whatever the subject of discourse is), are to be taken as legitimate; grand theories are invariably wrong or oppressive or both. (To repeat what was said above, standpoint theory is not the same as localism, since it claims that some perspectives are objectively better than others.)

Jacques Derrida, another leading postmodern figure, has pronounced that any attempt to say what postmodernism is (or what it is not) will invariably miss the point. Bruno Latour, a source of inspiration for some postmoderns, has declared that we have never been modern, much less postmodern. Such claims put the would-be expositor in a difficult position. Nevertheless, it seems reasonably fair to say that these three ideas are central to postmodernism: one is the *anti-rationality* stance, a second is the *rejection of objective truth* and the third is *localism.* There are other ingredients such as *anti-essentialism*, but they would seem to follow from the initial ideas. In any case, this short list is not meant to be exhaustive.

Postmodern accounts of science are not easily identifiable. Feminist and SSK approaches usually announce themselves as being feminist and sociological, respectively, but postmoderns, who are often playful with language, find telegraphing prose to be plodding. Nevertheless, we can probably say something by way of characterising it, realising that what we say might be contentious.

The principal characteristic of postmodernism is the rejection of modernism. Modernism, or its equivalent, the Enlightenment, holds that we can and do make progress. This progress is due to reason; tradition and authority are impediments that we can overcome. Needless to say, science and technology are central to this outlook. Postmodernism can now be easily characterised as the rejection of all that. This is true for postmodern science and philosophy, but something like it would be true for postmodern art, music, architecture and so on. Modernist aesthetic principles are similarly rejected. Whereas modernist architects would aim for some sort of unity or symmetry in a building, a postmodern work might be composed of very different styles and building materials. While postmodern science is far from postmodern art, there is still a common spirit underlying each.

One of the striking features of postmodernism—admirable or disconcerting, depending on one's outlook—is the cherry picking of parts of science. While there is widespread distain for science as a 'totalising narrative', particular achievements are celebrated. Heisenberg's uncertainty principle, chaos and catastrophe theory are warmly embraced. It's easy to see why, since these theories involve the unpredictable and the uncontrollable. If it seems strange to embrace some parts of science and not others, remember that unity and coherence are modernist values, cheerfully abandoned by postmodernists. Of course, it makes debate rather difficult, since there seems to be no common ground from which to start.

Obviously postmodernism and the social constructivism with which it is associated pose a challenge to standard views of science, the views most commonly embodied in science curriculum and in arguments for the compulsory study of science in schools. The role of social factors in science is increasingly acknowledged and is now admitted to some extent in all quarters. The stronger forms of constructivism and postmodernism, however, have not been accepted by the general academic community of those who do serious research into the nature of science. On the contrary, postmodern and constructivist views have often foundered and many of their early champions have significantly modified their views and now acknowledge that reason and evidence do after all play a significant or even a determining role in the development of science.

32.5 Part Four [R.G.]

32.5.1 Postmodernism Exposed: The Sokal Hoax

The attempt to subject science to postmodernist interrogation received a major setback when New York University physicist Alan Sokal submitted his parody paper titled 'Transgressing the Boundaries: Toward a Transformative Hermeneutics of Quantum Gravity' to the leading postmodern journal *Social Text.* Embarrassingly the manuscript which was full of gibberish and nonsense that anyone with decent high-school science and mathematics should have detected, passed review and was published (Sokal 1996). Seemingly the journal's readers knew no more about science than its reviewers. The gibberish was 'music to the ears' of postmodern critics of science, speeded its publication, and led to dancing in the Cultural Studies corridors, if not streets. The music can be heard in a few quotes from Sokal's original paper (reproduced in *Fashionable Nonsense*):

- Over the past two decades there has been extensive discussion among critical theorists with regard to the characteristics of modernist versus postmodernist culture; and in recent years these dialogues have begun to devote detailed attention to the specific problems posed by the natural sciences. In particular, Madsen and Madsen have recently given a very clear summary of the characteristics of modernist versus postmodernist science. They posit two criteria for a postmodern science: A simple criterion for science to qualify as postmodern is that it be free from any dependence on the concept of objective truth. By this criterion, for example, the complementarity interpretation of quantum physics due to Niels Bohr and the Copenhagen school is seen as postmodernist. (pp. 223–4)

- In Andrew Ross' words, we need a science that will be publicly answerable to progressive interests. From a feminist standpoint, Kelly Oliver makes a similar argument: …in order to be revolutionary, feminist theory cannot claim to describe what exists, or, 'natural facts.' Rather, feminist theories should be political tools, strategies for overcoming oppression in specific concrete situations. The goal, then, of feminist theory, should be to develop 'strategic' theories—not true theories, not false theories, but strategic theories. (p. 235)
- The teaching of science and mathematics must be purged of its authoritarian and elitist characteristics, and the content of these subjects enriched by incorporating the insights of the feminist, queer, multiculturalist, and ecological critiques. (p. 242)
- Finally, the content of any science is profoundly constrained by the language within which its discourses are formulated; and mainstream Western physical science has, since Galileo, been formulated in the language of mathematics. But whose mathematics? The question is a fundamental one, for, as Aronowitz (1988) has observed, neither logic nor mathematics escapes the 'contamination' of the social. And as feminist thinkers have repeatedly pointed out, in the present culture this contamination is overwhelmingly capitalist, patriarchal, and militaristic: mathematics is portrayed as a woman whose nature desires to be the conquered Other. Thus, a liberatory science cannot be complete without a profound revision of the canon of mathematics. (Aronowitz 1996, pp. 244–245)

Sokal used over 200 references in his parody paper as he repeatedly praised leading PM 'thinkers' for showing how to interpret quantum physics, relativity theory and even mathematics in ways that seemed to provide a sound basis for the various PM agendas. After publication Sokal revealed the hoax and lampooned many of the PM and SSK gurus, including Jacques Lacan, Bruno Latour, Stanley Aronowitz, Jacques Derrida, Sandra Harding and Steve Woolgar. Not surprisingly, *Social Text* did not publish Sokal's revelation and explanation (it did not meet the journal's 'intellectual standards').

Fashionable Nonsense (the work was also published with another title: *Intellectual Impostures*) tells the story behind the parody paper, and in the Epilogue explains why PM can be dangerous to our intellectual health. In doing this Sokal and Bricmont suggest seven lessons (pp. 185–189) that can be learned from the hoax:

1. It's a good idea to know what one is talking about. This is especially true of the natural sciences where technical, abstract ideas are involved for understanding at more than a superficial, popular level.
2. Not all that is obscure is necessarily profound. Much of the discourse of cultural studies is laden with obscure jargon.
3. Science is not a 'text'. Postmodernists often use terms like uncertainty, chaos, theory and nonlinearity in ways that mislead nonscientists. Pseudoscience uses technical, scientific terms to fool people into believing their products have a real scientific basis.

4. Don't ape the natural sciences. The social sciences study people and their institutions, while the natural sciences study nature and these domains often require different assumptions and research methods.
5. Be wary of argument from authority. The tendency to follow gurus like Lacan and Freud in the social sciences is much more prevalent than in the natural sciences. Nature is the final authority in the natural sciences, not sacred texts or respect for culture.
6. Specific scepticism should not be confused with radical scepticism. The relativism inherent in postmodernism allows followers to question the value of logic and evidence. Embracing radical scepticism can result in the absurd conclusion that astrology and astronomy are equally valid.
7. Ambiguity as subterfuge. Postmodernists are often ambiguous on purpose as this allows one to claim, I was misunderstood. Deliberate ambiguity in their writing is a common strategy among postmodern authors.

These lessons from the Science Wars and the exposure of the severe intellectual problems surrounding the sociology of science knowledge (SSK) programme should have meant that postmodernism would lose its appeal by the end of the twentieth century. However, that is not the case; postmodernism survives, and as documented in Part One of this chapter, even thrives in some science education circles under the guise of 'cultural studies' or 'radical constructivism'.

32.6 Part Five Conclusion [R.G., J.M. & J.R.B.]

The anti-science attitude fostered by postmodernism and relativism can lead to habits of mind that diminish concern for evidence, for logic, for clear writing and for finding out the truth of the matter. A good example of this is the widespread rejection of the findings of modern climate science. Despite overwhelming evidence that burning fossil fuels results in a warming of Earth's climate, with potentially devastating results for all living things, many people reject the scientific findings. When ideology trumps science, as in climate science debates where oil and coal companies resist scientific findings and related implications for action, we are left with no reasonable way to solve problems. The same pattern is repeated in campaigns against child and adult vaccination. When scientific knowledge is seen as a 'regime of truth' that endangers our freedom and democracy, as suggested by PM proponents, then political and religious ideologies can replace knowledge gained through scientific methods; it becomes much more difficult for people to recognise and reject pseudoscience. Science's most precious gift, the phrase used by Albert Einstein to describe the great value of modern science to society, is its ability to reduce the influence of cultural ideologies in judging the truth value of competing claims. Postmodernism offers little that can be used to improve the scientific literacy of our citizens, little that can be used to improve teacher education and a lot that can be used to diminish literacy and distract good teacher education.

Jim Mackenzie is retired from the Faculty of Education and Social Work at the University of Sydney. He completed his Ph.D. in Philosophy at the University of New South Wales, had lectured for many years in Philosophy of Education and has published on the formal logic of dialogue and on various aspects of educational theory and practice.

Ron Good Professor Emeritus, Science Education, Louisiana State University (1987–2002) and in a similar position at Florida State University (1968–1986). He is a former editor of the *Journal of Research in Science Teaching* and a Fellow of the *American Association for the Advancement of Science* since 1995. Research interests include science misconceptions, nature of science and pseudoscience, evolution education and habits of mind in science and religion. His books include *How Children Learn Science* (1977) and *Scientific and Religious Habits of Mind* (2005) and he has contributed many articles, conference papers and symposia on science education. He began his career in 1962 teaching high-school physics and chemistry in schools near Pittsburgh, PA and currently enjoys the island life at his beach house on St. George Island in Florida.

James Robert Brown is Professor of Philosophy at the University of Toronto. His interests include foundational issues in mathematics and physics, thought experiments and the relations of science to society. The last of these includes religion and science, the effects of commercialization on medical research, and equity issues in science and in the larger community. His most recent book is: *Platonism, Naturalism, and Mathematical Knowledge*, Routledge. Earlier books include: *Who Rules? An Opinionated Guide to the Epistemology and Politics of the Science Wars*, Harvard, *Smoke and Mirrors: How Science Reflects Reality*, Routledge, new editions of *The Laboratory of the Mind: Thought Experiments in the Natural Sciences,* Routledge, *Philosophy of Mathematics: An Introduction to the World of Proofs and Pictures* Routledge. His forthcoming books are on philosophy of science, foundations of seismology, and a history of aether theories. He is a Fellow of the Royal Society of Canada and a member of *LeopoldinaNationaleAkademie der Wissenschaften, and AcadémieInternationale de Philosophie des Sciences.*

Chapter 33
Philosophical Dimensions of Social and Ethical Issues in School Science Education: Values in Science and in Science Classrooms

Ana C. Couló

33.1 Values in Science Classrooms?

To date, there is no unanimous consensus on the “fundamental” notions related to the nature of science that should be taught within a history and philosophy of science (HPS) frame. However, the role of values in science has usually been a key element of the list, both in curricular proposals and in science education research (Adúriz-Bravo 2005a; Clough 2007; McComas 2002). Science has a significant impact on the way we live our lives, either through its products and processes or through the impact of new ideas on the ways we think about ourselves and the world. Scientific and technological developments raise many controversial issues: cancer treatment isotopes, increased-yield crops and xenotransplantation which saves human lives, on one side, and nuclear warfare, pesticide-induced diseases, undesirable social impacts and suffering and death for animals, on the other.

The way we think about things is often shaped by ideas born and matured within scientific projects, while scientific questions are frequently situated and related to the philosophical debates faced by contemporary societies. Science prides itself on widening our knowledge of the world, but is the discovery of true propositions *always* a good thing? It can be argued that some scientific ideas, however well grounded, have harmed people or diminished their happiness by leading them to change or question their self-images, their aspirations and their self-conceptions. And though counter-intuitive, this assertion merits consideration (Forge 2008, pp. 149–151; Kitcher 2001, Chap. 12). In short, the many ways in which science affects us are impregnated with value issues, while the ethical and political responsibilities of scientific work and knowledge impact scientists and science as an institution.

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_33,

So what are the values manifested and expressed in scientists' behaviour and in scientific practices? How are they embodied in scientific institutions?[1] These questions should be contemplated in science education at all levels.

There are several compelling reasons for advocating teaching science and technology students the ethical and political questions they will have to address in their lives as professional researchers, designers and citizens. For example, values are implicit in the choice of research subjects and research methods. Philosophers, historians and sociologists have debated the scope and significance of values in science, including consideration of whether scientists are accountable for not anticipating the consequences of their enquiries. Kitcher rejects the "myth of purity" that assumes that "there is a straightforward distinction between pure and applied science, or between "basic research" and technology" (Kitcher 2001, p. 86). Forge (2008) argues that scientists can be held responsible for the foreseeable results of their research, whether the outcome is a technological object or a published paper detailing new information on a given phenomenon.[2] Rollin (2009) points out that the invasive use of animals in experiments presupposes moral choices. It could be argued (and it *has* been argued) that animals cannot or do not feel pain in the same way that humans do. Nonetheless, in psychological research, animals are used to model harmful or undesirable psychological states. Researchers are then confronted by a dilemma: if animals cannot feel fear, pain, addiction, etc. as humans do, then what would be the point of inducing that state in the animal? And if they can feel fear, pain, addiction, etc. as humans do, then why is it morally acceptable to induce those states in animals? Answers to this dilemma cannot escape an ethical dimension, i.e. that the knowledge gained from the experiment outweighs the discomfort, pain or death suffered by the animal. And what are the ethical and political dilemmas that should be faced in biomedical research on human beings? Serious issues about the different layers of vulnerability should be addressed by potential researchers (Luna 2009). Individual scientists choose to engage in certain kinds of research, while different societies and institutions (scientific or not) encourage some of them and discourage others (Forge 2008, pp. 179–183).

However, this chapter will focus on teaching the role of values in science at high school level. Several rationales have been given for bringing these issues into schools. For example, teaching and learning about the role of values in science in socio-scientific and controversial issues can play a role in humanising sciences and illustrating their ethical, cultural and political facets (Matthews 1994). It can help to foster an appreciation of the nature of science (Bell and Lederman 2003). It is dependent on and contributes to core abilities in reasoning, dialogue and argumentation (Simmoneaux 2008; Zeidler and Sadler 2008; Zohar 2008). Furthermore, it encourages a richer and more comprehensive construction of the

---

[1] I would like to thank John Forge for his helpful suggestions on this paragraph and successive references to this point.

[2] For an interesting example, see the discussion on the Manhattan Project and especially on Frédéric Joliot-Curie's refusal to join the moratorium in publishing results on neutron multiplication in an assembly of heavy water, in 1939 (Forge 2008, pp. 72–76).

social and political aspects of science, avoiding trivialised images (Adúriz-Bravo 2005b). In the last couple of decades,[3] curricula in several different countries have regarded understanding of values-related issues as an important goal. Moreover, the consideration of ethical, political and other value outlooks in science content and research creates a particularly fertile ground for interaction between teachers of different curriculum subjects, such as natural sciences and philosophy (which has long been a high school subject in its own right in many countries)[4]. Even where philosophy is not part of the curriculum (not even as an elective course),[5] humanities subjects and civic and citizenship education offer many possibilities for collaboration, provided teachers adopt a controversial issues perspective rather than a more descriptive one (Kolstø 2008; Ratcliffe and Grace 2003). Appropriate teaching and learning of values-related questions in the nature of science should include involvement in reasoning and rational debate about controversial issues. Then, students can become more ready, responsible and adept at participating as citizens in science and technology-related issues both inside and outside their local communities, and even globally. Also, environmental, medical, biotechnological and telecommunication issues usually stimulate interest, so teaching science in socio-scientific contexts enhances motivation to learn the relevant scientific content (Grace 2006).

For science education, it is relatively easy to find interesting and relevant material from a socio-scientific point of view (SSI),[6] on the role of noncognitive values in the funding of scientific research and on the technological consequences of scientific inquiry. It is much harder, though not impossible,[7] to find related works framed in a more closely philosophical perspective. But philosophical reflection on values-related dimensions of scientific knowledge and inquiry has been on the increase in contemporary philosophy of science since 1970.[8] Philosophical debates have often distinguished cognitive (or epistemic)[9] values from noncognitive (non-epistemic, such as moral, political, economic) ones. The significance of cognitive values has become more or less commonly accepted, although there are several different standpoints on which constitute the relevant cognitive values and which should have precedence (Lacey 1999, Chap. 3). The place of noncognitive values, on the other hand, is much more controversial. For instance, different viewpoints can be found pertaining to the difference between the external impact of such values

[9] Throughout this paper we will take "cognitive" and "epistemic" as synonymous.

(on the funding or on the consequences of research) and the internal ones (the role of non-epistemic values in theory choice or theory validation, i.e. the presence of noncognitive values in science *content*).[10]

In sum, the thesis that science is not value-free has been steadily gaining acceptance. But this does not automatically mean abandoning every ideal of objectivity. Since the full meaning of the thesis that science is not value-free is the focus of heated philosophical debate, this chapter will aim first at presenting an overview of some issues pertaining to the role of cognitive values, and of the significance of noncognitive values on theory choice, validation or acceptability, from a philosophical point of view.[11] It will then address the question of why and how these philosophical issues and debates deserve to be engaged with in school science education.

33.2 Is Science Value-Free?

What are we speaking about when we discuss "values"? In the eighteenth and nineteenth centuries, a theory of economic value developed in the works of Smith, Ricardo and Marx, and even today, many people think of *economic* value when they hear the word "value". But the term has much wider scope: values (such as beauty, goodness, justice or sanctity) on one hand, and judgments of value on the other, have long been the focus of philosophical consideration.[12] Since the 1850s, debates conducted by philosophers and philosophical schools such as Nietzsche, Brentano, Dilthey, the utilitarists and the neo-Kantians at Baden have developed a theory of values that became a major concern in philosophy in its own right. The debates encompassed many issues related to the ontological nature of values; their scope; the existence of "intrinsic" values, as distinct from "extrinsic" ones; the notion of a polarity of values (for every positive value there is a related negative one); etc. (Ferrater Mora 1975; Frondizi 1982).

Although it isn't possible to address all these matters here, the question of the relationship of facts and values has led to a long-standing philosophical debate that has a special bearing on the central issue. It can be traced (at least) to Hume's discussion of the difference between matters of fact and matters of value: can *ought* be logically deduced from *is*? In some moral systems, reasoning goes from premises

---

[10] I take SSI to refer to issues based on scientific results or practices that have an actual or potential relevant impact on society (Ratcliffe and Grace 2003). They may be considered either from the (frequently descriptive and explanatory) social sciences point of view (sociology, economy, anthropology, some theories of psychology, etc.) or from a philosophical (usually normative) standpoint (ethics, political philosophy, philosophical anthropology, aesthetics, etc.).

[11] Given that the emphasis is on a general overview of the issue and on the way science education in schools may address it, some philosophical depth will be inevitably lost. Interested readers can find that depth in many of the books mentioned in the references list.

[12] Many Platonic dialogues contemplate the nature and scope of specific values such as justice (first book of *Republic*), beauty (*Greater Hippias*, *Phaedrus*) or piety (*Euthyphro*).

that are related by "is" to conclusions where the components are connected by "ought". This inference seems to be "inconceivable". There have been multiple interpretations of the relevant passages, but the most common one has been to assume that no moral judgment and, more generally, no judgment of value ("ought") can be logically derived from a judgment of fact ("is").

The logical positivists and the logical empiricists, in the Humean tradition, were concerned with emphasising the distinction between facts and values, both in general and in relation to science. Values-related statements were deemed to be neither factual nor analytical statements, and therefore they lacked truth value. Ayer (1952) and Stevenson (1960) thought that they expressed emotions: acceptance, support and approval or else refusal, denial, and rejection. In the Anglo-speaking philosophical community, the stance that values are subject-related and that they express subjective preferences was prevalent in the first half of the last century, though philosophers of ordinary language contested the image of value statements as mere expressions of emotion. But it had a significant impact on the scientific community where it has been a widespread belief that since ethical (and other values) judgments have no empirical content, and therefore cannot be tested and verified, neither values clarification nor ethical debate of any sort has any relevance in science (Rollin 2009, 2012 calls this stance "scientific ideology"). However, this conclusion missed some of the points that positivist philosophers of science tried to make.

The value-free ideal maintains that science should be axiologically *neutral*. Mainstream epistemology and philosophy of science, until the middle of the twentieth century, had stated that science is supposed to be objective and rational in a strong sense, implying that it should depict the world as it *is* and not concern itself with how it *ought to* be. Therefore, scientific knowledge is not value-laden, since it aims at an empirically grounded understanding of the world. In the 1950s several factors started to undermine this position. On one hand, Quine's holism contested the idea of a precise distinction between statements of fact and statements of reason. Hypotheses cannot be confirmed (or refuted) independently, and there are no algorithmic rules for theory choice. So considering the *actual practices* of scientists when they decide on theory choice becomes more relevant than it had previously seemed. Later, Nelson (2002) built on Quine's arguments for holism to argue for recognition of the role of non-epistemic values in scientific practice.

In an influential paper, Rudner (1953) discussed the idea that the "scientist qua scientist makes value judgments" insofar as she must decide, for instance, when the evidence is *strong enough* to accept a hypothesis or how to balance simplicity against generality. Further discussions brought to the fore the role of the epistemic values. The context of discovery/context of justification distinction restricted context of justification to epistemic values related to logical soundness and empirical evidence and excluded subjective, social or contextual particularities. On the other hand, non-epistemic values (moral, political, economical, etc.) were still assigned to contexts of discovery or application, while deemed inadmissible as criteria for theory validation or theory choice.

Douglas (2000) explains how Hempel, in his 1965 essay, *Science and Human Values*, supports the idea that science should be pursued in such a way that only epistemic values have relevance with regard to hypothesis confirmation. But when we come to hypothesis *acceptance*, a proviso should be made concerning those instances that have direct consequences on practical issues (ethical matters, social impact, safety risks and so on). Inductive risk, the possibility that a confirmed hypothesis might be (ultimately) false, or that a rejected hypothesis might be (ultimately) true, gives cause for concern regarding the outcomes of a wrong decision.[13] In those cases, non-epistemic values become very relevant, by way of consequences and risk assessment. But in other cases of "pure scientific research", with no practical applications, epistemic values would suffice for hypothesis acceptance. From Hempel's point of view, not only the physical sciences but the social sciences as well should be conducted in accord with these principles.

At the same time, questions about the responsibility of scientists as individuals and as members of institutions became a matter of common concern, especially after World War II. From a sociological point of view, Robert Merton suggested that the *ethos* of science could be described as being composed of a small set of "moral" norms that summed up the ideals into which scientists (actual or in the making) are socialised: communalism, universalism, disinterestedness, originality and organised scepticism (Ziman 2003).[14] These moral norms express the values that govern the way scientific activity is run. They constrain practices and provide a standard against which they can be measured. Confidence in Merton's *ethos* has usually underpinned confidence in science and scientists as objective, honest and free of bias. But it has also undergone discussion and criticism. What is the role these values actually play? Further discussion, even by Merton himself, suggests that this ideal is normative, not descriptive: scientists should behave in accord with it, even if their primary motivations go a different way. However, in 1974, sociologist Ian Mitroff published a study on the ambivalence of norms within scientific institutions. Mitroff's research was based on a case study conducted with 42 scientists who were part of the Apollo mission. For every Mertonian norm, he proposed a counter-norm.[15] Mitroff posited that ambivalence is not only a characteristic of science but that it seemed necessary both to the existence and to the rationality of science (Mitroff 1974). In sum, a wide range of questions about the value-ladenness of science may be addressed both from inside and outside the scientific community. Debates develop in a theoretical, highly technical philosophical context, and also in a practical, widely public one.

For instance, recent philosophical discussions of mind–body relationship and the theory of actions are wont to explain human action as intentional, that is, in terms of beliefs and desires. We perform the action A because we desire to achieve E, and we believe that A is conducive to attaining E. So we may say that desires are one of the

[13] Research on the safety of a new drug, for instance, may result in a false negative, with dangerous consequences for future users (see Douglas 2007, for an interesting example).

[14] There were also "technical" norms, pertaining to reliable empirical evidence and logical consistency.

[15] Emotional commitment, particularism, solitariness, interestedness and organised dogmatism (Mitroff 1974, p. 592).

causes of action. But individual desires do not stand alone: they are related to other desires (and beliefs) in a spreading network. Eventually, they depend on a person's basic beliefs and desires, that is, on the person's values. Discussing the fact–value dichotomy with regard to theory choice, Putnam (1990) states that terms such as "coherence" and "simplicity" are

> *action guiding* terms: to describe a theory as "coherent, simple, explanatory" is, in the right setting, to say that acceptance of the theory is *justified;* and to say that acceptance of a statement is (completely) justified is to say that one ought to accept the statement or theory (p. 139).

Therefore, values are a basis for action, particularly in terms of choice and decision. And they can become manifest in behaviours and expressed in practices both as personal and as social values (Lacey 1999).[16] If we try to explain how scientists choose between possible explanations of a phenomenon, we will eventually have to take values into consideration.

33.3 Science and Values

In the last half century, questioning of the idea of value-free science has raised many important issues in philosophy of science: realism, rationality, objectivity, demarcation, scientific change, scientific controversies and the role of gender, race or class (Doppelt 2008; Dupré et al. 2007; Machamer et al. 2000). It also has a significant role in discussions on applied science, technology, Big Science issues (such as trust and authority) and risk assessment. Even without rejecting empiricism and some conception of objectivity, science content and scientific activity (and not just its consequences) may be regarded as value-laden.[17]

With Kuhn's *Structure of Scientific Revolutions* (1962) a turning point was reached. Along with the renewed interest in the history and actual practice of science came the notion that values (whether those of society, scientific communities or individual scientists) have a relevant part to play. They are present not only in the choice of problems and in the technological or applied aspects of science but also in the evaluation of hypotheses, in theory choice and in conceptual change, which cannot be described simply in terms of logical inferences. A heated discussion ensued regarding whether the presence of noncognitive values resulted in less objectivity, leading to downright relativism.

---

[16] Lacey (1999) states that personal values may be *manifested* in behavior, *woven into* a life, *expressed* in a practice, *present* in consciousness, *articulated* in words and *embodied* in social institutions and in society (pp. 25–6). Social values are *manifested* in the programmes, laws and policies of a society; *expressed* in its practices; *articulated* in histories, traditions and institutions; *woven into* a society when they are manifested constantly and consistently; and can be *personalised* when persons act on behalf of a society where particular values are embodied (pp. 28–9).

[17] Kitcher (1993), Lacey (1999), Longino (1990), Machamer and Douglas (1999), and Wylie and Nelson (2007)

That science is value-laden is now accepted by most philosophers of science, although the scope of this assertion should be clarified. The Hempelian distinction between hypothesis confirmation and hypothesis acceptance is still part of the debate. The thesis that only cognitive values are necessary for scientific knowledge[18] clashes with the notion that other noncognitive values are constitutive of proper scientific practice. Cognitive values may be regarded as constitutive of theory choice both with regard to s*ignificance* requirements (choice of problems, selection of hypotheses and theories) and in connection with *confirmation* requirements (assessing the relevance of the evidence supporting hypothesis or theories) (Carrier 2012). But does science exclusively aim at understanding the world, or is scientific knowledge inextricably entangled with the purpose of making objects or solving problems? Is there a multiplicity of possible goals interacting within scientific inquiry (such as maximising human happiness, or economic profit, or political success)? Even if the answer is weighted towards understanding, noncognitive values are still in evidence.

Dupré and colleagues (2007) suggest that arguments against the idea of a value-free science may be categorised into three main groups: "(1) arguments from denying the distinction between fact and value, (2) arguments from underdetermination, and (3) arguments from the social processes of science" (p. 14). The first set criticises the possibility of a clear demarcation between fact and values, either by offering counterexamples or by theoretical discussion against the independence of both terms. The second group alludes to underdetermination either of theory by data or of theory choice by epistemic values, drawing from the original Duhem-Quine thesis and from Kuhn's claims, respectively (Carrier 2012). The third set encompasses different studies aimed at showing how scientists interact among themselves and with society at large and how values, interests and commitments shape these interactions. As is usually the case with classifications, this one may help us organise the multiple discussions on the field, but it is not supposed to cover all possible standpoints on the value-ladenness of science (see discussion of Lacey's arguments below, for instance).

Dupré and colleagues also suggest four dimensions that appear in philosophical debates with regard to values: the *kind* of values involved, the *way* in which they are involved, *where* they are involved and what are the *effects* of their involvement. As for the kind of values, the distinction is usually made between cognitive values, directly related to truth and knowledge, and noncognitive values, such as moral or political ones, though this distinction is itself subject to debate. There is no agreement on which values should be included under the labels of "epistemic" or "cognitive" and what the standards for their application are or the relative importance of each one. For instance, in reworking Kuhn's 1977 list, McMullin (1982) proposes predictive accuracy, internal coherence, external consistency, unifying power,

---

[18] Space precludes discussion of this position here. For a survey of the relevant arguments, the reader is referred to Doppelt (2008), Haack (1993), Laudan (1984), and McMullin (1982, 2008). The very distinction between epistemic–non-epistemic values has been discussed at least since Rooney (1992).

fertility and simplicity. Doppelt enumerates: "epistemic values include properties of theories such as simplicity, unification, accuracy, novel in prediction, explanatory breadth, empirical adequacy, etc." (Doppelt 2008, p. 303). Lacey (1999) reviews a list of items suggested by a range of authors: empirical adequacy, explanatory and unifying power, power to encapsulate possibilities, internal consistency, connectivity or holism, inter-theory support, source of interpretive power, puzzle-solving power, simplicity and fertility.

How are values involved? A first question to address is whether the involvement is unavoidable (essential) or only possible. And, in the latter case, whether it is something to be avoided, i.e. whether value-laden science is bad science. Where are values involved in scientific inquiry and knowledge? The authors discern three broad areas of science: the fields under research, the hypotheses that are posed and the evidence that is taken to support one hypothesis over others and, finally, the use of these results to generate explanations. In the first case, a division is made between the natural and the social sciences, in the sense that it could be possible in principle to investigate in a value-free way in the first group but not in the second. Or values (both epistemic and non-epistemic) would be present in funding decisions: choosing which projects to fund implies evaluating both the soundness of the proposal and the priorities of the government or agency providing the funding. A deeper consideration goes into establishing the entities that populate the area to be researched. Also in explanations, the choosing of one factor over the (multiple) others as *the* cause of a phenomenon may be determined by value considerations (Longino 1990). In the second question, there is a particularly sensitive point: if non-epistemic values have a bearing on the selection and confirmation of hypotheses, then the term "value-laden science" acquires a much stronger meaning than in the previous cases. Lastly, what would be the effects of a value-laden science? The authors state that given the variety of issues and the multiple possible positions, this question will have many answers, related to the different ways in which values may be involved in science.

33.4 The Value-Ladenness of Science: Some Philosophical Perspectives

The following reviews a few examples of relevant philosophical approaches to the question of value-ladenness with regard to noncognitive values.[19]

---

[19] There are many interesting approaches to this problem in the recent literature in philosophy of science. Because it would have been impossible to address even a representative selection, three have been selected as a first approach to the range of views expressed. See Doppelt (2008); the papers in Dupré et al. (2007), Kitcher (2001), and Laudan (1984). Also, Douglas (2009) *Science, Policy and the Value-Free Ideal*, University of Pittsburgh Press, and Machamer and Wolters (2004) *Science, Values and Objectivity*, University of Pittsburgh Press.

In *Science as Social Knowledge* (1990), Longino sets out to address the relationship of science and values in the terms of her *contextual empiricism*. She calls it a "modest" empiricism related above all to epistemology and the notion that knowledge depends on experience, and much less to metaphysics (see later discussion). *Experience* constitutes the basis for knowledge claims, coupled with an emphasis on *context* in a twofold sense: with regard to background assumptions to reasoning; and to the cultural milieu in which scientific inquiry takes place. Data cannot be considered as evidence per se: whether some fact or state of affairs will be considered relevant evidence is determined not with reference to natural relations but in connection with background assumptions. These may convey, on one hand, "constitutive values" internal to science and expressing cognitive virtues; and on the other hand, "contextual values" expressing social or practical interests. Background assumptions introduce contextual values into proper scientific inquiry: contextual values "guide interpretations and suggest models within which the data can be ordered and organized" (1990, p. 219). Their presence is not the consequence of methodological limitation or error: it does not imply bad science. Nonetheless, methodology does have a role to play: not all values are admitted without restrictions. Judgment about data changes when the meaning of terms is adjusted, but if the meaning were the same, the same earlier judgments would be made. Also, observational judgments may change places regarding their significance within a theory when assumptions change. Then, central judgments may become peripheral, and previous seemingly unimportant judgments may become significant.

Hence, we can discern an empirical dimension of science, concerning evidence retrieved from observation and experiment, and a theoretical dimension of science. Both are linked by evidential reasoning: reasoning from and to data and hypothesis. Reasoning is understood by Longino as a practice. It is not mere decontextualised computation, but an interaction that takes place in a context. And hypothesis may also change when contextual assumptions change: there is interaction between background assumptions, general theoretical perspectives and experience.

Longino emphasises the differences between her outlook and those of positivism and realism: observation and reason on their own are not enough. They are supported by assumptions that express social and cultural values. But she also distinguishes her position from the relativism linked to holism: not all statements are context relative in the same way. The role of social and contextual values does not rule out objectivity. The scientist's desires for some kind of knowledge may configure the objects of her inquiry, but the existence of background assumptions that introduce social and contextual values becomes a basis for relativism only in an individualist conception of scientific inquiry. Scientific inquiry is the undertaking of a community, and not of individual researchers. It depends on the collaborative social interactions of "transformative interrogation". In this way, the impact of subjective preferences is minimised through criticism and interrogation by the scientific community. The more diverse and heterogeneous the community, the more diverse their assumptions will be. More of them will be made explicit, scrutinised and eventually modified. Discovering where inferences and experiences differ presupposes a minimum communicative context: shared standards for criticism, recognised public forums for its presentation, community responses and an equality of intellectual authority (Longino 1990, pp. 76–81). This also leads Longino to support a minimalist realism: "there is a world independent of our senses with which those senses interact to produce our sensations and the regularities of our experience"(Longino 1990, p. 222). Criticism and interrogation go a long way to minimise the impact of assumptions, but they cannot eliminate them: those assumptions shared by all the members of the community will not be made explicit; they will remain invisible and thus evade examination.

Furthermore, and directly relevant to science education aims, Longino states that the view that science is value-neutral may have the undesirable effect of disempowering non-scientists from understanding not only the technical, disciplinary content of inquiry that inform technologies but the contextual dimensions that shape inquiry. So they will have fewer possibilities of being adequately critical when dealing with the products of those technologies (Longino 1990, p. 225).

Lacey (1999, 2009) partially agrees with Longino's thesis, insofar as cognitive and noncognitive values may be clearly distinguished. Science should aim at empirically grounded and confirmed knowledge and understanding of phenomena. Inside these limits, it may be conducted within a plurality of worldviews and their associated value outlooks. "Science is value-free" is not meant in the sense that science and values don't touch. Science itself can be regarded as a value (as far as knowledge is a value); value judgments may be informed by scientific knowledge of the relationship between means and ends; scientists must display personal and moral values in their scientific practices (the "ethos of science"); and so on. However, these interplays should not touch the three component notions: impartiality, neutrality and autonomy. Neutrality means that scientific theories and practices do not imply or favour any value judgments or outlooks, cognitively or with regard to applications. Impartiality entails that criteria for the appraisal and acceptance of theories or the making of scientific judgments should not include noncognitive values. Autonomy asserts that scientific communities claim sole authority in the choice of problems, the evaluation of theories, the content of scientific education and in prerequisites for being admitted to the scientific community.

Lacey revises these three notions. Impartiality presupposes that cognitive and noncognitive values can be discriminated. Theories are accepted if and only if they display cognitive values to the highest degree, in agreement with relevant empirical data and other accepted theories. They should be subject to the most rigorous standards of evaluation. Neutrality presupposes, first, impartiality. Also it entails that there are accepted scientific theories that are significant for every viable value outlook and that no value outlook is noticeably favoured by accepted scientific theories. The notion of *value outlook* means that different kinds of values (moral, social, political, etc.) may be ordered coherently and rationally founded by a set of presuppositions about nature and human nature and about what is possible. Such presuppositions may be scientifically investigated to some extent. Inquiry may then support or oppose the presuppositions of a given value outlook. So, for a value outlook to be *viable*, it must be in accord with the results of accepted scientific knowledge. Scientific knowledge constrains the range of viable value outlooks, but still leaves a plurality of them open to explore. Lastly, autonomy is subordinated to impartiality and neutrality. Accepting a theory implies exclusively the play of cognitive values. But since the previous moment of adopting a strategy leaves an important role for social values to play, autonomy cannot be well embodied.

Modern science has been predominantly associated with a particular worldview: materialism. This has led to science being conducted under a certain strategy that constrains potentially admissible theories to those that can

> represent and explain phenomena […] in terms that display their lawfulness, thus usually in terms of their being generated or generable from underlying structure and its components, process, interaction and the laws (characteristically expressed mathematically) that govern them (Lacey 2009, p. 843).

Consequently, empirical data are chosen and reported typically in terms of quantitative categories, related to measurement and instrumental and experimental operations. Both data and theoretical representation of phenomena are "stripped of all links with values and dissociated from any broader context of human practices and experience" (Lacey 2009, p. 843). Lacey calls this way of conducting science the "decontextualised approach" (DA), which is associated with the "modern value scheme of control" (Lacey 1999b). Materialism is widely associated with the values of technological progress (VTP) that favour control of natural objects. This way of conducting science means that science is not neutral, but it can still be impartial, as long as cognitive and social values have a role in scientific judgments at different logical moments (i.e. adopting a strategy or soundly accepting a theory). But carrying out science within the DA is not the only possibility of conducting science impartially. The exclusive association of scientific research and materialism must be challenged not only in philosophy of science but in sound science teaching as well. With regard to applied science and technological innovation, DA may be useful to explain its *efficacy*, but it is certainly not enough to establish its ethical or political *legitimacy*. There is an interest in conducting systematic empirical research under other strategies which do not uphold materialism. For example, Lacey discusses how genetically engineered transgenic crops, produced under DA and in accord with VTP, differ from organic or ecological agricultural alternatives. These alternative strategies privilege sustainable ecosystems, agency and community and, therefore, different socio-economic relations of production (Lacey 1999, 2005, 2009).

Neutrality (in the sense discussed above) is better served by a plurality of strategies that address the interests of different value outlooks, instead of reducing options to the materialist strategies which exclude value-laden terms from theories and methodologies. Nonetheless, admitting a plurality of options does not support any or every worldview and value outlook, which may mean abandoning impartiality. For instance, religious outlooks inconsistent with accepted scientific results, such as intelligent design, are incompatible with the scientific attitude.

Spanish philosopher Echeverría (1995, 2008) characterises scientific activity as a value-laden transformation of the material world and of human beings. He proposes a variation on Reichenbach's distinction between context of discovery and context of justification into a new categorisation of four contexts: innovation, evaluation, application and education. Contexts of innovation and evaluation loosely resemble the original proposal of Reichenbach. However, context of evaluation widens to comprise the different practices scientists perform when they evaluate products of scientific activity as they are achieved: not only hypotheses and theories but also data, measurements, experiments, proofs, papers and other publications. Context of application relates to science-related activities that aim at attaining changes in the world. This includes the manufacturing of artefacts but also the modification of images, languages and social relationships. Expert consultation in problem solving is also part of this context. Context of education consists of two reciprocal activities: teaching *and* learning, not only of conceptual and linguistic systems but also of representations, scientific images, notations, operating techniques, relevant problems and instrument handling procedures.

Echeverría advocates for axiological pluralism in science: scientists share a common collection of values, practices, habits, goals and, of course, knowledge. Scientific practice is axiologically meliorative: new actions improve on previous actions because they increase the degree of satisfaction of some value or decrease some disvalue. Different contexts imply different activities and agencies (educational, investigative, evaluative and application-oriented). Therefore, axiological rationality does not exclude conflict of values, but it requires specific procedures for its resolution.

Core values may differ in scientific practice in different contexts. For instance, science teaching and learning hold their own criteria and procedures for enunciation, justification, evaluation and application of scientific theories, which may occasionally diverge from those present in other settings of scientific activity. It does not entail mere transmission of information or even knowledge. In the context of education, the main value is "*communicability* of scientific content to every human being and therefore a requirement for publicity"[20] (Echeverría 1995, p. 125). Scientific content alludes to knowledge but also to skills and abilities. And also, and here we find an occasion of tension, on one side it should aim at the normalisation of those knowledge, skills and abilities, but on the other it should foster freethinking, criticism and creativity. Furthermore, within the context of education itself, criteria for evaluation of popular communication of science may differ sharply from those of investigative or academic education. Therefore, education becomes a pertinent frame for the philosophical consideration of the historical and conceptual development of scientific content and practices, and of the interplay and conflict of values within them.

33.5 Science, Values and Science Education: Two Debates

While the foregoing outlines some of the richness and relevance of the question of values in contemporary philosophy of science, it is important to consider how philosophical discussions about values and science relate to science education.

---

[20] "…la *comunicabilidad* de los contenidos científicos a cualquier ser humano; de este se deriva la exigencia de publicidad"

This section begins by synthesising some interesting debates in two special issues of *Science & Education* (1999, 8(1) and 2009, 18(6–7)) to illustrate some of the questions at stake. Both publications share the same structure: an author posits a thesis on a controversial philosophical and metascientific question, and a number of colleagues respond to that core article. Authors come from diverse professional origins: philosophers, scientists, educators and historians engage in multidisciplinary interchange. Finally, the first author makes a synthesis and response to the critics or to the alternative viewpoints stated.

Many of the topics addressed in the first special issue (*Science & Education*, 1999, 8(1)), under the title *Values in Science and Science Education: A Debate*, concern philosophical discussion about the relationship of science and values, as outlined above in the *Science and Values* paragraph. Discussion here highlights the relevance of these issues to science *education* and readers are advised to refer to the actual papers for deeper understanding of the philosophical points. The first round of debate starts with a paper by Lacey (1999b). He states that different standpoints on human values and human flourishing may affect the strategies under which science is conducted. So, science education should foster not only a sound understanding of science knowledge and practices but a critical self-consciousness about scientific activity and applications. This means understanding how cognitive and social values interact in scientific activity, what the limits and risks of that interaction in the making of theoretical judgments are and how noncognitive values may affect the achievements of scientific inquiry. This understanding should also encompass the knowledge and evaluation of different points of view. For example, this would mean challenging the exclusive association of scientific research with materialism within science education. Debates should include not only scientific practices and results under the materialist strategy but also the desirable strategies to further human well-being. This, however, would not mean accepting those worldviews or value outlooks that clash with the scientific attitude, such as creationism. Also, Lacey still upholds, as a main goal of scientific education, the teaching of scientific knowledge, the methods for discovering and the criteria for evaluating it obtained within DA. This may even constitute the core of first approaches and experiences with science learning (Lacey 1999, 2009).

As Machamer and Douglas (1999) and Davson-Galle (2002) emphasise, Lacey's position entails making the values that inform science knowledge and research explicit so that alternative value outlooks become visible and evaluation becomes possible. In a response to Lacey's paper, Cross (1999) indicates that these suggestions for science education belong within a rich tradition of like-minded proposals from different ideological perspectives. He points out that Lacey's call for sound and critical understanding of scientific activity and applications may be interpreted in two different ways. On one hand, it may be thought of as a somewhat insufficient proposal to discuss science from within a "traditional conception of scientific literacy". This option entails the difficulty of integrating these metadisciplinary aspects of science in the science curriculum, where they tend to be relegated to the periphery as mere illustration, and traditional content and values will still constitute core science teaching. Alternatively, he recommends a more "transformative" scheme to initiate a thorough revision of science education in schools in order to promote citizens' engagement and participation.[21] In his *Reply*, Lacey agrees with the desirability of teaching science in such a way that it enables an integration of the philosophical, historical, economic and social context of science. This would mean favouring a richer understanding of science for those who will go on to be active scientists, but also for those who will not but still need to be able to judge the significance of scientific research and knowledge with regard to cognitive and social values.

Though not directly referring to Lacey's paper, Allchin (1999) discusses the relationship of science and values with an emphasis on the educational point of view. He argues for science teachers to explicitly address the various ways in which values and science may intersect: epistemic values in scientific research; non-epistemic values in individual practitioners of science and methodological provisos against potential biases; and social and cultural values' challenges and novelties deriving from scientific results. Teachers should help students develop the relevant skills for a critical consideration of these roles of values in science. And he argues that this will be best achieved through reflexive analysis of students' own "modest" scientific modelling practices in classrooms and of historical cases. Reflexive analysis may also foster argumentative skills oriented to public rational justification of values (ethical or otherwise) avoiding common sense, naïve recourses to individual, personal "feelings" or values.

The second *Science & Education* issue we will consider, *Science, Worldviews and Education* (2009, 18(6–7)), has a much larger scope than the first one, since the idea of "worldview" encompasses not only values-related questions but also metaphysical, ontological and epistemological standpoints (see Chap. 50). The focus here is on some arguments linked to the relationship of values and science and its consequences for science education.

What is a worldview? If we accept that worldviews imply ontological, epistemological, ethical and sometimes religious commitments, is there a scientific worldview or is science worldview neutral? How does science engage with religious, philosophical, ideological or cultural worldviews? How do philosophical systems relate to science (and the putative scientific worldview)? What are the educational consequences of these questions? Should science education inform student worldviews, promoting worldview-related beliefs and ways of life or should science be learned only for instructional purposes? Should they promote students' *acting* upon those beliefs and ways of life? Some of these questions aim for descriptive, factual research; others require normative, regulative argument.

The lead essay by Hugh Gauch, Jr. (2009), delineates seven key features or "pillars" of science, derived from AAAS and the US NRC position papers: realism, the presupposition that the world is orderly and comprehensible, the role of evidence, use of logic, the limits of science, the universality of science and its ambition to contribute to a meaningful worldview. Reasoning from those "pillars", and from a

---

[21] See Kutrovátz and Zemplén (Chap. 34), and Vesterinen, Manassero-Mas and Vázquez-Alonso (Chap. 58), for a discussion on research in sociology of science and science education and of STS and HPS traditions in science education. Also, Aikenhead (2006), Hodson (2011), and Pedretti et al. (2008).

discussion of scientific method, Gauch argues against naturalism as a necessary commitment for science[22] that "the presuppositions and reasoning of science can and should be worldview independent, but empirical and public evidence from the sciences and humanities can support *conclusions* that are worldview distinctive" (p. 667, emphasis added). So, science does not imply distinctive worldview beliefs. Scientism is unacceptable. While science can say something about worldviews, it is not the exclusive provider of knowledge; philosophy, religion and art can offer it, too. This means that natural theology is not impossible in principle: empiric scientific evidence may address conclusions that derive from non-natural premises. So, from Gauch's standpoint, worldview-specific implications have a place in individual beliefs and in public debate, but not in institutional (including educational) requirements. In his paper, Fishman (2009) agrees that science does not presuppose naturalism as an a priori commitment, and therefore, science can evaluate supernatural theses or claims as far as evidence supports them. So, the rationale for not teaching intelligent design as an alternative to evolution in public schools (for instance) rests on the basis that evidence does not support it, regardless of whether it is labelled as "natural", "supernatural", "religious" or "paranormal".

An interesting historical illustration of the relationship between a theistic worldview and a demand for empirical evidence to support belief may be found in Matthews' article on the life and works of Joseph Priestley (Matthews 2009a). Irzik and Nola (2009) oppose the idea that science can be worldview independent: since a "pillar of science" answers a worldview question, and it also contradicts other possible answers (other worldviews), it cannot be assumed to be worldview independent. For example, they contend that Gauch presents methodological naturalism as a "mere stipulatory issue", while they claim it to be one of the "essential and distinctive features of science": abandoning it is tantamount to abandoning science (p. 741).

However relevant this discussion, worldviews issues should not be reduced to metaphysics questions such as the existence of God or the purpose of the universe. Irzik and Nola (2009) present a series of questions worldviews seek to provide answers for. Among them are questions such as "How should we live our lives?" "What is good and bad, right and wrong?" and "What is the best form of government?" that deal with ethical and political issues. The authors argue that it is possible to offer naturalistic answers even to these questions.

Do worldviews necessarily imply particular value outlooks? What are the consequences of adopting a scientific worldview for the understanding of moral behaviour? What are the consequences for the conduct of science in adopting value outlooks associated with non-scientific worldviews?

---

[22] For the sake of concision, we will refer to methodological naturalism as claiming that natural entities and means only can be called upon in scientific knowledge and practices and that natural sciences are a paradigm of epistemic research. This does not exclude by itself the existence of supernatural beings. Ontological naturalism states that only natural entities *exist* as a content of reality and no supernatural explanations whatsoever are acceptable. Irzik and Nola (2009, p. 733) point out that in some versions of naturalism, mentalistic and even mathematics items can be legitimately involved, since "natural" not necessarily implies "physical". Finally, materialism or physicalism affirms that only *material* (i.e. physical) entities exist.

The relationship between religion, philosophy and science (or natural philosophy) has long been the object of examination. It fuelled heated philosophical debate in the Middle Ages and has been a leitmotif in studies of the Copernican Revolution. Also, evolution-related issues frequently involve arguing on this relationship. Recently, Stephen Jay Gould coined the acronym NOMA to refer to one of the stances in the debate: the idea that science and religion each has a legitimate *magisterium* or teaching authority (from *magister*, Latin for "teacher"), and these *magisteria* do not overlap. Science has nothing to say about the domain of ethics, while religion rightfully deals with questions of ultimate meaning and moral value. Furthermore, scientific and religious *magisteria* do not exclude other possible inquiries (for instance, philosophical ones).

On the other hand, it may be argued that deciding which theories belong in the scientific canon and whether they have worldview content is something that cannot be determined necessarily or a priori (Cordero 2009, pp. 757–8). In fact, the limits for scientific understanding of the world (Gauch's Pillar 5) change over time. The scope of naturalistic perspectives, such as Darwinist theory of evolution, has been widened to explain human mind and culture, including political and moral issues. Sociobiology and evolutionary psychology endorse the idea of a naturalistic approach to ethics and moral behaviour. For instance, Ruse and Wilson (2006) contend that offering materialistic explanations for the basis of human culture and human mind undermines the foundations of any a priori philosophical or religious (extra material) ethics. Evolutionary biology and cognitive psychology may be expected to explain feelings of right and wrong, and so offer a basis for morality; "a naturalistic ethic developed as an applied science" (Ruse and Wilson 2006, p. 558). But showing the links that go from factual premises to normative conclusions (from *is* to *ought*) is harder than it seems: "the connections between biological facts and questions about the status of morality are extremely complicated" (Kitcher 2006, p. 181)[23]. This cautions us against assuming that the relationship between biology and ethics in questions pertaining to, for instance, moral objectivity or moral progress, has been addressed in a way that does justice to its complexity. But it does not mean discarding research aimed at connecting biological knowledge and moral philosophy. Cordero (2009) argues that scientific content and scientific methodology can establish some constraints on which worldviews should be marginalised.

Conversely, a case can be made to show how religious worldviews imply an associated value outlook that includes a set of moral imperatives, some descriptive and normative framework of the mutual relationships of human beings and of human beings and nature. And Fishman argues (2009) that this poses a renewed challenge to science educators: how to maintain the desirable intellectual integrity without offending students in a way that impedes science education. Also, Reiss (2009) focuses on scientific and religious comprehensions of biodiversity to show how science and religion can be seen as distinct or related worldviews, depending on the aims of school science education. Arguments may be raised for and against

---

[23] See his outline of three meta-ethical questions for an example of how complicated this can become.

teaching about religion in science classes. Reiss reviews some of them, and contends that science teachers can be respectful of students' personal positions while at the same time fostering their engagement with science and helping them understand the strengths and limitations of science with regard to specific issues.

33.6 Science Education and Philosophy Education: Teaching Controversial Issues

Even with the previous brief summary, it can be seen that teaching about the role of values in science content and practice may present diverse challenges to science (and other) teachers. Certainly, it will seem controversial to those who still think science teaching should aim at the transmission of facts and the scientific method (or methods), and to those who think of science as value-free. They will probably argue that ethical, aesthetic, political or social issues are simply not relevant to science teaching. Even cognitive values may not be easily identified or taken into consideration by science teachers (Figueiredo Salvi and Batista 2008). Furthermore, those who are committed to taking nature of science into consideration in their classes may find it hard to decide how much time to devote to values-related issues. Teaching controversial issues with an acceptable degree of depth might take too much time, detracting from "regular" scientific issues demanded by the curriculum. This could be perceived to be a loss to "real" scientific content, and not even central to nature of science teaching. Also, value issues imply taking into consideration a multiplicity of variables: incomplete or insufficient information, uncertainty and risk, multiple and sometimes incompatible ethical and political philosophical, psychological and sociological frameworks (Ratcliffe and Grace 2003; McKim 2010). Science teachers may feel daunted by this complexity. Some of them may feel uncomfortable with their lack of information or expertise regarding such issues as ethical or political theories, or moral reasoning. And they may not have adequate resources and strategies to cope with the teaching of open-ended issues. Also, teachers may feel concerned about being suspected of bias or of having a hidden personal or political agenda. Some issues may be "too" controversial in particular institutions, for instance, those that collide with religious faith, which is the case with many bioethical questions such as abortion or stem cell research (Grace 2006). So why bring value issues into the science classroom?

Nowadays the idea that the aims of science education should include teaching some significant scientific knowledge along with some metascientific knowledge and understanding about the nature of science is broadly accepted. It has long been argued that the purposes of science teaching at school level must expand from the traditional initial training of the next generation of scientists. It should involve preparing students who will not go on to a scientific career for a more ready, responsible and adept participation as citizens in scientific and technologically related issues. In a well-known work, Driver and colleagues (1996) stated five rationales for teaching about the nature of science, two of which are relevant here: the democratic argument and the moral argument. On one side, students should leave school with enough understanding of scientific knowledge and practices that they may be able to appreciate and engage with the dilemmas posed by value-laden ethical, political and socio-scientific issues. On the other, they should develop a significant awareness of the norms that guide the activities of the scientific community, norms and values that are of general worth. Students should be able to explore their own (frequently tacit) knowledge, beliefs and values, and learn to assess science and technology knowledge and artefacts with regard to individual, social and global responsible action concerning that knowledge and those artefacts. Also, ethical and citizenship education is an educational aim that can be enhanced by including reflective consideration of the traditional Mertonian values, the so-called countervalues (Mitroff 1974), and other epistemic and non-epistemic values in scientific practice.

The teaching of the role and impact of contextual values, especially with regard to biotechnology and environmental challenges, has been fully addressed in the SSI literature,[24] and it is not possible to review it here. Discussion here focuses on some questions related to ethical issues and education that have been brought to the fore both in science and in philosophy education from a philosophical point of view. This does not imply teaching philosophy of science (or philosophy in any other sense) in the science classroom as a pure discipline (Adúriz-Bravo 2001; Matthews 1994/2014).

Although from a philosophical point of view it would be difficult to find any accord on the nature of science, from the standpoint of the wider community of science education (including philosophers but also historians of science, sociologists, natural scientists, science educators, science communicators, policymakers, science teachers), a corpus of themes or strands worth teaching on the nature of science can be found. And values-related issues regularly appear in this corpus.[25] Furthermore, noting that this description is intrinsically problematic (but not arbitrary) may encourage a richer and more comprehensive construction of the ethical, social and political aspects of science. In this way, "straw-man" perceptions of science as a deceiving harbinger of oppression, or as a faultless and providential supplier of truth and human progress may be avoided or at least discouraged (Adúriz-Bravo 2005b). Kitcher (2001, p. 199) describes these two images as (i) the version of the faithful, "which views inquiry as liberating, practically beneficial, and the greatest achievement of human civilization", and (ii) the image of the detractors that portrays science as "an expression of power, a secular religion with no claims to "truth," which systematically excludes the voices and the interests of the greater part of the species".

On the practical side, many curricula from different countries[26] regard understanding of values-related, socio-scientific and ethical issues as an important goal.

[25] Adúriz-Bravo (2005b), Osborne et al. (2003), and Lederman et al. (2002)

[26] Among others, AAAS (1993), McComas and Olson (2002), Conseil de l'Education et de la Formation (1999), National Research Council (1996), OECD (2001), Consejo Federal de Cultura y Educación (2006), and Secretaria de Educação Básica Brasília (2006).

Also, many of these issues occupy a relevant space in the media. They are present in social and political debates, and even day-to-day subjects of discussion, decision-making and social and political participation. The topics may range from global dimensions (e.g. nuclear plant safety, which was lately in the news after the Fukushima Daiichi incident), to regional or national dimensions (for instance, grandparent's DNA evidence in determining the filiation of the *desaparecidos* (Disappeareds') offspring in Argentina), to personal decisions (shall I vaccine my children against H1N1 influenza or MMR?). Science teachers may help students acquire the relevant scientific information that has to be considered in these controversies. They may provide conceptual and procedural knowledge that enables students to evaluate scientific content, distinguishing mere opinion from well-substantiated evidence. They may highlight the importance of sound scientific knowledge to appraise the premises in the arguments provided, therefore inspiring new interest in the relevant scientific content. Students would then become acquainted with a more accurate portrait of the nature of scientific activity and the work of scientists, and develop a more sophisticated awareness of the scope and limits of scientific knowledge that will help them to evaluate the reasons provided and the conclusions arrived at.

Conner (2010) proposes another rationale: the appreciation of cultural determination of the solutions to ethical problems. This would help "develop tolerance and an appreciation of other viewpoints". Some questions can be noted here. For instance, we find again the normative–descriptive choice of stance. What is and what should be the relationship between philosophical ethics and social sciences empirical research? What *empirical* psychological or social traits do philosophical ethics theories presuppose? Are they sound? What do anthropological or sociological differences between cultures tell us about the different values embraced and the distinctive ways of resolving conflicts? What are the *normative* principles about truth, duty, happiness, a good life and justice? What are the different perspectives on toleration and rights that may apply?[27] On one hand, philosophical ethics or theory of knowledge may be supported and influenced by empirical findings (though some philosophers will argue that this influence is inappropriate). On the other, empirical research may be shaped by (sometimes tacit) philosophical frameworks. This can be extended to the teaching and learning of ethics (in science classroom and elsewhere): should we present different ethical perspectives and help students make informed decisions about them? What would be the impact on actual behaviour? Should teachers aim at the internalisation of specific moral codes? Or should they present a plurality of moral systems and a diversity of ethical theories and help students develop the requisite skills and attitudes conducive to making autonomous, reflective choices? Ethics teaching in a vocational education setting, for instance, would strongly aim at an impact on students' beliefs and behaviour. Discussion on research ethics in most scientific schools, of the moral status of animals in Veterinary school, or reproductive ethics in Medical school (particularly in Obstetrics and

[27] For a first approach to the philosophical problems posed by the notion of tolerance, see Forst, R. (2012), Toleration, In E.N. Zalta (Ed.), *The Stanford Encyclopedia of Philosophy* (Summer 2012 Edition, forthcoming). http://plato.stanford.edu/archives/sum2012/entries/toleration/.

Gynaecology) (Gillam 2009; Rollin 2009), for instance, will aim at fostering behaviour and exceed the understanding of ethical theories and the training in ethical reasoning typical of Humanities education.

Reiss (2008) enumerates four possible aims for teaching ethics in the science classroom: heightening students' ethical sensitivity, increasing students' ethical knowledge, improving students' ethical judgment and making students better people. Increasing student knowledge does not necessarily imply moral transmission. Moral transmission aims at the internalisation of a set of principles, values and rules. It implies the choice of a particular value outlook and a specific conception of the good life; it intends for students to adopt that outlook and that conception, and act accordingly. Ethical inquiry approaches, instead, aim at helping students develop the requisite skills and attitudes conducive to making autonomous, critical and reflective evaluation and choices on specific values, actual moral codes and ethical dilemmas (Gregory 2009). Since there is no philosophical consensus regarding the relationship of values and science, a plurality of views can be addressed. However, this standpoint requires a certain engagement with a minimal set of moral principles and does not imply a relativistic stance. From a Habermasian point of view, for instance, it would presuppose the requisite conditions and rules to conduct a genuine dialogue, that is, rational argumentation as the only authority, open choice of problems, unrestricted participation of any interested party that can make a relevant contribution, no coercion exercised, equal possibilities for everyone of expressing themselves and everyone being internally free to be honest and not deceive others or oneself.[28]

Political literacy, as an indispensable stage in the development of a democratic society, presupposes an education that, among other things, fosters skills related to rational deliberation and argumentation in the elucidation and resolution of social and political conflict (Gutmann 1999). From this point of view, philosophy, civic and science teachers can be regarded as epistemic agents, able to evaluate beliefs (own or other's) and to rationally sustain or change them. They should also be prepared to educate their students to attain the same abilities and dispositions.

There are no shared criteria in philosophy (including ethics) to identify universal problems or methods (since Plato and the Sophists to the twentieth-century analytic–continental divide) and no reaching a satisfyingly wide and stable consensus (Rabossi 2008; Rescher 1985). Value-laden questions are common in the social sciences and the humanities, and explicitly explored and addressed in philosophy education. Philosophy and civics education entail teaching and learning to pose questions, to analyse potential answers and to make decisions and act responsibly upon them. Students who encounter philosophy for the first time frequently have difficulties in dealing, intellectually and emotionally, with the mix of lively debate; rigorous, sophisticated reasoning; and the impossibility of reaching a sole, commonly accepted answer, typical of the philosophical outlook.

---

[28] See also Ratcliffe and Grace (2003) (pp. 21–24 & pp. 29–32) for related questions in environmental education.

Since one or more philosophy courses (including ethics) have long been mandatory in the French, German, Italian, Spanish and most South and Central America curricula, a rich corpus of research and scholarship has been growing on philosophy education in the last few decades.[29] In particular, relevant work is taking place on topics such as how to teach and learn to ask philosophical questions and the art of posing relevant problems. Just as science education research has shown students (and even teachers) to display a tendency to "black or white" positions, from a naïvely realistic and dogmatic view of science to a (equally naïve) relativism or scepticism, a similar phenomenon has also been reported with regard to ethics teaching and learning (Allchin 1999; Paris 1994). Naïve dogmatic students display an unjustified belief in rules or principles learned from their family, friends, school, church or the media. They may be reinforced by teachers who adopt some normative ethical stance (say, Kantianism or rule utilitarianism) and present it as the best (or even the only) one. Crude relativistic students tend to regard everything as a matter of taste or opinion and lack any form of justification beyond personal likes or dislikes. Consideration of these issues is usually part of the training and practice of philosophy teachers. Research from the Philosophy for Children programme and from subsequent investigation in the field (UNESCO 2007; Kohan 2005) can offer interesting approaches to ethics education in primary and secondary education classrooms.[30] In science classes, tendencies to dogmatism could lead to a simple presentation of the "right" values in science (usually epistemic ones) coupled with a hagiographic (Adúriz-Bravo and Izquierdo-Aymerich 2005) view of scientists. On the other hand, presenting the class with a variety of ethical stances may lead them to an increasingly relativistic picture of ethics, wherein anything may be acceptable so long as the right ethical theory that supports a particular position may be found.

Value issues in science education share philosophical traits such as their intrinsic controversial nature, the lack of a single or even a more or less commonly accepted framework for analysis, the complexity of the discussions and the inexistence of a simple answer or commonly accepted conclusion for debates. This makes their teaching a particularly promising ground for the interaction and communication of different curriculum subjects that are usually kept apart. This interaction will be more fruitful on those occasions when science teachers adopt a controversial issue perspective rather than a descriptive one (Kolstø 2008). Different standpoints

For a perspective on moral education from a theory of care point of view, see Noddings and Slote (2003).

regarding specific moral and ethical vocabulary and problems, such as freedom, responsibility, diverse theories on moral good, duty and rights that are frequently attended to and discussed in philosophy classrooms, can be reviewed and engaged with in science classrooms.[31] For instance, Conner (2010) presents and comments on several approaches to bioethics education: values clarification and values analysis; individual or collaborative inquiry approaches; futures thinking models. Ratcliffe and Grace (2003) discuss several structured learning strategies for whole-class and small-group discussion.

A significant consideration of ethical issues also entails core skills in reasoning, dialogue and argumentation. Value issues in science education are both dependent on and can contribute to developing these abilities.[32] When debating values-related issues, students should have the opportunity to consider the different, and sometimes conflicting, reasons there might be for accepting or opposing a position. And they should be able to foster the abilities to reason soundly about them and evaluate others' reasoning. But argumentation on its own is not enough to ensure the development of good ethical thinking. Reiss (2010) argues for three complementary criteria: first, the arguments must be reasonable. This does not mean that they must exclusively answer to the formal (classical) deductive logic validity criteria. Rational revision and change of beliefs imply the capability of logically, pragmatically and rhetorically producing and evaluating arguments, that is, the knowledge and correct application of both formal (validity) and non formal (acceptable, relevant and sufficient) criteria (Govier 2010). Sound arguing also requires a good understanding of the meaning of the terms employed and of whether the premises are warranted.[33]

In social, ethical and political issues, the premises may originate in natural, social or philosophical theories, making communication across the disciplines not only possible but highly desirable. A working understanding of ethical frameworks that have been developed throughout the history of philosophy is a fundamental help in avoiding those naïve extremes sketched above or mere common sense exchanges. There is no unique, universally accepted set of moral values, and in most multicultural societies there is only a partially shared set of commonly accepted values. But there are moral traditions (religious or otherwise) and philosophical theories that can give a framework to moral reasoning. So, in the second place, moral argumentation should be placed within an established, explicit ethical structure. Virtue ethics (whether of an Aristotelian persuasion or not), consequentialism (for instance, utilitarianism), deontological theories (Kantianism) and other philosophical frameworks may provide teachers and students with sophisticated arguments and examples to support discussions on ethical issues in scientific activity and scientific outcomes. An additional question is whether moral reasoning can be independent from an ethical theory: Aristotle's way of reasoning may be thought of

[33] Adúriz-Bravo and Revel Chion (2005), Adúriz-Bravo (2014), contributions to Erduran and Jiménez Aleixandre (2008), and Matthews (2009b)

as quite different from Kant's categorical imperative (Reiss 2010). Reiss outlines another issue worth exploring: the need to widen the moral community. He mentions two instances: interspecific ethics (Do animals have rights? Should those rights be taken into consideration, for instance, in experimentation with animals? (Rollin 2009; Lindahl 2010)); and intergenerational ethics (consequences for those far away in the geographical or in the historical sense, climate altered for generations, nuclear disposals). Lastly, conclusions must be arrived at as the outcome of genuine debate. Also, and this point would probably be contested by other philosophy educators, discussions should aim at consensus. Consensus should be understood as being coherent with one of the well-established traditions of ethical reasoning. At the same time, it cannot be permanent, but provisional, subject to discussion and change. Finally, Reiss emphasises that consensus should not be equated with a majority vote, since minority rights and interests and those of other interested parts without a voice (children, non-humans, the mentally infirm) ought to be taken into consideration.

Moral development of students is another relevant issue (Reiss 2010; Zeidler and Keefer 2003). Piaget (1948) presented his studies on the moral development of children in *The Moral Judgment of the Child*, based on how children viewed and responded to rules in the games they played. Later, Kohlberg developed Piaget's conclusions by conducting a series of interviews that included the discussion of several dilemmas (Kohlberg 1992; Kohlberg and Gilligan 1971). From the results of that research, he described three levels of development of moral judgment (preconventional, conventional and postconventional), each of them subdivided into two stages. The topmost stage presumed the notion of justice as a universal regulative principle, and the acceptance of universal, unconditioned ethical principles (akin to Kant's ethical theory). Therefore, his results should be considered as culture independent. Kohlberg's standpoint presupposed cognitive development, since changes in moral outlooks should be not only explicit but explained and justified by the individual. The passage from one stage to the other implied *learning*, in the sense of reconstructing and enriching the level below as a consequence of facing a dilemma that could not be solved satisfactorily. In the 1980s one of his disciples, Carol Gilligan (2003), criticised Kohlberg studies, indicating that all of the participants in them had been male. She proposed a new account that considered gender differences: a principle of justice on one side and a principle of caring on the other "voice" (as Gilligan called it) that constituted an acceptable basis for moral judgment. Caring implies a more contextualised point of view, different from the decontextualised, universal stance of Kant's deontological ethics. From a philosophical point of view, though, Kohlberg's project (and in this sense, Gilligan's too) should be reviewed. The idea of "development" implies a normative stance on morality, i.e. an ethical standpoint. It would be incorrect to assume simply that a Kantian conception of ethics could replace an Aristotelian or utilitarist outlook, or *vice versa*. Also, in each of the stages Kohlberg describes, morally responsible behaviour can coexist with a less responsible one, whether the underlying rationale corresponds to the Golden Rule or to a utilitarian analysis of consequences. Reiss (2010) suggests a set of indicators of progression in ethical reasoning that may be a useful tool for teachers in designing strategies that would help students move from a lower level of ethical thinking to a higher point. This set, though akin to Kohlberg stages, refers to different perspectives on normative ethics. Although it could be revisable from different philosophical and ethical points of view, it represents an interesting starting point for teachers to consider the sense of the progress they want to help their students achieve.

But it can be argued that in-depth teaching of ethics theories and moral reasoning cannot be the object of a natural science course: teachers will probably not have the time nor the specific knowledge or abilities to embark on it. A reasonable discussion of these theories would be impracticable, turning the science classroom into a course on normative ethics (Crosthwaite 2001). And other subjects in the curriculum, in the humanities or the social sciences, will probably find it more congenial and specific. Here again, the dilemma becomes less pressing in those educational systems that include a philosophy course in its own right. But, at the same time, natural, social sciences and philosophy teachers should have enough familiarity with their mutual frameworks to be able to orientate moral reasoning, and, where possible, open up fruitful collaboration between subjects or departments in schools. This does not mean ignoring that in most countries a discipline-based curriculum poses obstacles to cross-curricular cooperation. Although teacher education may not be a sufficient condition towards changing this situation, it may be thought of as a necessary one.

33.7 Conclusion

Science education does not need to encompass all aspects of education. Certainly, not every NOS issue may be fully addressed without running the risk of turning science classrooms into philosophy, history or sociology ones. Machamer and Douglas (1999, p. 53) put it nicely:

> We realize that no one can do this all the time, or else science would never get done. But to know how to do so, and that the possibility always exists for questioning the data, the reasons and the goals – this is what philosophy of science can teach, and what the history of science demonstrates is necessary.

On the other hand, philosophy teachers will address ethical or political problems from a different point of view. They would rightfully not feel constrained by the need to exclude perspectives that clash with the scientific worldview. So, there will probably be divergences with the aims and strategies of science education.

However, philosophy and science teachers, as all teachers, are educators in the broader sense of the term. As such, they need a wide knowledge of scientific, ethical and political issues, values and practices that would allow them to be critically aware and to avoid inadvertently conveying an unconsidered stance (a hidden curriculum), and here collaboration between science and philosophy education may have a fundamental role to play.

Also, this familiarity may enable teachers to respond to students' emergent or spontaneous questions in class and facilitate the interaction between colleagues from different disciplines in designing joint school projects which would benefit from a mutual acquaintance with each other's outlooks, values and languages. Active engagement in reflecting on standing practices and designing and implementing new ones seem to be particularly relevant to an adequate understanding of social, political and ethical issues in science knowledge and practices. Practising teachers may therefore find that these issues can be integrated in their own ongoing teaching strategies and, hopefully, act upon it.

Ana C. Couló is Associate Professor of Didactics of Philosophy (i.e. Philosophy Education) in the Department of Philosophy at Universidad de Buenos Aires. She also teaches History and Philosophy of Science to in-service science teachers. Her undergraduate degree is in Philosophy, and she is an advanced student at the Ph.D. level at UBA. Her research interests include students' misconceptions and errors in logic, epistemology and philosophy of science and the professional development of philosophy, logic and science teachers. She has served as a high school teacher of Philosophy and has taught graduate courses in Logic and Philosophy of Science. She has published papers in educational journals such as *Paideia* and *Diotime, Revue Internationale de Didactique de la Philosophie*. Recent publications include "Systematic Errors as an Input for Teaching Logic", with Gladys Palau (2011), in Blackburn, van Ditmarsch, Manzano and Soler-Toscano (Eds.); *Tools for Teaching Logic*, Springer Verlag; and "Enseñar filosofía y aprender a filosofar: la experiencia del CPF". En Pérez y Fernández Moreno (comps) (2008) *Cuestiones filosóficas. Ensayos en honor de Eduardo Rabossi*, Catálogos, Bs.As. She has co-authored (with A. Cerletti) two compilations on philosophy teaching, *La enseñanza de la filosofía: teoría y experiencias* (2009) and *Enseñar Filosofía: enfoques y propuestas* (2013) OPFYL, Bs.As.

Chapter 34
Social Studies of Science and Science Teaching

Gábor Kutrovátz and Gábor Áron Zemplén

Sagredo: As educators of science, we face fundamental problems like what kind of science we ought to teach in schools, how much, in what manner, and for what purposes. In the past decades, these questions have received increasing scholarly attention, and the enormous complexity of the field of relevant issues and approaches has been broadly recognized (McComas 2000). "Nature of science" has been identified as a core problem: how the teaching *of* science is, or should be, related to, supported by, and reconciled with teaching *about* science. In other words, science education is now believed to serve several purposes, and providing students with scientific knowledge is only one of them. Another purpose is to convey a general understanding of science, the scientific method, the reliability of scientific knowledge, and how and in what form it is accessible and useful to nonscientists and what social, cultural, or educational roles science can and does have. These questions have been raised in various fields. Philosophers of science have been investigating the most general problems concerning scientific enterprise for at least a century now, and historians of science have their own, equally important and partly overlapping, tradition of studying the dynamics of science (Holton 2003; Machamer 1998). But what about sociology? Various views and approaches, together with their merits and drawbacks, limitations, and contexts, need to be studied to find out for ourselves what we, educators, can best learn from them. Here is my suggestion for today: let us have a look at some of the most important views and approaches within the social studies

of science and submit them to the scrutiny of our discussion.[1] After all, we are all familiar with the pedagogical values of presenting ideas in dialogue form.

Simplicio: I see no reason why "philosophy" can't be replaced by "sociology" or "social studies" in a favorite quote of mine. According to Feynman, "philosophy of science is about as useful to scientists as ornithology is to birds" (Kitcher 1998, p. 32). Do you really think that "hard" sciences can be meaningfully analyzed with the toolkit of "soft" social sciences, having a far less secure methodological base than their subject? Should we teach "xxx studies" in the little time allotted to the "science of xxx"?

Salviati: "Most scientists tend to understand little more about science than fish *about* hydrodynamics," as the philosopher Imre Lakatos (1970, p. 148n) offered another concise judgment. That's a shame, as there are a number of things "about science" (Barnes 1985) that would-be scientists can find very important to learn in school. When they enter the scientific field, they are often unprepared to cope with what they encounter and what they did not learn from studying scientific theories. Moreover, not every student of science will become a scientist, and those who will not may find philosophical perspectives as useful as sociological ones. All in all, science seems to be similar to other aspects of human society.

Simplicio: Similar? Science is special exactly because it is dissimilar. In what relevant way would it be similar?

Sagredo: For example, power is concentrated in the hands of a small minority, just like in most areas of human activity. Sociological studies have revealed serious inequalities in science, an enterprise that seems, to many, to represent democratic values. A vast majority of all publications is written by a small minority of all scientists (Lotka 1926). And it is not only that some scientists try to publish more simply because they are more prolific, but the more credit one gets, the easier it is to publish. Moreover, publication forums also receive unbalanced attention: from the 30,000 scientific journals of the 1960s, approximately 170 were the most prestigious, and half of all the interest in libraries was focused on this tiny proportion of the entire body of journals (Price 1986, p. 67). Similar inequalities were identified in citation patterns: while, on average, every scientific paper is cited only once by later publications, in reality, most papers will never get cited later, which leaves us with a few influential and highly visible papers that others read, surrounded by a myriad of papers lost in collective ignorance (*ibid.* p. 73). Robert Merton, a founding father of the sociology of science, called this the Matthew effect (Merton 1968), based on a quote from the Bible: "For whosoever hath, to him shall be given, and he shall have more abundance: but whosoever hath not, from him shall be taken away even that he hath" (Matthew 13:12, King James Bible, Cambridge Ed.). Scientists learn to live with this distribution of power, but it may take them a long time to find

---

out from bitter personal experience what they could have learnt already in school about the peculiar meritocracy of science.

Simplicio: I concur, every student should know a bit of sociology, probably about this much: if you look at science as an activity, you will see that it is an institutionalized subsystem or field of society, with its own rules to follow, values to respect, goals to pursue, norms to be governed by, etc. This activity is performed by a social group, that of scientists, which is structured both "vertically" in a hierarchical order, and through complex power relations, and "horizontally" according to disciplinary maps, national and geographical factors, to start with. Science relies on a number of different resources to comply with its primary function, i.e., the production of reliable knowledge, or empirically fruitful theories, theoretical and practical knowledge, or even legitimizing various democratic functions of the society, as Salviati may claim. Certain resources are "material" like sites of activity (institutes, universities, etc.), financial conditions (salaries, grants, scholarships), and other technical and instrumental resources. Others are "symbolic" like the structure of ranks, degrees, and honors or protocols of formal communication and publication and all kinds of norms and values as mentioned above. Sociology of science, as I see things, investigates precisely these things…

Sagredo:…and more. In the past few decades, all disciplines examining science have developed a growing sensitivity to insights coming from the social sciences. "Sociology of science," "sociology of (scientific) knowledge," "social studies of science and technology," and "science (and technology) studies" are promising labels referring to a complex array of research traditions investigating how the study of society and the study of science can inform and supplement one another.

Simplicio: Despite the field's popularity, it remains unclear to me from a science education perspective how relevant these approaches are and what lessons we can take home from consulting them. And here is my answer. If we introduce a distinction between the form of scientific activity and the content of scientific knowledge, I expect that sociologists have a lot to say about the first, but are wrong if they think they can teach us anything about the second. Sociology of science and sociology of knowledge are different enterprises. Proper sociologists of science restrict themselves to the study of the social dimensions of scientific activity, like the analysis of the Matthew effect, and this is what I find promising about sociology. On the other hand, sociology of knowledge addresses the problem on how social factors affect what and in what way a certain culture thinks about the world – their conceptual categories, systems of classification, and so on. I believe that this is where sociology is *not* able to examine science meaningfully. Even prominent figures of this field admitted that when it comes to scientific knowledge, these external factors cease to matter and the "sociology of knowledge" perspective loses all power (Mannheim 1936, p. 239, as interpreted by Bloor 1973).

Salviati: An outdated and narrow view, as I hope to show later. But supposing for a second that you are right, what are the "social dimensions of scientific activity" that sociologists can legitimately study?

Simplicio: Sociologists of science provided a number of statistical analyses of the institutional patterns of science. Investigations, similar to those of Merton, were carried out from the 1960s and 1970s by Harriet Zuckerman, Jonathan Cole, Stephen Cole, Joseph Ben-David, Derek J. de Solla Price, and many others. I would be very surprised if you told me that this quantitative trend, opening a perspective on a measurable science, is uninteresting or irrelevant to students who need to understand what science is.

Sagredo: True. For example, Merton's study of publication patterns included the analysis of rejection rates for the publication of manuscripts in various academic journals. By comparing these rejection rates in different academic fields he found that, perhaps contrary to our prior intuition, journals in the arts, humanities, and social sciences are more strict than journals in the natural sciences. While an average of 90 % of the manuscripts were rejected by the most important history journals considered by Merton in 1967 (closely followed by literature, philosophy, political science, and sociology journals), only 20–30 % of manuscripts were rejected in biological, physical, and geological journals (Zuckermann and Merton 1971). How interesting, as if candidates for publication found it far easier to comply with the publication standards of scientific fields than those within the humanities….

Salviati: This is a red herring… Surely, these isolated sets of data can be interpreted in many different ways (Hess 1997, pp. 65–66), and I am afraid it is too rash to jump to unjustified conclusions concerning the strictness of publication standards. I can readily offer other explanations for the phenomenon. Consider, for instance, a different statistical tool, introduced by another prominent sociologist of science, Derek de Solla Price (1986, pp. 166–179). The so-called Price Index tells us the proportion of those publications, cited by a scientific journal of field or discipline, that are not older than 5 years, relative to the number of all citations. What he found in the 1960s (and this hasn't changed significantly since his time) is that the proportion is 60–70 % for hard sciences like physics, while only 20 % for philosophy. What this means is that in hard sciences, the immediate knowledge base that researchers rely on is far more up-to-date and recent than in softer fields. In my opinion, this fact discourages amateurs (i.e., alleged contributors with insufficient professional background) from submitting their pet theories to science journals, seeing how unable they are to participate in the technical discussion. Self-made academics in the humanities, on the other hand, may believe that rules are less esoteric and therefore the boundaries of scholarly discourse seem less strict, and they try to put their voices in – just to find themselves rejected as well in the end….

Simplicio: I loathe to interrupt, dear Salviati, but do not forget the serious methodological problems inherent in social sciences. As opposed to the natural sciences, social sciences have not yet crystallized their sound methodological foundations, and high rejection rates of publication, as well as intensive use of older technical literature, stand witness to this methodological uncertainty. Around the beginning of the twentieth century, a number of authors argued for a fundamental methodological difference between the natural sciences on the one hand and humanities and social sciences on the other. Others believed that there is some kind of unity to all the sciences, and an overarching methodology unites all scientific enterprises. This *Methodenstreit* lasted at least three generations…

Sagredo: … and participants were lost in an ocean of complicated problems. I wouldn't be happy to lose the focus of our discussion. Both of you made a point though. Simplicio is right when urging the importance of statistical, quantitative findings about science: they largely contribute to our complex understanding of the phenomenon. But Salviati was also right when he pointed out that statistics can be very misleading without sufficient care and precaution.

Salviati: It is a general problem that statistics leaves us in partial darkness about the significance of the data. For example, sticking to publication patterns, the numbers show that when scientists become referees of their peers' papers, the younger referees are usually more strict (and more likely to reject) than older colleagues. Similarly with respect to rank, researchers with higher ranks are more admissive of manuscripts than those of lower ranks (Zuckermann and Merton 1971). Now this is all fascinating, but what does it mean? Not even those publishing these statistics seem to know the precise reasons and underlying mechanisms. What do we gain if we teach such things to students who need to understand what science is?

Simplicio: As Salviati noticed, teaching nature of science (NOS) includes teaching the would-be scientists, the academic *Nachwuchs*, and if you think of performance assessment, the study of publication patterns has obvious advantages that we already utilize in our everyday scientific activity. If you want to assess scientific performance, the most obvious way is to look at individual researchers: how many papers and in what journals did they publish.

Sagredo: "Scientometrics," as they often call this field (and also one of its flagship journals), aims to measure scientific output by counting and ranking publications, calculating impact factors and other indicators. While it has its roots in quantitative sociology of science, by today it has become an independent field that we often find indispensable… even though indicators for institutions are more reliable than any measurement tool that compares individual researchers…. It is a tool that we frequently rely on when it comes to assessment, despite some fundamental problems like the gradual shift from descriptive measurement of scientific productivity to a normative prescription of what counts as scientific productivity. The numerous difficulties would boil our discussion down to nitty-gritty details, so let us declare that quantitative sociology of science and the study of scientific institutions have some clear lessons to teach….

Salviati: Like in the case of the Matthew effect, one of the things I tend to emphasize about science is that it is a human enterprise, with all the typical features and "imperfections" all human enterprises have in common. Power inequalities are part and parcel of any human activity, and science is no exception. It is a simple game of power with winners and losers.

Sagredo: Such a profane claim would do injustice to Merton who did more than studying statistics. Above all, he sought to identify what distinguishes science from other things that humans do. He found that it is a peculiar set of norms that govern scientific activity, amounting to a "scientific ethos" (Merton 1942). There are four elements to this. Universalism means that the acceptance or rejection of theories is an impersonal process, where the origin of the scientist making the claim (e.g., class, gender, ethnical identity) is irrelevant to the acceptability of the claim. Communalism (or communism) means that knowledge is the intellectual property of the community, and every member has equal right to access it, contribute to it, or criticize it. Disinterestedness means that the assessment of scientific claims should be kept independent of the local interests and biases of certain groups. Finally, organized skepticism means that all scientific claims must be submitted to the scrutiny of critical thinking, and no dogmas should be considered as beyond skepticism.

Salviati: I have to admit that I find these expectations entertaining, given the mentioned profound power inequalities in science. Can we really expect scientists to have no personal interests, ready to share their most cherished results with everyone, and eager to criticize even the most central beliefs of their disciplines? Do we get closer to what science is if we teach this utopistic vision? Or do we believe that scientific education should include some training in ethics to implant these noble norms in students?

Simplicio: Salviati, I am never sure whether you are ironic or simply ignorant. Merton's norms of scientific ethos have puzzled many authors, but it is clear from the original texts that Merton did not intend to present these as "personality traits" of actual or ideal scientists. On the contrary, Mertonian norms do not hold at the level of individuals, and they are certainly not meant as behavioral prescriptions. Scientists are humans; their local interests, biases, dogmas, and secrets of the trade motivate individual scientists in doing what they do and inform them how to do it. So Merton's norms are general and symbolic value orientations that, at the collective level, govern the formation of rules and behavioral patterns in such a way that the final result of the entire activity, i.e., scientific knowledge, will accord to these general expectations.

Salviati: And how does this happen? Through some "cunning of reason"– out of the sum of individual selfishness and social contingency, something emerges that can be seen as pure and disinterested knowledge serving the ends of humankind.

Sagredo: And indeed, something like that does happen. The conditions of the "miracle" are embedded in the institutional patterns of scientific activity. It is precisely by studying these patterns that we can tell how individual interests, biases, commitments, and contingencies can result, through an institutionalized collective cognitive process, in a beneficial advancement of global science and human knowledge. And this is one of the most important reasons why a scientific approach to the workings of science is essential today.

Salviati: Fair words. Still, I feel uneasy about overemphasizing the statistical study of institutions when addressing the question of what science is. First, science may be seen very differently from the perspectives of other metascientific approaches: while it is a system of organized action for sociologists, it is also a body of texts and instruments for historians, or a world of abstract propositions and their logical relations to philosophers, to mention just a few views. In order to grasp science, all these perspectives should be taken into account simultaneously. Science, for example, may be seen as an institutionalized social field in modern times, but before the nineteenth century, the general institutional structure was very different, and before the seventeenth century, there was nothing similar to what science seems to be from the perspective you described. Yet most histories of science will go back to far earlier times. Would you tell your students that Euclid didn't do mathematics, or Ptolemy astronomy, just because science – as the sociologists describe it – did not exist in premodern times?

Sagredo: You are provoking us again. To say that institutionalized social action is a fundamental aspect of what we mean by the term "science" is not to claim that it is all there is to science. But the point you've just made is important: science is not something static and unchanging. The development, or to use a more neutral term, the dynamics of science does not only consist in ever better theories or more precise and comprehensive knowledge, whatever these mean (see the chapters on philosophy). On the contrary, the real dynamics of science can be revealed only by addressing its social and cultural conditions. For example, when Merton sought to identify the norms of scientific ethos, his real question was, in what social circumstances do we find a wholesome scientific activity? He believed that the Nazi Germany or the Soviet Union did not provide ideal conditions for doing science, since some norms were not respected. The norm of universality is clearly violated when ethnic and cultural circumstances of the proponents influence the reception of ideas. Merton's fundamental question was to find the norms that can provide the most ideal circumstances for scientific development when implemented in institutional practice (Merton 1938a).

Simplicio: From early on, Merton's work was imbued with a historical perspective. In his doctoral thesis, he investigated how modern science was formed in seventeenth- and eighteenth-century England. His central claim was that Protestant ethics based on Puritan principles proved beneficial for the development of "natural philosophy" (Merton 1938b). The two basic tenets of this philosophy were doing things for the glory of God and for the utility of mankind. Merton quoted many passages from prominent scientists of the era to show how these principles lead to the intellectual pursuit we call science, being both rationalist (by seeking a theoretical understanding of the Creation, i.e., nature) and empiricist (by submitting this understanding to the special needs and purposes of humans). He also relied on statistical analyses to establish the connection between scientific performance and social institutions and found both that Protestants were overrepresented in scientific societies (like the Royal Society) and that novel scientific views and results found their way to Protestant school curricula faster than to Catholic ones.

Sagredo: And this is just part of the story. The "utility of mankind" aspect is clearly visible if you look at the practical problems that early scientists of the era sought to solve. As England's power was largely dependent on sailing the seas, it comes hardly as a surprise that scientists addressed problems relevant for sailing: they studied astronomy in order to improve navigation and determine the position of the ships; they studied the motion of the pendulum to build better clocks, as precise timekeeping appeared to be essential for the determination of longitude; and they studied hydrostatics to build ever larger and faster ships. Mining, another vital area behind industrial growth, was laden with problems that could be addressed by hydrostatics and aerostatics, like circulating water and the air in mines. And, of course, the power, efficiency, and accuracy of guns and cannons raised many questions related to projectile paths, the compression and explosion of gases, rigidity and constancy of metals, etc. – all popular research areas of the time.

Salviati: All this seems to indicate that the direction of scientific research is a function of society. Soviet historians, most prominently Boris Hessen (2009), held similar views already in 1931. They pinpointed the role of military and information technologies during the scientific revolution and claimed that all important results of the era were rooted in practical questions. But even if their findings were similar to that of Merton, their starting point was different. Hessen and his colleagues worked in a framework that Merton later found inadequate for the purposes of science.

Simplicio: They dogmatically followed the Marxist ideological assumption that it is modes of production in the material world that determine the “superstructure,” i.e., the conditions of social, political, and intellectual processes. From their point of view, the interconnectedness of scientific research and social conditions is anything but surprising. But if you want to understand the real dynamics of science, you had better consult statistics. Did you know that the total population of scientists is growing more rapidly than the population of nonscientists? This tendency was recognized by Derek de Solla Price in 1963 (Price 1986), who claimed that science (number of scientists, journals, papers, institutes, etc.) had been growing exponentially since the end of the seventeenth century when modern science had been created. Most indicators of the size of science double in a period of approximately 15 years, and that means that, on average, science becomes 1,000 times more populous in a span of 150 years. Merton also realized that in the modern societies of his time, the age distribution of researchers is different from that of the entire population: in science younger age groups are overrepresented.

Sagredo: Surely this has profound consequences for our understanding of how science works. It is always in the present: taking any moment in time, about half the scientists of the history have worked in the past 15 years, so an old scientist having worked 45 years can say that he or she has been contemporary to more than 90 % of all the scientists who have ever lived so far. This may tell us why, in most research areas, the Price Index is so high: recent science is not only more developed, but is also far more detailed and populous, than past science. This inevitably leads to increasing specification, since a research area becomes too large to handle when the number of experts exceeds a practical limit, so new research areas split from others to make room for an ever-growing number of newcomers.

Salviati: And how long can this miracle last? If the ratio of scientists increases in modern societies, there must come a time when everybody becomes a scientist. True that human population is growing in a more or less exponential manner, but the doubling rate is closer to 30 years than 15, so scientists will have to fill up the future. Fine with me, but who will work then?

Sagredo: Price asked the same question. Surely, such a growth must cease before every single person becomes a scientist. Practically, science is becoming simply too expensive to be paid by the rest of society. By analyzing the growth curves, Price came to realize that the growth was about to end soon, in his lifetime. After that, science needs to transform radically in order to survive….

Salviati: So you are talking about what Nowotny et al. (2001) called Mode 2 science. They realized that the social context of science was changing in a way that favors multidisciplinary projects focused on specific real-world problems, while traditional long-term theoretical research confined within certain disciplines ("Mode 1 science") was losing its former ground. According to this view, contemporary scientists are problem-solvers in the context of technological, social, and everyday needs. Is that your solution?

Sagredo: Exactly. Or, to use another term, John Ziman (2000) coined "post-academic" science to describe how academic science, funded more or less independently by the state in order to conduct free research, is gradually replaced with a research culture that is supported by multinational industrial or corporate actors for dealing with well-defined and context-given problems. If the state can no longer quench the ever-growing appetite of science, researchers have to find other forms of support. This looks inevitable, but the consequences are as yet far from clear. It seems probable that the role of "basic research" (a free pursuit of knowledge) will be reduced radically, while "applied research" (seeking a solution to a specific given problem) will dominate science. Moreover, the primary social function of science is no longer providing knowledge of how the world is, but finding answers to "external" questions, given to researchers by whoever pays them. All this affects the institutional structure of science, since the primary sites of research are less and less the state-funded research institutes or the universities… Students who are considering a career in science would clearly find these trends essential in terms of their career choices.

Simplicio: And as the institutional structure is transforming, so are the norms themselves that guide behavior in science. Ziman (2000) argues that Merton's norms are becoming obsolete. Knowledge is not universal any more, since scientific answers are strongly influenced by the circumstances of production. Results are increasingly unavailable in a free and public way to other members of the community, as they are the property of the patentee. Science is obviously far from being disinterested, for research serves the immediate interests of the sponsor. Finally, there is no time for organized skepticism in a world of deadlines and short-term projects: a firm result is expected by the end of the given period of research. If Merton's norms describe an ideal state in which traditional science can proliferate, Ziman opens our eyes to a different and more mundane reality.

Salviati: I see no reason for despair. In my understanding, science is adapting to a changing social environment. The dynamics of science is analogous to biological evolution, to invoke another classic from the social studies of science (Thomas S. Kuhn 1970, pp. 171–173, 2000a, pp. 96–99). The evolution of a complex system of theories and paradigms is not a linear progress aimed at some desirable end like "truth" or "ever better theories"….

Simplicio: Are you sure that the science/evolution metaphor implies the lack of a final truth? You say that "paradigms" (a term that is used in radically different senses throughout Kuhn's main work; see Masterman 1970) are like biological species adapting to a changing environment. Yet biological evolution produced us, humans, and while other species are adapted to different specific environments, human culture is a universal solution to an unlimited range of environments. So, why rule out that science is a similarly successful, potentially universal epistemic tool…?

Salviati: … one that threatens us with a general epistemic and social collapse, just like human behavior may easily trigger a global ecological catastrophe?

Sagredo: Before science can look back on as long an evolutionary path as nature can boast with, let us suppose that the process is driven by the past failures, rather than drawn toward a goal. What Salviati's Kuhn implies to me is this: there is no need to look for an "essence" of science, like Merton's norms or methodological rules prescribed by philosophers. Science is an ever-changing enterprise, and turning our attention to its past development opens a perspective that is at least as informative as the quantitative study of its present form.

Salviati: And this approach is more profoundly historical than Merton's analysis of the seventeenth century or Price's statistics about growth.

Simplicio: Let me ask this: if we dispense with the idea that science has an "essence" or, to put it less loftily, it has some constant and unchanging core of commitments and orientations, then what are we left with to teach as "nature of science"? Can we avoid discussing Salviati's post-Kuhnian relativists at this point (see also the special issue Matthews 1997)?

Salviati: These "relativists" or, more precisely, constructivists have provided us with the most detailed case studies of science in action, how good (or bad) science is actually done. Didactic transposition of any one of these detailed case studies can give a glimpse of the whole of science, instead of focusing on declarative statements (Allchin 2003).

Sagredo: Overemphasizing one perspective can be as deceptive as sticking to another. Still, I find Kuhn's emphasis on differences insightful. If we want to understand what science is, we need to look at it in various times and cultures and to identify the contingencies that help us see better behind the contingent and ephemeral.

Simplicio: Everything seems to be contingent for Kuhn in my reading. Salviati was proud to drop in the term "paradigm," as if the popularity of a term would do justice to its adequacy. But in Kuhn's view, paradigms come and go, they replace one another, and their relation is described by him as "incommensurable" (Kuhn 1970). He argues that there is no rational stance from where we could tell that the new paradigm is better than the old, and thus overall progress disappears from science. Would you tell your students that Copernican theory of planetary motions is just as good as the Ptolemaic system, since there are no universal standards to compare them? As an educator, I strongly protest!

Sagredo: Kuhn is a tad more complex than that, as it is not theories he holds incommensurable but, as you say, paradigms. Paradigms are not theories and sets of propositions about the world, although they contain theories and propositions. They also involve more basic elements such as rules and methods to conduct inquiry, successful solutions that serve as models for solving future problems, and ontological commitments about the entities our explanations rely on that help us interpret phenomena. In short, paradigms are ways to see the natural world. Of course, we do not want to teach our students to see the world as the ancient Greeks did, and we can argue efficiently that the Copernican theory is better than the Ptolemaic, just as Newton's theory of motion is better than that of Aristotle. But it is important for us to bear in mind that these "theories" as we present them are interpreted in our paradigm, relying on our own questions and evaluation criteria, and our judgments are guided by our own interests and predispositions.

Salviati: Exactly. And I believe that this radically historical perspective may help students to see science from a healthy distance, by contextualizing those elements of modern science that they otherwise would see as evident. Take Newtonian physics as an example. In order to show its merits, we present to them the very same solutions that made the Newtonians so successful: we talk about swinging pendulums, colliding balls, the elongation of springs, or the motion of planets – and lo and behold, these are phenomena where Newton's theory provides simple and efficient explanations, so Newton was correct! But are pendulums, colliding balls, springs, and planets important to an average student? We implicitly suggest that the key to understanding the physical world is by addressing these phenomena, and many find this kind of physics irrelevant and boring. If we teach any history of science before the early modern period, we simply say that Aristotle's physics was obviously naïve and dull, but we do not tell students that the phenomena that the Aristotelians wanted to explain, and the criteria of what counts as successful explanation, were radically different then. My point is, if we told them about these differences, they would better understand what modern physics is good for (for a general appraisal, see Matthews 2000, 2004)…

Simplicio: …and we would have even less time left to teach them proper modern science. After all, Aristotle lived a long, long time ago, and I don't see why he would be of any interest to us if you are correct in claiming that his world was radically different. I don't believe in radical raptures, and I can't accept that every new paradigm starts everything completely anew. Otherwise, how could we learn from the past if there is nothing in common between him and us? The concept of incommensurability is highly questionable….

Sagredo: The concept has drawn similar reactions from many scholars, and Kuhn seems to have softened his views. The emergence of new paradigms is analogous to speciation in evolution, and this evolutionary metaphor became more prominent in his later writings. The gap between paradigms is radical, but "lexicons" of research communities can be translated, by learning the conceptual system guiding their world view. Communication between lexicons is possible (Kuhn 2000b).

Simplicio: And this is where I firmly protest. When Kuhn claims that general conceptual structures orient our scientific theories, he simply ignores that science is an enterprise that, by studying nature and nothing else, helps us get rid of specific social conditions and contingencies. Remember the distinction I made between the meaningful study of institutional structures and the misguided sociological analysis of the contents of scientific knowledge? While Kuhn was not a sociologist, his views prompted many tenets in what is called post-Kuhnian science studies, and I think these tenets were a change for the worse.

Sagredo: You probably think of the most explicit and most influential theoretical backing to post-Kuhnian science studies developed by the Edinburgh School including David Bloor, Barry Barnes, John Henry, and others. They launched what is called the Strong Program in the sociology of scientific knowledge (SSK), characterized by four planks: (1) causality, it is "concerned with the conditions which bring about belief, or states of knowledge"; (2) impartiality, "it would be impartial with respect to truth and falsity, rationality or irrationality, success or failure"; (3) symmetry, "the same types of cause would explain, say, true and false beliefs"; and (4) reflexivity, "its patterns of explanation would have to be applicable to sociology itself" (Bloor 1992, p. 7). The main project of the program was to construct the theoretical underpinning of a scientific understanding of science…

Salviati: … and let us add that they seem to have failed in that, since most subsequent authors in the field of science studies disputed several central points in the theoretical core of SSK. Still, and more importantly, SSK motivated many basic trends in the social studies of science. Versions of this program were employed in studies of scientific laboratory work (Knorr-Cetina 1981; Latour and Woolgar 1979), analyses of scientific controversies (Collins and Pinch 1982), histories of older (Shapin and Schaffer 1985) and recent (Pickering 1984) science, theories of technology (Bijker et al. 1987), etc. They all acknowledge their debts to SSK.

Simplicio: Relativists! I find it hard to keep calm when I meet their views. The people you mentioned might be simply wrong but benevolent, but they encouraged a hoard of hostile intellectuals – think of the various postmodernist, post-structuralist, neo-Marxist, feminist, environmentalist, etc., criticisms of science. Remember the Science Wars! A great number of scientists and philosophers pointed out that (i) the SSK tenets and their intellectual offspring are simply wrong and (ii) these views give rise to a general social hostility toward science.

Salviati: But these charges are seriously mistaken, as the science studies authors attacked in the Science Wars clearly showed. But if you haven't read them, I am happy to accept your challenge right here and prove the validity of "relativist" approaches….

Sagredo: But that would lead us into philosophy and a dense discussion. Still, it is worth considering the main charge concerning why SSK is wrong, emphasized by Alan Sokal and Jean Bricmont (1998) in their sweeping criticism of relativist science studies. When studying scientific knowledge, sociologists tend to refer to all kinds of social and cultural factors when explaining why a certain community accepted specific beliefs, but they forget about nature and its causal responsibility for the beliefs we hold. Isn't it a strongly one-sided perspective? If we tell our students that scientific theories are caused by social factors, how can we encourage them to carry out empirical investigations and the study of nature itself?

Salviati: You've just committed a widespread mistake: you seem to read SSK inattentively. With regard to the first plank of SSK, Bloor and his colleagues stress that all beliefs have various causes, but not all of these causes are social (Bloor 1992, p. 7). Natural causes obviously play their role.

Simplicio: This sounds promising, yet does it not undermine the symmetry principle, since true beliefs surely have more natural causes and false beliefs must have more social causes? If sociologists examined all the causes prompting a belief, they would certainly realize that much (Slezak 1994a). So why don't they talk about natural causes?

Salviati: The reasons are manifold, and they vary from author to author. The simplest reason is that sociological research has no access to nature independently of natural science as the very object of its study, so "nature" appears only in beliefs about it. This is a purely methodological interpretation advocated, e.g., by Harry Collins, called "methodological relativism" (Collins 2001a, p. 184). David Bloor offers another methodological explanation when he claims that sociologists are interested only in the differences between rival theories, and since nature that researchers study is the same, it is the different social factors that result in different interpretations of the same thing (Bloor 1999, p. 93). But the same Bloor gives philosophical arguments too, similar to that of some constructivist authors such as Karin Knorr-Cetina (1993). According to this view, since nature's causal role (*an sich*) is entirely unspecified (and inaccessible independently of the beliefs we hold about it), everything we conceive is constituted by our prior beliefs and categories. Kuhn's epistemological perspective building on "lexicons" supports a similar tenet, no wonder that he saw himself as a Kantian with movable categories (Kuhn 2000a, p. 264). There are even more radical views like that of Bruno Latour who denies the distinction not only between nature and society but also between things and beliefs about them, at an ontological level (Latour 1993), or post-humanists like Andy Pickering who mix every possible cause in their narrative and call it the "mangle of practice" (Pickering 1995). These radical views come very handy when it comes to understanding and discussing atypical or Oriental science....

Simplicio: Please stop! This much has been more than enough to illustrate that there is no theoretical consensus within the social studies of science. Just think of the "epistemological chicken" debate between relativists, where the stake was who dares to come up with the more extreme epistemological position (Collins and

Yearly 1992), or the controversy between Bloor (1999) and Latour (1999) where, intimidated by the criticisms they received in the Science Wars, they reproached each other for adopting harmful philosophical views. This proves not only that relativists stand on highly problematic theoretical ground but also that teaching their theories to students would result in confusion and despair (Slezak 1994b and Chap. 31).

Salviati: Science studies are manifold, as the term "studies" indicates – and we haven't mentioned a number of approaches yet. But then, to return to an earlier problem we raised, do you really think that science is a single and unified entity? While the positivist illusion of unity was expressed by launching the ambitious *International Encyclopedia of Unified Science*, the planned 14 or 26 volumes (Morris 1960) never came out. The second and last volume ironically contained Kuhn's revolutionary book on revolutions (1970). Post-Kuhnian science studies authors argue for the disunity of science (Galison and Stump 1996), and constructivists like Knorr-Cetina (1999) view different scientific fields as disconnected epistemic cultures. And we can go further than simply acknowledging disunity: thanks to science studies, we now have conceptual tools to study boundary phenomena between and around scientific areas. Think of "boundary work" introduced by Merton's student Thomas Gieryn (1983, 1999) to describe the ideological and rhetorical efforts that draw and shift different boundaries. Or think of "boundary objects" (Star and Griesemer 1989), entities that connect various groups in the large networks of science, "boundary organizations" (Guston 1999), "boundary infrastructures" (Bowker and Star 1999), or the "trading zones" that emerge when groups with different enculturation do research together (Galison 1997)….

Simplicio: I can't think of so many things simultaneously, and I am repelled by this conceptual and methodological cacophony. But I can anticipate your point: if there is no such single entity as "science," but only networks of "sciences," then what are we left with to teach as "nature of science"? And here is my answer: everything we normally teach, perhaps supplemented with some insights from the sociology of scientific institutions. I simply cannot accept claims or conceptual tools from a field which is so heterogeneous that its representatives can't agree on how to start building a minimally common theoretical core.

Sagredo: Your favored sociology of scientific institutions was not free of fundamental divergences in theoretical and methodological questions – emerging fields usually aren't. I agree that introducing too many theoretical positions in science classes could prove less useful than harmful. Still, what unites these authors is not the theory but the general perspective and the resulting approach to science. As Salviati mentioned earlier, science can be seen as a set of human practices that are as contingent, political, interest-driven, opportunistic, and mundane as any other human enterprise.

Simplicio: And this is the second mistake of SSK I mentioned, and a very bitter one. Why do we do science? Because we believe that it is the most reliable cognitive enterprise we have, resulting in the most secure knowledge about the world. The question in this case is not how science is the same as other cultural fields, but how it is different, something more. If we teach our students anything "about science," the guiding question must be, what's so special about science (Bauer 2000)?

Sagredo: But then it is useful not to tell idealized half-truths about it. Those who become scientists will learn of the imperfections soon enough, but it may take them by surprise and make it difficult for them to adopt to the reality of actual practice, as opposed to the ideals they pursued when choosing this profession. And those who will not do science professionally may find, when confronted with science depicted in the media, that scientists are not the good guys in flawless white lab coats that popularizing efforts try to show, and they might get disappointed and disrespectful.

Salviati: Importantly, SSK-type relativists try to follow the most general scientific principles. Scientists explain phenomena by referring to causes, and sociologists of science do the same….

Simplicio: But they do not agree in what type of causes they use! Some of them explain the general with the general: for Marxists larger formations of knowledge (cognitive styles, conceptual schemes, paradigmatic theories, etc.) are explained with reference to broad social characteristics. Others explain particular knowledge claims with reference to general social settings. Here the particular cases to be explained can range from specific beliefs to small-scale theories, advocated by a particular scientist, and the general basis of explanation can comprise the norms within the wide community, or general interests of cognitive, economic, or political kind, or technological possibilities available at a wider sociohistorical level. In these cases the source of explanation expands far wider than the local topic and its immediate environment. Still others, and probably the largest bulk of recent work in science studies, are constructivists (Golinski 1998), and they explain specific instances from specific sources, i.e., the range of explanatory principles does not extend beyond the immediate environment of the local phenomena under study. What are we to do with this mess?

Salviati: Again, the point is not the details of their theories, but the general attitude. Causes are neutral, as opposed to reasons which always include some normative or evaluative element. Just as physicists don't evaluate natural processes but simply describe them, sociologists do not evaluate scientific beliefs. Descriptive neutrality requires that "true," "rational," "objective," "better," and other strongly normative concepts be withdrawn from scientific discourse (or, rather, better be made topics as connected to norms rather than resources). This lack of evaluative tone is often seen as evaluation itself, when it replaces a discourse which is usually evaluative.

Sagredo: A fine point. To cite a fitting analogy from Harry Collins (2001b, p. 157): sociologists want to explain why members of a certain community believe that wine can turn into blood, while members of another community don't. Because the "Yes" community maintains a positive evaluation of the norms that justify their belief, the analysis will be seen as downgrading their claim and its entire cognitive background together with it. At the same time, the "No" group will have the same impression regarding their own position, and for the very same reason, but the sociologist simply did not want to decide and hence take into account whether or not the wine can "indeed" turn into blood. Seeking a causal explanation as to why participants in the

Nazi regime behaved in the way they did, the account will be seen as making unwarranted excuses – this time because of the lack of the generally accepted negative evaluation attached to the matter. Now, we are accustomed to a discourse about science that is highly praising, and the lack of this positive tone seems degrading to many.

Simplicio: But this "neutral" discourse is useless when the educator's purpose is to build respect for science!

Sagredo: But it is only one of the purposes. Understanding how science works is another, and the heroic stories about Great Achievements of Great Minds do not do justice here.

Salviati: Let me offer another aspect here. Historian of science Steven Shapin (2001) added his voice to the Science Wars when, paraphrasing Sokal's famous hoax (Sokal 1996), he collected a list of statements expressing the credo associated with relativists and then revealed that all the statements were made by prominent scientists. One moral of the story is that while scientists agree in most scientific questions (i.e., their consensual knowledge base, excluding the very recent problems they dispute), they strongly disagree when it comes to metascientific commitments, since some share many relativist views (about the political nature of science, or the social contingency of our scientific concepts), while others stick to a picture of science as the inevitable voice of nature.

Sagredo: Statements, including these, "There is no such thing as the Scientific Method," "Scientists do not find order in nature, they put it there," "New knowledge is not science until it is made social," and others, are generally associated with constructivist and sociological approaches (Shapin 2001, pp. 99–100). A fine illustration of the point you cited from Lakatos early in our discussion.

Salviati: The claims that Simplicio would find degrading are made in specific contexts when "secrets of the trade" are revealed to attentive audiences, and this is the more relevant conclusion. In formal public settings where the esteem of science is at stake, the very same scientists pronounce more "polite" statements in better accordance with the usual expectations. Quite contrary to metascientific statements in mathematics (Davis and Hersh 1981, p. 321), many scientists are constructivist on weekdays and inevitabilist (Hacking 1999, p. 79) on Sundays. Just like in a family, problems are explicit only for friends, but everything is fine for the wider public. Trevor Pinch (1986), when interviewing researchers of the solar neutrino project, found that those who admitted possible weaknesses in their work did it in a form resembling secret initiation rituals. But if we rely on scientists' white lies in science classes, students are misled – and, as Sagredo pointed out, they get disappointed later when they face reality.

Simplicio: Alright, I concur that this enthusiastic but small circle of SSK offers their descriptions with fair intentions. But what about those numerous "xxx-ist" and "post-xxx-ist" people from the humanities I mentioned earlier, whose explicit goal is to criticize, desacralize, and "unmask" science? Am I supposed to tell our students that modern science is capitalist, masculinist, and politically oppressive and that it is an obsolete “grand narrative” that we should best dispense with?

Sagredo: It is virtually impossible to pretend that science is for the pure benefit of humankind, in an independent and culture-transcendent niche. Science has always been embedded in a cultural environment interwoven with technological, economical, social, political, and all kinds of aspects, and it is hard to deny that science has grown huge and powerful, fundamentally shaping modern technological and information societies. A large proportion of recent sociological case studies therefore focus on science policy, politics of science, innovations, risks, stakeholders, and all kinds of stuff that are clearly relevant to students, regardless whether they would become scientists or not.

Simplicio: I understand how these matters are relevant to would-be scientists, but I am not sure why they could be of great interest to laypeople.

Sagredo: Consider “the third wave” in science studies, advocated by Harry Collins and Robert Evans (2002) in a paper that has become one of the most cited works in the field. By blurring the boundary between experts and the public and replacing it with a “periodic table of expertises” (Collins and Evans 2007, p. 14) in a program called “Studies of Expertise and Experience” (SEE), the paper attempts to conceptualize decision making in mixed policy settings. The first wave tried to account for the success of science as taken for granted – and traditional sociology of science would represent this tenet. The second challenged the automatic respect and offered naturalized descriptions of science as a profoundly human endeavor – that would be SSK and its many subsequent versions.

Salviati: I like toying with the idea of different kinds and degrees of expertise, especially “meta-expertise” (Collins and Evans 2007, pp. 45–76) that refers to the skills by which we, laypeople, become able to assess expert claims….

Simplicio: You must be joking. If an expert, by definition, is far more knowledgeable than a layperson, how can the latter legitimately evaluate what the former states?

Salviati: By relying on social discrimination rather than technical knowledge. If two experts disagree, I can check their credentials, positions, ranks, track records, etc. Most people have no sufficient grasp, for instance, of the theory of evolution to judge whether Intelligent Design protagonists are probably right or probably wrong, but they can still assess the approximate proportion of experts supporting the confronting views, or the statuses of their publication forums within the scientific community, or their ranks and credentials, or the relevance of their research background, or the origin of funds supporting their institutes, and so on. And I claim that one can reach a pretty secure judgment here, without having to become an expert oneself. However, and this is what makes me uneasy here, SEE explicitly rejects the purely descriptive stance taken by what they call Wave 2 and advocates normative intentions to guide us in our meta-expert decisions.

Sagredo: And why does this bother you? Why not be normative in classrooms? Descriptive neutrality becomes impotent when your students ask you whether they should believe the theory of evolution or supporters of Intelligent Design, or when they ask your opinion about table dancing, or when they seek your advice in going to see what kind of doctor or spiritual healer or shaman…Would you leave them with a Feyerabendian riddle about "anything goes" for the lack of no rational decision standards?

Salviati: I may be an expert at science education, but I am no scientific expert in all questions. I want to prepare my students to be able to decide for themselves, rather than follow my authoritative voice.

Simplicio: And then they need to acquire criteria according to which they make their decisions, and I do not see how you can avoid being normative here. You can't introduce your students to every single approach that ever existed and say, I don't know which one is the best, see for yourselves! … I actually like the idea of social discrimination. If meta-expert assessments depend on judgments about ranks, publication forums, institutes, and such kind of things, then it is the first wave, sociology of institutions, that we need to teach – but only the essential basics, of course. The relativist second wave is useless here.

Sagredo: Far from that. The emphasis for most relativist authors is not on the theories we discussed, but on the detailed case studies they offer to reveal how science works. If you want to understand the social dimension of science, you need to see the contingencies inherent in laboratory research, communication and interpretation of results, choices of method and theory, settling controversies, etc. – and this is precisely what the so-called Wave 2 has taught us. The image of science offered by popular movies and books or, for that matter, the image offered by popularizing literature can hardly be matched with the actual practice of science. If SEE calls for the use of social intelligence and argues that modern people acquire a fair bit of this intelligence just by being immersed in society, then my answer is that this general discrimination becomes insufficient when facing science. Laypeople hardly know any details of how scientists work, so how could we expect them to be meta-experts in a world of scientific expertise?

Simplicio: Why not let them rely on expert testimony? Let them believe what expert say, for this is why we have experts: they bear the epistemic authority and responsibility.

Salviati: Your suggestion turns on the validity of the so-called deficit model for the public understanding of science. It sees laypeople as passive in receiving scientific knowledge, and it relies on a premise that is modeled on the traditional science classroom situation, namely, that laypeople (like students) are viewed as yet ignorant of science but capable of having their head "filled" with knowledge diffusing from centers of knowledge production.

Simplicio: Such a process is beneficial since it increases laypeople's scientific literacy (and their ability to solve related technical problems), and their degree of rationality (following the rules of scientific method), and finally, their trust in and respect for science. Can you offer something better?

Sagredo: Surely, if you consider the way laypeople and scientists meet in our present cultures. According to the far more plausible premise of the so-called contextual model (Gregory and Miller 2001), members of the public do not need scientific knowledge for solving their problems, nor do they have “empty memory slots” to receive scientific knowledge at all. Instead, the public’s mind is filled with intellectual strategies to cope with problems they encounter during their lives, and some of these problems are related to science. So the active public turns to science, more precisely to scientific experts, with questions framed in the context of their everyday lives. After all, we live in a world where most tasks are best performed, and most questions best answered, by specific people with outstanding skill and knowledge base, called experts.

Simplicio: And what is the difference between saying that scientists teach us how the world is and saying that our questions are answered by scientific experts? Isn’t it a fancy way to express old trivialities?

Salviati: Not at all. The questions the public is interested in can rarely be answered by “ready-made science” deposited in textbooks; they belong to “science in the making” (Latour 1987). Instead of asking how planets or pendulums precisely move, to which there exist answers that are consensual and yet mostly irrelevant to the public, they want to know, e.g., what materials or activities are healthy. These questions are (still) controversial in science, and nonexperts are faced with a plethora of different and partly contradicting expert opinions, from which they have to build their own system of beliefs.

Simplicio: I may object that scientific experts would always reach a consensus if they were given enough time, but you would probably object that decision making in politics and economics is usually faster than consensus making in science, if we take the post-academic scenario for granted…

Salviati: Or the post-normal scenario (Funtowicz and Ravetz 1993), according to which decisions in the science and technology of our age are achieved under the circumstances of high risk and uncertainty.

Sagredo: So many concepts, so many challenges and aspects and approaches… One thing we found is that the social studies of science has clearly developed, become a field of expertise that has increasing relevance for science educators. As our image of science and the institutions of science change, this is reflected in our educational system, in the mindset of students, teachers, policy makers, and other stakeholders. The lessons of this discipline – even when at times it appears that it is not too disciplined – can help inform both the teaching practice and the theory of science education. But I am afraid we need to conclude our discussion, as we all have our classes to teach. I hope that we will find our discussion inspiring.

Simplicio: No doubt. A major lesson for me is that sociologists have efficient tools to study the practices of science. To see their results is important not only to students planning to pursue a scientific profession but to the wider public also, for science is an essential vehicle of modern social progress.

Salviati: To which I may add the following: student understanding of science can fruitfully extend beyond popular and ideological representations, by utilizing the knowledge of the discipline that pursues the practice of scientists in a historical, cultural, technological, and economic context.

Sagredo: And all this implies that one-sentence retorts about science, sold as "nature of science," watery metaphors, fancy analogies, or simplified algorithms of methodology can hardly capture the knowledge needed to develop understanding of what science is. The knowledge that scientists know about nature and about science are both essential ingredients of science education.

Gábor Kutrovátz Assistant Professor at Eötvös Loránd University of Budapest (ELTE), Department of History and Philosophy of Science. With a background in physics, astronomy, and philosophy at graduate level, he received his Ph.D. in HPS from the Budapest University of Technology and Economics. He taught over 20 different courses on logic, argumentation, the history of sciences, and science studies. He has studied the impact of Hungarian historians of science (Imre Lakatos, Árpád Szabó). His recent field of interest is framed by argumentation studies and the social studies of expertise. He was a Bolyai Postdoctoral Fellow in Budapest and a Lakatos Fellow at LSE London. He is on the editorial board of the journal *Argumentation in Context*.

Gábor Áron Zemplén Associate Professor at the Budapest University of Technology and Economics (BME). After his Ph.D. (BME) and various teaching positions (in England, Switzerland, and Bavaria), he received postdoctoral fellowships at the Max

Planck Institute for the History of Science, Berlin, and the Collegium Budapest, Hungary. He works on the history of optics and theories of color (sixteenth to nineteenth century), on models of argumentation, and on specific aspects of NOS education. He is on the editorial board of the journal Argumentation and is editor of the book series *History and Philosophy of Science* published by L'Harmattan, Hungary.

Chapter 35
Generative Modelling in Physics and in Physics Education: From Aspects of Research Practices to Suggestions for Education

Ismo T. Koponen and Suvi Tala

35.1 Introduction

The past decade in science education research has seen extensive discussion of the model-based view (MBV) of science education. Much of the inspiration of the model-based view derives from the notion that models are central knowledge structures in science and vehicles for developing, representing and communicating ideas. Hopefully, focusing attention on models as core components of knowledge will make it possible to produce a more 'authentic' picture of science than that currently offered in school science. Consequently, educational researchers expect the model-based approach to deeply affect future curricula,[1] instructional methods and teaching and learning in general, as well as teachers' conceptions of the nature of science.[2] The views put forward in favour of the model-based view have generated discussion of the epistemological goals of science education as well as produced new approaches to science education. However, question remains: In what areas has the MBV brought us closer to an authentic picture of science and in what areas is there still work to be done?

Many researchers advocating the MBV have sought support from the philosophy of science for the focused and coherent use of a philosophical framework for purposes of research in learning,[3] for practical teaching[4] and for designing didactical approaches in general (Izquierdo-Aymerich and Adúriz-Bravo 2003). However, not only are views of the philosophy of science of interest but also the philosophical

underpinnings of the recent science studies on scientific practices still need attention and reconsideration. Such reconsiderations are needed to define the essential epistemic aspects of models and modelling in building scientific knowledge and how education could highlight such views on modelling practices. For example, what the MBV has not yet taken into account is that the value of models in scientific practice largely depends on how they can serve as somewhat autonomous, freely developing tools of creative thinking and for exploring theoretical ideas. Indeed, from the viewpoint of the goals of science education to promote higher learning and creative thinking, models as tools of thinking deserve attention. Consequently, this article focuses on the role of models as tools of thinking and as vehicles for creative thought, which we refer to here as 'generative modelling'. Such generative modelling shares many aspects with the 'constructive modelling' and 'generic modelling' discussed by Nersessian (1995, 2008). Following Nersessian, we also draw support from recent science studies of ways of thinking and of practising scientists' use of models. The viewpoints of practising scientists are often flexible and dynamic (as we will discuss later in this article), allowing the employment and development of different kinds of models in the different states of knowledge-building practices. In generative and constructive modelling, the 'running of a model' – either mentally in the form of simulative reasoning or more methodically by using computing algorithms and computers – unfolds the system's dynamical behaviour. The dynamic unfolding of the model in simulations is important because it plays a role both in developing the model and in understanding the processes behind various phenomena through modelling. However, although the purpose of such modelling is to understand phenomena, the models may not be always realistic representations of the systems of the processes. Nevertheless, such models can often play an important role in creative knowledge building because they act as tools for exploring theoretical ideas.

In Sect. 35.2 of this article, we first briefly describe contemporary views of models and modelling in the philosophy of science while emphasising the autonomy of models and their use as tools of thinking and reasoning and in exploring conceptual ideas. A brief summary of current model-based views in science education appears in Sect. 35.3. Because both areas are too broad for a thorough review here, we discuss them insofar as to show that the practices of modellers support the idea that in modelling, (1) models serve in semi-autonomous ways, (2) models mediate between experiments and theory and (3) models are instrumentally reliable rather than 'true'. Sect. 35.4 develops these theses in more detail on the basis of the background outlined in Sects. 35.2 and 35.3. Ultimately, Sect. 35.5 embodies the claims in Sect. 35.4 by providing empirical data from interviews with modellers in the field of materials physics and nanophysics. Lastly, Sect. 35.6 discusses the implications for science education.

35.2 Views of Models and Reality

The philosophical underpinnings of models and modelling directly touch upon philosophical issues concerning the relationship of theory to the world as experienced or how we access reality through experiments and how we express this understanding in abstract theoretical form. In this process, models play a central role. Current science education discusses these relationships and the role of models in it under various names, such as the 'new view on theories' (Grandy 2003), 'new history and philosophy of science' (Izquierdo-Aymerich and Adúriz-Bravo 2003) and 'cognitive theory of science' (Giere 1988). All these views are more or less related to the semantic view of theories (SVT) that originates from the work of Suppes (1962), Suppe (1977), van Fraassen (1980) and Giere (1988). In the SVT, the task of theory is to present a description of phenomena within its 'intended scope' so that one can answer questions about the phenomena and their underlying mechanisms (Suppe 1977). In the SVT, the phenomena (as isolated physical systems) are addressed in terms of models, and theory is identified with a set of models (van Fraassen 1980, Giere 1988, 1999). The best-known positions within the SVT are probably the constructive realism of Giere (1988) and the constructive empiricism of van Fraassen (1980), which offer somewhat different answers to the question of how models represent and what their relationship is to theory.

Within the SVT, researchers in science education have recognised the realistic position of Giere (1988, 1999) as a viewpoint which may more closely link science and science education.[5] One reason for this is that Giere's philosophy of science focuses attention on the cognitive and pragmatic factors involved in *doing science*. Another reason is that Giere outlines the relationship between models and reality through realism as embodied in the *notion of similarity*. The model presumably represents, in some way, the behaviour and structure of a real system; the structural and process aspects of the model are similar to what it models. According to Giere, one can describe the theory in general as a cluster of models or 'as a population of models consisting of related families of models' (Giere 1988, p. 82). In Giere's model-based view, the question of theory is therefore not central, because there is already 'enough conceptual machinery to say anything about theories that needs saying' (Giere 1988, p. 83). It seems that such a semantic view, with its accompanying realism, is the favoured position of current views within science education that seek an authentic image of science.[6]

Currently, the SVT and versions of it within philosophical realism provide a robust background to use models and modelling for purposes of science education in the context of predicting and in explaining. However, the current positions must be reconsidered in order for it to correspond to scientific knowledge building. For example, the most favoured contemporary views say little about the methodological aspects of producing a relationship between models and the world, as one accesses it through experiments. However, this question is of central importance for both building scientific knowledge and learning science and thus deserves further consideration. A suitable departure point for this is to examine scientific practices in modelling.

The SVT and versions of it within philosophical realism are thus promising candidates for a robust background philosophy for science education, but they require further development. At least in physics and physics education, Giere's conception

---

[5] See, e.g. Adúriz-Bravo and Izquierdo-Aymerich (2005), Crawford and Cullin (2004), and Izquierdo-Aymerich and Adúriz-Bravo (2003).

[6] See, e.g. Gilbert et al. (2000), Matthews (1994/2014, 1997), and Nola (1997).

of models (as well as the SVT itself) requires some revision for the following reasons. The SVT does not consider the bidirectional relationship between the model and the experimentally accessible phenomenon. It is helpful to compare the bi-directionality with Giere's views of how models are matched with experiments (Giere et al. 2006). In that picture, the similarity or fit of models with real systems is evaluated on the basis of agreement between experimental data and model predictions, but these schemes entail no feedback between the construction of models and the design of experiments or the process of isolating phenomena by altering the experimental setup (Giere et al. 2006, pp. 29–33). To properly and explicitly take into account the bi-directionality, one must realise that when models serve to explain phenomena, the phenomena are not only modelled but are also fitted to the models (Cartwright 1999). Indeed, the concept of similarity (Giere 1988) must be clarified in order to understand the process of matching a model to real systems – and what such matching really achieves. Taking similarity in as strictly realistic a way as possible (as a similarity of representation) is questionable in physics education, because physics offers no compelling reason to include this requirement among the attributes of good models. In what follows, we discuss in greater detail what such empirical reliability means and how it is achieved, as well as the extent to which these are pragmatic, methodological and epistemological questions that can be approached by examining scientific practice.

A second revision – or rather extension – of the standard SVT involves the semi-autonomy of models (from both theory and experimentation) noted in science studies focusing on the usage and development of models as tools in scientific practice (Morrison and Morgan 1999; Morrison 1999). The autonomy of models is closely related to the question of the relationship between models and theory. In the description provided by Morrison and Morgan (1999), models are largely independent of theory. As Morrison argues, the autonomy of models hinges on two notions:

> (1) the fact that models function in a way that is partially independent of theory and (2) in many cases they are constructed with a minimal reliance on high level theory. (Morrison 1999, p. 43)

However, this does not mean that theory plays a negligible or small role in model building and design. Morrison also emphasised this point noting that models 'are not strictly "theoretical" in the sense of being derived from a coherent theory, some make use of a variety of theoretical and empirical assumptions', which means that models 'obviously incorporate a significant amount of theoretical structure' (Morrison 1999, p. 45). Physics offers several examples of this kind of model-theory relationship. For example, models within complex systems – in particular the archetypical cases of the Ising model and spin-glass models – cannot be 'derived' from any theory, nor it is necessary to define exact 'similarity' between the spin elements of the model and their counterparts in the reality they are intended to model. Instead, the elements and the interactions of the model are meant to stand in some relevant structural relationship to each other, corresponding to the real system, so that the model can reproduce the generic features of the real system (e.g. collective behaviour in some physical disordered or magnetised system but equally well in a sociological or ecological system). Although such a model is not derived from theory, the construction of such models entails many theoretically guided steps.

The theory-to-model relationship has been discussed also by Winsberg (2001, 2003, 2006), who remarks that even though models are not derived from theory, theory nevertheless guides model development. The examples Winsberg provides are typically instances in which a rather well-established theory, such as hydrodynamics or continuum mechanics, already exists, and which allows derivation of a set of dynamic equations in the form of differential or difference equations, but which are not necessarily solvable without further modelling. Consequently, Winsberg argues that such models and modelling are rather semi-autonomous than autonomous. In addition, Winsberg seems to hold position that modelling aims to represent real systems, which, on the other hand, he takes as the most essential epistemological dimension of the use of models and modelling. There is no doubt that Winsberg's position is good departure point in cases that involve established theory as a starting point for modelling a known target, such as hydrodynamic flows, nuclear explosions or the behaviour of plasma, where one can derive a governing dynamic equation for the collective behaviour of a system or its parts. Upon closer inspection, however, Winsberg's examples differ substantially from cases encountered, for example, in complex system behaviour, or even more traditional field of nanosystems, where neither an established theory nor well-known targets exist in the sense discussed by Winsberg. In such fields of research, modelling is more a tool for thinking than a tool for realistic describing and predicting. Consequently, the purpose of modelling is to provide a means for simulative reasoning (cf. Nersessian 1995, 2008) and extended means for performing thought experiments. To perform in the desired manner, such models and modelling must be sufficiently autonomous. However, as Winsberg (2001, 2003, 2006) noted, this does not mean complete independence from theory; theory plays the role of providing guidance, but at the same time, much freedom to use non-theory-derived elements is necessary.

In what follows, we focus on the example of nanophysics, which provides an interesting border case; we have every reason to expect a clear theory-to-model relationship (the research field is, after all, rather conventional branch of materials science), a preference to strive for realistic descriptions and attempts to establish similarity. Somewhat contrary to these expectations, however, simulation practices in nanophysics reveal several extra-theoretical elements, clear instrumental rather than realistic positions are recognised, and instead of similarity with real systems, practical values for reasoning and a certain type of mimetic similarity (though not in the sense of direct visual similarity) emerge as a part of it. Since these findings are from the field of materials science, similar attitudes and stances may also be typical of many other branches of the physical sciences. After all, using models as tools of thinking rather than as tools for realistic representations, or striving for instrumental and practical values instead of realism, may in practice prove far more common than that envisioned by philosophers holding to realism and especially to representational realism.

Nersessian (1995, 2008), who viewed models as means (and tools) to represent ideas as well as reality, emphasised the cognitive aspect of using models with no overarching emphasis on philosophical realism. For this, the SVT is a suitable framework, as it suits views inclined towards philosophical empiricism, realism and pragmatism equally well. The SVT can be seen as a structure or net of models related to each other in different ways and in which mutual relationships are under development. Viewing the SVT in this way leaves room for the generative, mediating models. Such an interpretation of the SVT permits greater independence of models from theory as well as a loose relationship within the set of models, yet without requiring a hierarchical relationship of models, as Giere describes (1988, 1999). Such interpretation provides sufficient, if not complete, freedom from theory and empiry to warrant the phrase 'autonomous models'. In what follows, we show that the modelling practices encountered in physics quite well support the argument that models are semi-autonomous but that at the same time, their design is theoretically guided (without being derived or deduced from theory). Such semi-autonomous models are sufficiently free from theory to be useful for developing of theory and making them interesting enough as objects of research in their own right.

From this background, we propose here a revision which, for the most part, still fits within the SVT but relaxes some of its restrictions. The decision to concentrate on physics stems from the notion that in physics, the role of models and modelling is epistemologically and methodologically essential. Consequently, the process whereby theoretical predictions are linked to the outcome of measurements plays an important role (Koponen 2007). One goal of the present study is to encourage science education to reflect as much as possible the epistemological aspects of doing science as well as aspects with which practising scientist can also agree. This goal can be called providing an 'authentic picture of science'. The current study attempts to provide just such an authentic picture of models and modelling in physics. From this viewpoint, there is no compelling reason to limit views only to those within philosophical realism, which seems to be the preferred way for the current science education literature to view models and modelling.

This article discusses models and modelling from the viewpoint of physics, which then serves as a philosophical background for developing physics education. We first scrutinise recent views of models and modelling in science education in order to outline their philosophical underpinnings and to support the argument that this philosophical basis requires revision. Next, we discuss the question of making a match between theory and experiment, and the role of models and modelling therein, from the viewpoint of recent science studies. We then explore these ideas in the light of an empirical study of modelling scientists' views of their knowledge-building practices. Against this background, we argue that an authentic image of models and modelling in physics requires a certain bi-directionality; models, which respect central, established theoretical ideas, are developed to match phenomena as they take place in laboratory experiments. Indeed, what matching produces is both a functional model, a particular experimental system which can then be modelled, and new knowledge about the phenomenon under consideration. Finally, we suggest that, at least in physics education, the requirements of empirical reliability and empirical success in advancing experimentation are attributes that better correspond to an authentic image of scientific modelling than those of realism and truth, as understood in the philosophy of science.

35.3 Models and Modelling in Science Education

The role of models in providing explanations and predictions is perhaps the most common area in which epistemological questions are explicitly discussed, and in this role, models and modelling are often seen from the point of view of realism.[7] The moderate realistic viewpoint is clearly reasonable from the viewpoint of learning. However, the preferred role of realism in supporting a model-based view is often based on the notion that realism is also the preferred view of the scientists who employ models and modelling and that therefore this kind of approach ensures an 'authentic picture of scientific modelling' (see, e.g. Schwarz et al. 2009; Pluta et al. 2011). Such claims are mostly not justified by argumentation based on the philosophy of science nor are there evidence based on analyses of science practice.[8] Of course, claims of authenticity then rest on weak standing. Before we suggest how to expand viewpoints on models and modelling, we briefly discuss how the relationships between theory, model and experiments are conceived in certain practical solutions for school science.

One of the first suggestions for how to use models and modelling in physics education is Hestenes's (1987, 1992) approach, which underscores the relationship of models to theory and experiment. According to Hestenes, model construction follows comprehensible rules (the rules of the game); models are then validated by matching them with experiments. Hestenes draws insights from Bunge's conception of models and parallels Bunge (1983) when he emphasises the mathematical structure of models and their subordination to theory. Hestenes's ideas reflect a clear predominance of the verificative justification of knowledge, and the truth value of models is judged according to the success of such theory-based predictions. This reflects scientific realism, which adopts not only ontological but also epistemological and methodological realism. When known and accepted theory serves as a basis for making predictions, the aspects Hestenes stresses in modelling clearly constitute an authentic way of modelling in physics. Such theory-based modelling of physical situations also occurs in empirical research in mathematics education that aims to combine mathematical and physical modelling, most often in the field of classical physics (e.g. Hestenes 2010; Neves 2010). This view is justified in the context of making predictions and providing explanations, which are surely the most important aspects of school science, which typically employs models and modelling and presents them as a means to illustrate scientific content (Hestenes 2010). In addition, relying on Hestenes's modelling rules makes it relatively clear how to develop teaching solutions and design teaching activities. Following the modelling methods recommended by Hestenes, traditional physics teaching where theory comes first evidently leads to improvement (Wells et al. 1995; Halloun 2007). However, such an approach loses its teeth in the context of scientific knowledge building,

---

[7] See, e.g. Gilbert et al. (2000), Hestenes (1992), Justi and Gilbert (2000, 2002), and Nola (2004).

[8] Analyses of science practice in fact provide evidence pointing to the opposite conclusions (see, e.g. Koponen (2007) and Tala (2011) and references therein).

where the main interest is in the construction of theory or the acquisition of knowledge not already captured by existing theory.

A related approach from theory to models, but somewhat less theory subordinated, is found in the work of Crawford and Cullin (2004), where the main epistemological role of models is in explaining and developing understanding of the phenomena of nature. According to them, the scientific process can be depicted as a sequence of making observations, identifying patterns in data and then developing and testing explanations of these patterns; in their words 'such explanations are called scientific models' (Crawford and Cullin 2004). In the modelling activity described by Crawford and Cullin, students observe, indentify variables and conceive ideas about the relationship based on their own ideas, which they then test. These authors do not explain their epistemological position with regard to models, but the realistic stance and role of models in providing explanations is apparent on the basis how they refer to the philosophical works of Giere (1988, 1999), Hesse (1963), and Black (1962) in what they discuss about model-to-reality correspondence or similarity. In all cases, a question is the realistic one: How do models represent real systems and how can one improve this correspondence? An adherence to realism is also evident in their general purpose of 'investigating real-world phenomena; then designing, building, and testing computer models related to the real-world investigation' (Crawford and Cullin 2004, p. 1386). They do not explain how these models are produced or how they relate to theory, but taking into account the philosophical underpinnings to which they refer, something close to Giere's concept of similarity between the models and the real world seems to be involved.

The picture of models and modelling proposed by Halloun (2007) is closely related to Hestenes's views in that it sees the role and use of models in making predictions and explanations in a realistic sense. In addition, Halloun focuses to the role of models in investigating and controlling physical systems and phenomena, as well as in influencing the development of a scientific theory. These aspects are important for modelling, which is not theory constrained, but is instead theory generative (cf. Koponen 2007). In agreement with this, Halloun notes that

> For meaningful learning of science, students need to systematically engage in identifying and modeling physical patterns and explicitly structure any scientific theory around a well-chosen set of models. (Halloun 2007, p. 655)

To achieve this, he proposes a modelling scheme, which begins with (1) physical realities and then (2) identifies a pattern for which (3) a model is constructed. This continues with (4) analysing a model and (5) inferring pertinent laws on which one makes predictions (and perhaps also inferences) of the physical realities. Finally, on this basis, (6) the model is refined and integrated into the existing theory (theory may then change) (Halloun 2007, p. 663). In fact, these three steps can be seen as basic steps in creative modelling, which are capable of generating new knowledge, with the ultimate goal not only of predicting or explaining but also of intervening. The success in manipulating and intervening in the phenomenon then provides a basis for developing our understanding of the phenomenon in question. These aspects of modelling are seldom discussed in the context of the model-based view of science education, although such aspects are arguably the most central in advanced levels of scientific modelling (cf. Koponen 2007; Tala 2011).

One can hardly discuss models and modelling in physics without acknowledging the role of mathematics and mathematical thinking in knowledge in physics. To present modelling of a real system, the recent literature on mathematics education, often uses steps quite similar to those Halloun has suggested for modelling in physics. The steps constitute the modelling cycle of the iterative mathematical modelling process for a phenomenon as perceived in the real world. Mathematical modelling cycles are presented as including the identification and simplification of the problem or purification of the variables (cf. Halloun's step 1), formulation of the mathematical model of the real situation (cf. Halloun's steps 2 and 3), solving or studying the mathematical model (cf. Halloun's step 4) and then interpreting the mathematical results in the real world, which is then followed by an evaluation and the development of the model in a repeated modelling cycle.[9] Such mathematical modelling highlights the role of mathematising the phenomena and role of creativity involved in mathematical reasoning and thinking. Empirical research on such mathematical modelling education has proved to be an effective means for preparing students to deal with unfamiliar situations by thinking flexibly and creatively when solving concrete real-world problems by using applied mathematics (Haines and Crouch 2010; Uhden et al. 2012). Theoretical understanding requires focusing on the mathematical framework of modelling, which guides the analysis and simplification of the physical situation and interpretation of the results. Therefore, the viewpoint provided by mathematical modelling education can focus attention on the important role of mathematics in the physical modelling process and the development of mathematical or computational models in a modelling process.

Finally, discussing the creative process of modelling requires that one consider cognitive viewpoints. Nersessian (2008) has studied how scientists use models in discovery processes and to create theories and notes that in 'scientific discovery, models and modeling come first, with further analysis leading to formal expression in the laws and axioms and theories' (Nersessian 2008, p. 205). Scientists use models as cognitive tools, especially when creating, thinking and reasoning their way to novel conceptual representations by means of models.

For practising scientists, an important role of models functions as tools for intervention in and the manipulation of phenomena. Cartwright (1983, 1999) and Hacking (1983) and more recently many other authors (see Morrison and Morgan 1999) discuss this practical role of models. In addition some studies in science education (Izquierdo-Aymerich and Adúriz-Bravo 2003; Crawford and Cullin 2004) now also recognise this practical role of models as tools of thinking. For example, Izquierdo-Aymerich and Adúriz-Bravo (2003) discuss the role of scientific activity and scientific research as an attempt to transform nature and interact with it, rather than as an activity for arriving at truths about the world. They note that models (and theory) which fail to achieve these goals have little value in science education for students and teachers. Unsurprisingly, they follow Hacking (1983) in emphasising

---

[9] See, e.g. Blum and Ferri (2009), Haines and Crouch (2010), and Uhden et al. (2012).

that models serve to make sense of the world, with the ultimate objective of actively transforming the ways to see nature, where ‘facts of the world are heavily reconstructed in the framework of theoretical models’ (Izquierdo-Aymerich and Adúriz-Bravo 2003). These new aspects concerning the use of models and modelling agree with the physicist’s conception of acquiring and justifying knowledge.[10] However, understanding these aspects of transforming, manipulating and intervening in phenomena requires that models serve as autonomous or semi-autonomous agents, much like research instruments.

The viewpoint which sees models as research tools for constructing, understanding and generating knowledge is interesting for education, because it assigns models an active role in the generative and creative process of knowledge construction. Sensevy et al. (2008) have discussed such use of models and modelling in school science from a viewpoint of how the modelling process enables transitions between the abstract and the concrete. In that, they make use of the views put forward by Cartwright (1983, 1999), and Hacking (1983) in a manner similar to that proposed by Koponen (2007), who also endorses Cartwright’s and Hacking’s views among those put forward by van Fraassen (1980). Sensevy et al. called this emerging view of models and modelling the New Empiricism, which emphasises the integral role of empirical knowledge in model building. This New Empiricism captures quite well the bidirectional roles of empirical and theoretical knowledge, not only in model building and interpretation but also how theory guides the empirical explorations as well as framing of phenomena (cf. Koponen 2007). For this type of picture, a weak realistic position, which emphasises the pragmatic aspects of knowledge, fits very well. Indeed, in this way, education allows room for students to construct their knowledge in an equally flexible way as do the more radical constructivist positions.

The generative and creative use of models is challenging for practical solutions of education, because such use of models requires the means to explore the behaviour of the model and to unfold the dynamic evolution of the model system. The behaviour of the model is then compared to the behaviour of the real system in order to understand which aspects of the system model capture and how the model describes. This requires simulations. Insofar as simulations make the dynamic evolution of the model system explicit, science education literature seldom addresses them. Usually, computer ‘simulations’ in science education are either ready-made programs, controllable animations of theoretical situations or programs being based on object-oriented programming rather than real simulations[11] (Crawford and Cullin 2004). What is missing from these applications is the possibility to transform the original mental constructions first to more formal model structures (mathematical structures) and then these structures to a form which enables one to ‘run’ (i.e. simulate) the models. Nevertheless, when models serve as vehicles generating new ideas and as tools in the creative exploration of ideas, simulations are indispensable.

---

[10] See, e.g. Chang (2004), Heidelberger (1998), and Riordan (2003).

[11] See, e.g. Bozkurt and Ilik (2010), Finkelstein et al. (2005), Perkins et al. (2006), and White (1993).

Simulations in this sense, however, must not be conceived as ready-made computer programs or applets, which are rather simple animations with control parameters, but as computational or algorithmic tools which unfold or generate the dynamics the model relations contain, yet remain largely unseen in the model itself.

35.4 Generative Modelling and Simulations

Models in the role of constructing new knowledge, generating theory and as tools for discovery have seen relatively less discussion than have model-to-theory relationships, semantic conceptions of models or model-to-experiment relationships. According to Nersessian (1995, 2008), the role of models in constructing knowledge is most important for creative scientists but seldom addresses in teaching science. Of course, creative development and the construction of models are more difficult to discuss than, for example, theory-subordinated modelling, but on the other hand, having access to such modelling in teaching and learning science adds an important creative dimension to science education.

In her account of constructive modelling, Nersessian (1995, 2008) draws on historical analysis and its cognitive interpretation. According to Nersessian, constructive modelling is a kind of reasoning process that aims to integrate different types of knowledge structures, such as analogies, visual modelling and thought experiments, in order to provide cognitive means to explore and to reason about phenomena or target problems for which no direct model is available. The way Nersessian describes the content and purpose of such constructive modelling also applies into cases not only where direct analogies are missing but also where the ways in which to apply the theory remain obscure or attempts to do so fail (unlike in situations described by Winsberg, where seeing how the theory supports and guides model development is relatively straightforward). An important part of constructive modelling is so-called generic modelling, where ‘the generic model represents what is common among the members of specific classes of physical systems’ (Nersessian 1995, p. 212), which allows one to transform known models as a basis for exploring new unknown situations. Thus, generic modelling guides scientists’ problem solving or helps them recognise similarities between physical systems for new regularities. Constructive modelling, on the other hand, involves

> constructing analogous cases until the constraints fit the target problem. The models thus constructed are proposed interpretations of the target problem. Further, the ability to construct and reason with generic models is a significant dimension of the constructive modeling process. (Nersessian 1995, p. 209)

However, according to Nersessian learning such constructive modelling is challenging in teaching and learning, because it requires sound background knowledge and deep engagement to modelling and possibly also to simulations, knowledge and skills which cannot be expected in introductory levels of learning. These requirements shed some doubt on success of teaching solutions based on very simple ways to use models, very straightforward modelling tasks or on use of ready-made simulations, where the learners' own role in construction of models is moderate.

In what follows, we propose a view of modelling sharing many characteristics with Nersessian's constructive modelling but, here, in more restricted scope as they appear in higher education and in advanced education. In this type of modelling, simulations play a central role but now in the form of algorithmic simulations and computer simulations. Models and modelling, when used as tools to generate understanding and especially in the role of creating new knowledge, often require running models with a computer, namely, simulations. The purpose of such simulations is very practical: to acquire new knowledge of already familiar systems and to probe the behaviour of the simulations (used as tool of investigation) in new situations. This process also develops and transforms the simulation model itself. In simulations, models and modelling play a central role: Simulations are the process of 'running the models' in the virtual world in order to reveal the dynamic behaviour of a system of models. Here, such a combination of modelling and simulations is called *generative modelling*. The practical character of generative modelling makes it a promising case for learning about the epistemological purposes of modelling, to be implemented also as a part of modelling in physics education.

The epistemological value of generative modelling in physics derives from its ability to bridge theoretical ideas – conceptual reality – and real systems. To understand this role, we must consider the relationship of generative modelling to experiments and theory in a balanced manner. Interestingly, this relationship is autonomous; although theory is deeply involved in constructing the models behind the simulations, the models only seldom derive from some underlying theory. This means that a model and the virtual environment provided by simulation respect the central theoretical ideas, but are not directly derived or deduced from theory. In simulations of nanostructure growth, for example, the principles of statistical physics, such as general conditions for equilibrium states and detailed balance, are respected, but the form of probabilities determining the dynamics of the system comprises often purely phenomenological models. Similarly, the relationship of models and simulations to experiments is intriguing; although simulation results are often compared to experimental results in order to verify or develop the simulation model or the simulation environment, this comparison often does more in that it may even affect experimental design and strongly influence which aspects of experiments will be considered. This suggests that the epistemological importance of generative modelling is related to its semi-autonomous role in theory and experiments and that it is this semi-autonomous position which enables generative modelling to 'mediate between the theory and experiment' (Morrison 1999). The way this mediating presents itself involves not only constructing the models to fit the phenomena but also finding and isolating phenomena to fit the models used in the simulations (cf. Cartwright 1999). Consequently, the models need not be faithful to all experimental results; there is freedom to ignore experimental aspects considered irrelevant without strict criteria for how to assess such relevance. On the other hand, the models remain free from theory in the sense that they need not be derived from theory (they must be in accordance with most important theoretical principles, although the criteria for ‘most important’ change from one situation to another). It is this semi-autonomy and flexibility of models which makes them so useful and practical in fitting together the conceptual (theoretical) and material (experimental) control of the phenomena under study and, through that control, providing new knowledge and advance theory construction.

Recent philosophical analyses of simulations and modelling provide several insights into how to frame the idea of generative modelling. First, generative modelling aims to be representative, but does not aim towards a realistic representation of physical systems and their behaviour. Instead, modelling involved in simulations purposely distorts some aspects of the systems to be represented in order to achieve its goal of more effectively representing the features of reality under scrutiny. Such a position can be described as selective realism (Humphreys 2004) or moderate realism (Koponen 2007). Second, generative modelling uses nested structures of different types of models (some of which are theoretically guided, and others, purely phenomenological) but in such a way that they constitute co-ordinated parts of the model. This resembles Hughes’s notion of the nested structure of successive modelling steps with nested representations in an ascending level of abstraction (Hughes 1997, 1999). Also, running simulations in order to unfold the process aspects of the phenomena is central to Hughes’s scheme. Third, unfolding the processual aspects of model systems in simulations is closely related to the notion of mimetic capabilities and mimetic similarity (Humphreys 2004). On this basis, notions which must be taken into account when discussing the purposes and capabilities of simulative modelling are as follows:

1. *Mimetic similarity*. Simulative modelling aims to establish partial mimetic similarity between the processual evolution of systems in simulations and corresponding (though not exactly similar) systems in experiments.
2. *Instrumentally reliable models*. Simulative modelling serves to construct and validate *instrumentally reliable models for the processes* behind experimentally accessible phenomena. These models embody the knowledge achieved by producing and developing simulation models.
3. *Generative modelling mediates* between high-level generic models (or theory) and experimentally accessible phenomena by constructing instrumentally reliable models and fitting them to phenomena. In that process, laboratory phenomena are also designed to fit the models better.
4. *Generative modelling is an instrument* of investigation relating to the world of concepts and theories (and experimentation) in parallel fashion to the way in which the measurement instruments relate to real systems; both are probes in their own worlds, about which they deliver information.

The first notion takes mimetic capabilities as central to knowledge production. Mimetic similarity between processes in simulations and those observed in experiments is at the core of the model justification process. It should be noted that mimetic similarity as understood here, however, is not simply visual mimetic similarity. As Winsberg (2003) has noted, mere visual similarity is of little epistemic value and deserves little attention. Similarity in generic behaviour or in the succession of unfolding events or processes between model systems and real systems, however, is of epistemic value, because such similarity between connected events carries information about causal knowledge or the determination of events. Hughes, for example, refers to such mimetic similarity, achieved through simulations, when he notes:

> The dynamic has an epistemic function: it enables us to draw conclusions about the behaviour of the model, and hence about the behaviour of its subject. (Hughes 1999, p. 130)

Epistemologically, however, this is possible only if models have *representative capabilities*. But 'to represent' now means something other than simply picturing, mirroring or mimicking physical systems, or being 'similar' to a real system. Instead, as Morrison and Morgan outline,

> a representation is seen as a kind of rendering – a partial representation that either abstracts from, or translates into another form, the real nature of the system or theory, or one that is capable of embodying only a portion of a system. (Morrison and Morgan 1999, p. 27)

In their words, such a 'model functions as a "representative" rather than a "representation" of a physical system' (Morrison and Morgan 1999, p. 33). In nanophysics, for example, such mimetic similarity is achieved when a spontaneous selection of order or sizes of nanostructures are generically similar in both real measurable systems and a simulated generic model of self-organisation. Successfully acquiring this similarity in simulations leads to greater insight and understanding, thereby producing knowledge. Similar type of mimetic similarity and its importance for knowledge generation without visual similarity is discussed also by Humphreys (2004) and Hughes (1997, 1999).

The second notion claims that instrumentally reliable models are the goal of modelling. It calls attention to the notion contained in selective or moderate realism that models must be empirically reliable descriptions of only certain aspects of processes and that only some of these selected aspects must be empirically validated. Such instrumentally reliable models are often the products of simulative modelling and also enable one to match theoretical ideas with experimental data, thus bridging the conceptual and the real. Instrumental reliability is important to the credibility of models and their epistemic credentials. On such instrumental reliability, Suárez (1999) notes that the degree of confidence rather than degree of confirmation is essential. The degree of confidence in the model, on the other hand, increases through its successful applications. This is a pragmatic virtue, achieved through use of models. In addition, methodological questions about how the production and design of models relate to pre-existing models and modelling methods are also important (Winsberg 2006). This is a kind of methodological continuity which increases the models' reliability. For scientists, such reliability, achieved through pragmatic and methodological credentials, is often sufficient, and questions of 'truth' in the philosophical sense do not play a major role (see, e.g. Riordan 2003). As Winsberg has noted: 'The success of these models can thus provide a model of success in general: reliability without truth' (Winsberg 2006, p. 16). Together these positions mean that in terms of the reliability of and confidence in models, the 'truth' of the models is less important than the realistic position assumes.

The third notion details the well-known claim that 'models mediate' and suggests how to clarify the vague notion of 'mediating'. Namely, modern experiments provide opportunities for precise control, thus allowing us to 'build our circumstances to fit our models' (Cartwright 1999) and thus narrow the gap between models and real systems. As Cartwright notes:

> …we tailor our systems as much as possible to fit our theories, which is what we do when we want to get the best predictions possible. (Cartwright 1999, p. 9)

She argues further that it is this very aspect of experimentation that makes theories (and models) successful:

> We build it [the system] to fit the models we know work. Indeed, that is how we manage to get so much into the domain of the laws we know. (Cartwright 1999, p. 28)

Accepting these views – evident in the practice of physics – means understanding models as matchmaking tools as well as for manipulating and isolating phenomena.

However, between the real world of entities and phenomena and theory (with its concepts), no direct connection or correspondence exists. Neither are the entities of the real world or its phenomena directly accessible through observation and experimentation. Only through laboratory experiments and measurable quantities do the regularities contained in phenomena or the entities behind them become accessible, observable (or detectable) and discernible. It is such an experimental law – a kind of 'model of data' – that the theoretical models constructed in physics are meant to be matched. The form of models we are interested in here mediates between high-level theory and experimental laws in the above sense. Several philosophers[12] have recently discussed the role of models as mediators between theory and experiment. These views reminded us that models are seldom constructed or derived from theory, nor do experimental data necessitate the models; rather, the models are built using knowledge from many independent sources, sometimes even contradicting the theory.[13] Nevertheless, models carry a substantial amount of well-articulated theoretical knowledge through the theoretical principles involved in their construction; otherwise, they would fail to perform their task of mediating between theory and experiment (Morrison and Morgan 1999; Morrison 1999). To focus on the semi-autonomous role of models, relaxing only the models' close dependence on theory contained within the SVT seems sufficient.

If experimental laws are also taken as models representing the data in suitable form, the emerging picture begins to resemble Suppes's (1962) view, where a hierarchy of models mediates between theory and measurements. This is a process of mutual matching, which entails sequentially adjusting and transforming both kinds of models and involves different levels of models. An essential feature of this bidirectional process is that models can fulfil their task of connecting experimental results to theory 'only because the model and the measurement had already been structured into a mutually compatible form' (Morrison and Morgan 1999, p. 22).

---

[12] See, e.g. Cartwright (1999), Hughes (1997), Morrison (1999), and Morrison and Morgan (1999).

[13] See, e.g. Cartwright (1999), Morrison (1999), and Morrison and Morgan (1999).

Such a process of sequential matchmaking is inherently connected to the use of measuring instruments and the theoretical interpretation of their functioning, an aspect Duhem (1914/1954) already emphasised.

For Suppes, comparison between theory and experiment consists of a sequence of comparisons between logically different types of models. Darling (2002) has described Suppes's view by using the scheme of a 'data path' and 'theory path', which converge at a point where comparisons of data and theoretical predictions are possible. On the theory path, one begins by extracting from a physical theory principles or conditions relevant to the class of experiments under question. These data sets (or models of theory) are the theoretical predictions which, in the end, are compared to the results of the measurements. On the data path, one begins with the actual experimental setup. The essence of this process is that the measurement data (generated by the experiment) cannot be directly compared to the theoretical predictions. To make the comparison, the data must be transformed so that they form a 'model of the data' (Darling 2002).

For Duhem (1914/1954), the experimental results, the measurement itself and the instrumentation used in the measurements are all of central importance. Consequently, Duhem begins with experiments and introduces a sequence of 'translations' which transform experimental results into a form that theory can ultimately annex. The essence of Duhem's viewpoint is that the theoretical interpretation of the use of instruments and how they function is indispensable in every step of the translation sequence; the whole process of interpretation requires a number of theoretical propositions (Darling 2002). Yet, both employ a sequence of modelling steps needed to narrow the gap between actual measurements and the theoretical predictions; there is a mutual fitting of theoretical models to empirical results, as well as models of empirical results to theoretical models. Moreover, in the latter, not only are results idealised, but the experiments themselves are often altered, as is the manner in which the phenomena are produced.

The fourth notion summarises the role of simulative modelling by reiterating the notion of models as instruments (Morrison 1999; Morrison and Morgan 1999) and clarifying what it means to be a 'computational instrument of investigation'. These models emerge in the same cyclical process, where they serve as creative tools: Models bridge the experimental and theoretical world, because they embody both empirical and theoretical arguments in the modelling process. Simulations then serve as a tool for inferring relevant knowledge of the system and its emergent properties. Similarly, in Nersessian's (2002, 2008) view, the most valuable aspect of constructive modelling is that it provides cognitive means for simulative reasoning, mentally exploring or simulating the consequences of the model assumptions. Here, this capability of mental reasoning and simulating takes on a more formal appearance, as algorithmic simulation with the intent to reason and unfold dynamically the consequences of the model's assumptions.

The above four notions clarify the usage and development of models, what models are and how they relate to observable aspects of reality and theory. They also help to characterise the concept of 'model', which should be sufficient for practical purposes, but without attempting to define them. Several reasons compel one to resist the temptation to 'define' models; attempts to do so have turned out to be too restrictive in describing actual modelling practices. Rather than clear-cut definable objects in the philosophy of science, models are cognitive and pragmatic tools for exploring, understanding and manipulating the world with the purpose of constructing knowledge; they are undefinable, but understandable through the ways in which they serve these purposes.

However, an important question remains: How are models developed in the form of simulation models, which can be run in the virtual world of computers? In this we meet the technological limits and especially the idea of the computability, which Humphreys (2004) discusses extensively and in depth. When a model is implemented in a computer, it is simplified and rewritten in a form the computer can handle. Humphreys makes these ideas more transparent at the methodological level by suggesting that in simulations, one should distinguish between the *computational model*, *computational template* and *correction set* to the template. In Humphreys's scheme, the computational model is the model run in the computer, which is constructed on the basis of computational template. These computational templates are mathematical structures, such as formulas, which can serve fruitfully in different contexts; they are well known, and familiar moulds void enough content that they carry over to new unfamiliar fields of inquiry, but with the assurance of how they will work. In many cases, templates as such are insufficient and they must be augmented with correction sets. The correction set serves to match the simulation to the experimental process, thus allowing one to better pursue selectively realistic representations.

On the one hand, in this picture, the models are considered reliable, accurate and correct, but on the other hand, the model may contain sub-models in the form of local parametric models and parametric relationships which must – in a strictly realistic sense – have a direct counterpart in real systems. This, however, does not compromise the reliability of the models, nor does it mean that the models do not represent at all, because the purpose was to represent the real system only to a predetermined degree of realism. Already from the beginning, several possibilities to make the model more realistic are always known, but the increased degree of realism is nearly always sacrificed for the sake of the transparency of the pertinent phenomena, for the greater ease of its mathematical handling and, finally, for better computational tractability. Such a position is well described as selective realist (Humphreys 2004) or moderate realist (Koponen 2007).

The question of which follows is the one of how such selectively realistic simulations provide access to reality. To access real systems in practice, it is enough that they be controllable and manipulable and that new similar systems can be designed with desired features. This goal is realised through simulative modelling, which serves as an inference tool for producing instrumentally reliable models. First, by producing instrumentally reliable models, simulations help to isolate suitable real systems and phenomena to which these models apply. Second, through the bidirectionality of modelling and experimentation, simulative modelling provides a means to manipulate these systems through model predictions. Third, through these steps, simulations provide access to the real, as a means of manipulating and intervening, and for all practical purposes, it is here that the conceptual meets the real.

Thus far, we have discussed generative modelling on the basis of theoretical studies to understand what these ideas mean in the practice of knowledge building. It is now time to consider some examples drawn from practitioners' use of models and modelling.

35.5 Authenticity of Generative Modelling

The picture of the generative modelling painted here differs substantially not only from theory-subordinated verificative modelling but also from the strong realist position, where models' similarity to real systems is extremely important. Finally, this picture challenges the claim that the realistic position grants the authenticity. Of course, we must now respond to this challenge of authenticity and discuss the empirical evidence to support the views promoted here. We did this by exploring the modelling practices and practitioners working in the rapidly developing field of condensed matter physics. We interviewed (altogether ten) PhDs (apprentices, A) and more senior researchers (experts, E) about their knowledge-building practices through modelling (Tala 2011). This in-depth study will reveal clearly a stance of selective realism. The notion that the modelling topics studied are for systems in material sciences strengthens the weight of the argument put forward.

The interviewees' modelling activity focuses on understanding the nanoscale phenomenon through 'hands-on' manipulation of the various models by means of simulations. As one of the informants mentioned:

N1: our simulations are quite down-to-earth, but at the same time [they] make it possible to study general phenomena. (E)[14]

Such bi-directionality is at the core of the generative modelling; models can serve a twofold function: to improve both our understanding of a phenomenon in particular experimental settings and our understanding of the phenomenon on a more general level. Achieving such understanding also plays a role in the generic mental modelling that guides experts' problem solving in new situations (cf. Nersessian 1995):

N2: when beginning to simulate something new, we have often noted with happiness that we have already learnt this [kind of phenomenon] with metals. (E)

Selective realism is evident in many of model builders' comments; in comparisons of experimentation and modelling, only part of the models' features is selected. One interviewed expert explained what makes the models he develops valuable:

N3: In a certain way, in some cases the model is workable/usable for estimating certain things… What makes it interesting is that we can take into account certain important aspects – or the simplicity. (E)

---

[14] Nine interviews were in Finnish, and one in English; the authors translated the excerpts.

In following excerpts, a couple of younger researchers explain further:

N4: The whole of molecular dynamics, would not function if the frequently repeated calculations were not made as simple as possible and quick for the computer to calculate. (A)

N5: If it [the model] becomes too complicated, it is no longer intuitively clear. I am looking for an intuitively clear model which includes the essential [features of] processes and little else. (A)

N6: The models used to represent different viewpoints of the same phenomenon need not be consistent with each other. Nor do even the parallel models need be commensurable. (A)

Modelling thus captures the partial similarity between the dynamic of the model and the respective part of the laboratory phenomenon under consideration. These remarks suggest that the mimetic similarity of models and real systems is reached through a selective realistic attitude towards models and modelling; only part of the systems' behaviour was of interest in one modelling process.

Modellers' views also contain information about how they see models as autonomous instruments of thinking and exploration, sufficiently free from theory to relax some of its constraints, yet sufficiently close to theory to adhere to the modelling assumptions based on sound physical reasoning and a theoretically motivated basis; all aspects need derive from theory, but they do need to be acceptable and make sense from the viewpoint of the theory. As tools of thinking, models are semi-autonomous constructs that function in the conceptual or virtual world and allow one to explore theoretical possibilities. Note that this would be impossible if models were deduced and derived from theory; then, nothing new would come out of modelling. Moreover, if the connection to theory is thin, it would be impossible to say which aspect of the theory is explored and how the model helps to increase knowledge. The interviewees described several examples of how playing in the virtual world provides them opportunity to construct and study systems with properties which may not be (or at least are not yet known to be) real, but could be real within the given theory. Sometimes such systems extremely reduced or idealised, and when needed, even contradict some theoretical principles. Modellers also highlighted this autonomous role at the general level:

N7: A model lives its own life. (E)

Such remarks are typical among physicists. Indeed, they are unmistaken signs of the semi-autonomous use of models as tools of thinking and knowledge construction.

The modellers' conceptions of the ways in which the models mediate between theory and experiment also typically fall in selective realism and instrumental use of models. As three experts put it:

N8: Basically, what my experimental colleagues give me — as an example — Could you please explain why it [an experimental result] is like that. Not simply to explain, but sometimes [to support] a proof of why this [result] can be used as an effective rule for the construction of some materials and not others…. Not simply to explain, but also to understand. (E)

N9: It's very common that a theory creates reality in the sense that modellers propose some sort of explanation for phenomena, not necessarily only for this one, but a general one. (E)

N10: It is a model which explains a particular physical phenomenon. And then everyone follows that model. The model is probably fine and correct, and sometimes it is not. But experimenters start thinking in terms proposed by this'theory'. (E)

Thus, the experimenters need a model to plan the experiment and to interpret the data obtained from it. Some responses also mentioned that, at best:

N11: the simulation predicts something that will be found out through experimentation in the future. (E, A)

The modellers also described how they:

N12: develop new ideas and try them out [in the virtual world] to see which ones are worth testing in experiments. (A)

N13: discuss with the experimenter what can be done and what should be done. (E)

Such developments and discussions are conducted before launching a new research project. Both particular models and particular experiments can thus be more or less purpose-built to each other already from the beginning.

The interviewees also described how the computer model and experiment then become more closely fitted in the cyclic, iterative processes in which running the simulation plays a central role in understanding and developing both the model and the experimental process. Such a modelling process employs many sources of knowledge. In addition to available experimental data available or theoretical calculations, the interviewees compared simulations with other simulations and simulation results and employs practical knowledge:

N14: Everything available; even plain hand waiving in situations where we do not know what exactly is taking place. (E)

Naturally, these 'hand-waving explanations' are educated guesses based on scientists' experience in modelling practices and their understanding of the principles underlining physics. Referring to the origin of such constructive knowledge building, one expert noted:

N15: We should not forget that we are studying mental projections; we study mental pictures which are foundationally mental. It is what we see. (E)

In the interviews, instrumental reliability is most often about computational or algorithmic reliability or functionality. The capability of models to mediate, on the other hand, rests heavily on such instrumental reliability.

N16: A model doesn't care about the actual conditions or claims to explain them, since the only important property of a model is its functionality. (A)

In fact, the ideas expressed by the modellers are very close to the views what Humphreys has discussed under the rubric 'the template', meaning an established and shared algorithmic or computational structure. As the following response puts it,

N17: Simplified mathematical gizmos are the elements shared by the different models. (A)

N18: The harmonic oscillator is the most generally used model in physics; it is used nearly everywhere…. After all, nearly all interactions in these simulations are modelled by harmonic potential. (A)

N19: When a physical template is fitted to a computer, it becomes a kind of new theory… Owing to the digital nature of computers, the discretised template – which is the physical model fitted in the computer – is never the same as the original physical template which provided the starting point. (E)

The choice of 'simplified mathematical gizmos' (see N17) is justified by its tractability and ease of use:

N20: This mathematical model is used because it is computationally very undemanding and effective, … these models are naturally quite simple, and thus do not represent a system very well. (A)

Here, again selective realism is the unmistaken underpinning of the attitude towards modelling; the practical limitations of simulative modelling override even the desire for realism. And finally, what is achieved is an instrumentally reliable and functional model as well as knowledge about its functions. Moreover, the interviewed scientists frequently refer to practical values; a new model is good if it operates as intended, namely, if it produces the events observed in experiments or predicted by more general theoretical models.

Models and their simulation serve as valuable tools in the creative work of scientific knowledge building. They embody both theoretical and empirical ideas developed in the flexible virtual world. It is quite natural that only semi-autonomous models would be able to serve as an instrument. Few remarks refer to these aspects, but remarks N7 and N14–N17 do. Indeed, we noted that experienced modellers perceive the semi-autonomic role of models as a more covering aspect than novices do; understanding this autonomy seems to be characteristic of the expert-like approach.

The semi-autonomy of models is linked to the fact that scientists favour the functionality and computability of the models and selective realism over strict realism. Consequently, although the interviewees wield the models with a substantial, well-articulated theoretical knowledge, they are not mere deductions from the theoretical structures, nor are they deduced or induced from experimental results; rather, they are rich physical constructs which mediate between theory and experiment. Indeed, the bi-directionality of the model with the adjustments based on empirical evidence, coupled with the usage of the model as a tool for investigation – in the spirit of selective realism or weak realism – seems to be an obvious perspective for modelling practitioners working in many fields of physics. The picture that emerges from the practitioners' views lends little support to a strong realistic stance on modelling, or modelling seen as an essentially theory-driven endeavour. Rather, the picture contains many elements discussed here under the rubric of generative modelling, with a selective realistic position emphasising the instrumental use of models, and sees models as semi-autonomous, mediating tools of reasoning and thinking.

35.6 Implications for Physics Education

The generative modelling in physics could promote a more authentic view of models and modelling than the more traditional picture of modelling based on a strong realistic position with its emphasis on prediction and explanation. In short, we suggest that the models and modelling should not be introduced only as tools for explaining scientific content, but also as instruments for creative thinking with the purpose of creating scientific knowledge. In education that takes this notion into account, the points to be highlighted are (1) mimetic similarity, (2) instrumentally reliable models that are sufficient with very moderate realism, (3) generative modelling that mediates between theory and experimentation as an independent approach and (4) generative modelling that is an instrument of creative investigation. In implementing this generative perspective of modelling in science teaching, it is natural to use the research-based resources for science learning and teaching that we already have. For example, cognitive demands must be taken into account in planning, which means that such an approach is not easily adapted to preliminary levels of science learning. It becomes accessible perhaps in upper secondary school level, desirable in the first year at the university level, necessary at the end of advanced studies and, finally, indispensable at the expert level, where the role of generative modelling is easiest to see in new fields of research. Modelling in contemporary physics is still quite a challenging theme, even for teachers, and even more so in the current situation where implementing theory-derived and more straightforward modelling approaches into education is still relatively new.

One very clear requirement of generative modelling activity is that it should be a dynamic and generative activity that produces (processual) mimetic similarity with phenomena or with processes occurring in real world. At the practical level, this means that model relationships are couched in terms of changes and differences, technically as difference equations or differential equations with constraints. At a more untraditional level, the dependencies and interactions in model elements and their relationships come in the form of updating rules for states of the model, as in cellular automata or in agent-based models. Such models have no direct one-to-one relationship with the system that could be studied with the model and where one could assess the similarity of the system and model. In high school-level teaching and in undergraduate teaching, generative and simulative modelling means that more attention should focus on how certain kinds of dependencies of the model level generate certain dynamic behaviours in the simulation run. For example, what kind of motion is related to linear restoring forces, to inverse power law forces or to exponentially decreasing forces, how do these types of forces act in combinations, and what features of generic behaviour one can detect in real phenomena? Such a model-based approach in practice is quite similar to approaches suggested by Halloun (2007) and Nersessian (1995). In Halloun's and Nersessian's suggestions for perceiving modelling, the goal is to understand the generic mechanism behind the most important features of the phenomena. In this sense, simulative modelling through its capability to provide mimetic similarity provides new tools and new ways of thinking about how to see the world and how to make sense of its regular features. There is also considerable room for one's own invention and construction of models. Such objectives, implicated by the generative nature of scientific modelling, are unattainable with modelling that is too simplified. Indeed, the success of practical solutions requires sufficient domain knowledge (Nersessian 1995). Thus the difficulty of the suggested content of such examples of generative modelling makes implementing these ideas challenging at the lower levels of education.

Moreover, using the models as tools for creative thinking and the construction of knowledge can be challenging in the tradition of science education that emphasises realistic views of models and modelling and where the visual similarity of a model to the target system or the quantitative agreement of model predictions with a measured property of the system is of greater importance. The integration of mathematical or IT modelling lessons with modelling in physics could provide a natural place to introduce new perspectives. In mathematics and IT lessons, students may engage more easily in studying the dynamics of models and modelling in the virtual or mathematical world without striving for a direct one-to-one relationship with the physical world, thus enjoying more freedom to explore theoretical ideas. Practising scientists enjoy such freedom, so why not permit the same freedom and joy of invention in teaching and schooling. The role of mathematics in physics is then perceived as essential means to create and develop physical ideas, where mathematical structures themselves can provide new ideas, rather than of seeing mathematics only as a technical tool for making calculations (or, as sometimes seems to be the case, a nuisance which prevents the capture of the true 'conceptual understanding'). Furthermore, emphasising generative modelling may encourage the effective and efficient reorganisation and employment of mathematics in physics lessons, not as a rival to empirical activities, but as a natural counterpart on a par with experimentation – as it is in doing science.

Teachers' views strongly affect the ways in which models and modelling are used in practice in education, which then affects students' views of physics and learning physics. Therefore, generative modelling should be discussed not only in the education of experts in modelling but also in science teacher education. One obvious way to address generative modelling is to use examples drawn from practice (as in Sect 35.5 here) to show that models and modelling can serve not only as a means to demonstrate achieved and agreed consensus on scientific ideas but also as thinking tools in the construction of scientific knowledge, as well as justification strategies in discourse. Even if students have insufficient background knowledge in physics and mathematics to engage in generative modelling, in many cases they can follow the ideas behind a generative modelling process when it is reconstructed and discussed. Reconstructing such examples of a modelling process and how it relates to empirical evidence can serve in science teaching as well as, for example, reconstructed scientific historical examples. Students can also participate in the shared construction and development of a model by creating analogies and forming idealisation and generic abstractions. Indeed, in creative activities, teachers should be able to understand different ways of thinking (cf. Blum and Ferri 2009) when supporting students in constructing and developing ideas in modelling.

In summary, if we want school science to reflect useful and fruitful aspects of modelling in physics, we should focus much more to new types of creative, generative and simulative modelling. Instead of trying to show how models are produced and refined by relying on established theory, we should be able to show how to produce interesting and suggestive new models and how they can guide generation of new theoretical insights and guide us in seeking new empirical regularities in phenomena. Of course, because the more traditional modelling entails many similar steps, what has been said of this type of modelling remains valid and is not overturned.

35.7 Conclusion

The notions of simulative modelling discussed here call attention to several aspects of modelling one must take into account in producing modelling activities for teaching purposes. First, the essential part of modelling is its close relationship with experiments and experimentation: Models are mediators between the conceptual and the real and serve as means of intervention and inference. This means that in teaching solutions, we should carry out parallel and mutually supportive activities of modelling and experimentation. Second, in developing models, theory is not the only starting point of modelling. Rather, model development requires a variety of sources: theoretical, empirical and computational. The practice and purpose of modelling guides how these sources can be used and employed. This leaves much room for the creativity of modelling and also emphasises the constructive and cognitive aspects of modelling, fitting well constructively oriented teaching that supports students' own knowledge construction. Transferring the mathematical models between different fields of physics in modelling also provides room for understanding the role of mathematical thinking and reasoning in physics. Third, and finally, simulative modelling enhances the view that much of science involves not so much of finding the fundamental truths of nature, but rather constructing reliable and functional knowledge which can help us to cope with nature.

Ismo T. Koponen is university lecturer in physics and physics teacher education at the Department of Physics, University of Helsinki, Finland. He received his Ph.D. in physics and worked during 1990–2000 as a researcher in materials physics and statistical physics, in modelling and in simulations. From 2000 onwards his teaching and research interests have been related to physics education. In the Department of Physics, he is leading a research group concentrating on problems in physics education, in particular on problems related to concept learning and conceptual change. The focus of his research work is mainly on the university-level teaching.

Suvi Tala is researcher and teacher educator at the Department of Physics in the University of Helsinki. She has an M.Sc. degree in physics and expertise in teaching physics, chemistry, mathematics, philosophy and ethics. Her postgraduate research focuses on the role of technology in science and science education, including the nature of science and technology. Her research interest includes also learning in research groups. In addition, she is participating on a national project aiming to improve the public's awareness about science and technology.

Chapter 36
Models in Science and in Learning Science: Focusing Scientific Practice on Sense-making

Cynthia Passmore*, Julia Svoboda Gouvea*, and Ronald Giere

36.1 Introduction

Over the last few decades, there has been a “practice turn” in the philosophy of science and, more recently, in science education. That is, there has emerged in both fields an effort to understand and apply ideas about how science is actually practiced to issues in philosophy and education.[1]

What this practice turn has meant is that philosophers, along with other scholars in science studies, have turned from seeking an account of science as a singular, logical system for knowledge generation and evaluation and instead have begun to focus more carefully on an examination of the nuances and context dependencies of what scientists actually do to further their aims of making sense of the world. This turn has been described as naturalistic or pragmatic, because it abandons some of the assumptions and constraints of a more traditional philosophical approach in favor of a more empirically based one and, in this way, offers more authentic descriptions of the scientific endeavor.

Similarly, in science education, there has been much debate and discussion about the distorted and decontextualized version of science that has come to be known as “school science.”[2] There is an emerging consensus that the overarching emphasis on a singular “scientific method” combined with a focus on memorization and test

preparation has contributed to a crisis in science education. Many able students are turning away from science, and more worrisome, there is an alarming lack of scientific literacy among the general public (e.g., Bauer 1992). The practice turn in science education, like the turn in the philosophy of science, has manifested itself in calls for science learning environments to become more authentic to science as actually practiced.

There are two primary reasons to situate science education reform in a consideration of scientific practice. The first is that by engaging students—in explicit ways—with a version of school science that is authentic, students may emerge with a more accurate view of the scientific enterprise. Having such a view will be useful to students as they consider new advances in science and in making decisions about their own futures. Second, because there is a great deal of alignment between how scientists think and reason and the powerful learning mechanisms that all humans use to navigate the world, engaging students in contexts that are authentic should produce a deeper understanding of and insight into the content of science. Indeed, there is good reason to believe that these two aims can be achieved with science education that has been carefully crafted to be authentic.[3]

Meeting these goals requires developing learning environments that engage students in intellectual work that mirrors the work that scientists actually do. And, this means having a clear and coherent picture of the scientific enterprise, one that is developed by looking closely at how science is actually practiced with an eye to how that work can be productively *translated and enacted* in an educational context.

Thus, the practice turns in both science studies and in science education have parallel aims, to attend to the authentic nature of science as it is actually practiced, as well as a parallel challenge, to make sense of the messy intellectual endeavor so that some coherent understanding of the scientific enterprise can be described. Scholars in science studies have examined the complexity of scientific practice from a range of perspectives. Authors have focused on the social structure of science, the cultural and epistemological norms, the day-to-day practices and routines of scientists, the role of tools and material forms, and the reasoning and problem-solving strategies used in scientific practice. Given the nuances and complexities of scientific practice, it can be difficult to conceive of how it can inform the design of science learning environments without leaving us with an account of science that is so diffuse and unstructured to be of practical use.

One way to address the complexity problem is to emphasize the cognitive endeavor of science by focusing on the practice of science and how it supports making sense of how the world works. Such a view does not ignore other perspectives; as Giere and Nersessian have argued, scientific cognition is necessarily embedded in sociocultural contexts where it is shaped and supported by complex interactions with other humans and with material forms. However, a focus on cognition can provide one clear avenue for translating scientific practice into science classrooms.

---

[3] See, for example, Stewart et al. (2005), Duschl (2008), Engle and Conant (2002), Ford (2008), Duschl and Grandy (2008), Lehrer and Schauble (2004), and Roth and Roychoudhury (1993).

This account makes supporting sensemaking primary and asks how can the social, cultural, and material aspects of science classrooms can be structured so that scientific reasoning is supported. It is from this starting point—that a central aim of science education is to engage students in scientific sense-making—that we move forward with for this chapter.

Increasingly, scholars in the history and philosophy of science have turned to examining the pivotal role that models and modeling play in organizing the cognitive activities of practicing scientists. A recognition of the importance of models and modeling in science education has been on the rise as well. There are important connections to be made between the science studies efforts and those in science education around the centrality of models and modeling in the practice of science. A careful consideration of the nature and use of models in science can provide one way to organize our understanding of scientific practice and frame the way we translate this practice into science classrooms to support meaningful sense-making.

36.1.1 Driving Question and Overview

In this chapter we will examine how historians, philosophers, and psychologists have viewed the role of models in science. In particular we are interested in how models function as reasoning tools that allow one to bound, explore, organize, and investigate phenomena and to develop explanations, generalizations, abstractions, and causal claims about those phenomena. We hope to draw out the nature and function of models as context-dependent tools that productively organize a range of sense-making work that scientists undertake in their practice. Sections 36.1 and 36.2 of this chapter are intended to answer a particular driving question:

How do models function to structure and organize scientific practice around sense-making?

To address this question, we first present a rationale for focusing on models; then address ontological and epistemological questions about the nature, form, and development of models; and finally examine how models are actually used in scientific practice.

Ultimately, our goal with this chapter is to unify the views from the science studies literature on how models operate in scientific work and to explore the implications of this view for science education. In order for learning environments to reflect authentic science, they need to be designed to mirror the cognitive activities of scientists. In Sect. 36.3, we address the question:

How can a model-based view of scientific practice be leveraged to organize and focus classroom activity in support of sense-making?

To address this question, we propose a framework for organizing ideas about model functions in science education and apply that framework to a collection of studies in the science education literature. The chapter ends with a consideration of a number of practical and theoretical implications and recommendations.

36.1.2 Rationale for Model Focus: "Why Models?"

To begin, we briefly examine work in history and philosophy of science that motivates our examination of models in science and science education. Much of this scholarship draws on Giere's seminal work in this area, *Explaining Science*. In it he made a deliberate turn away from the "general program" in philosophy of science to a more naturalistic one that examined how scientists actually go about their work on a cognitive level. He began with the assumption that "the representations that scientists construct cannot be radically different in nature from those employed by humans in general" (Giere 1988, p. 62); that is, the sense-making apparatus common to all humans is at work in science as well. The layperson's mental model is not different in kind from the widely accepted scientific model; rather, scientific models are more carefully constructed and systematically evaluated extensions of a more basic cognitive strategy.

This turn toward understanding the meaning making that scientists, as humans, do, rather than characterizing the products of their work on a structural level, emerged from what became "the cognitive study of science," in which mental models play a central role. There was a historically parallel, but independent, move in the philosophy of science from a "syntactic" to a "semantic" view of scientific theories. The latter moves beyond the abstract structure of theories to include issues of the meaning of scientific terms and the truth of scientific statements. In the semantic view of theories, models, still understood as logical rather than mental constructs, are central. Melding these two traditions has been a complicated process (see Downes 1992; Knuuttila 2005). Neither tracking these historical developments nor analyzing their various commitments is our intent here as this has been skillfully done in a number of recent papers for the science education audience.[4] For our purposes, the significance of these developments is that they gave prominence to the idea that models play a central role in scientific sense-making. Fully unpacking why a focus on models in science is useful and how models operate in scientific sense-making requires moving beyond purely philosophical concerns and bringing together a more integrated science studies approach that combines cognitive-historical, psychological, and ethnographic methods.

For example, over the past 15 years, Nancy Nersessian and her colleagues have undertaken a psychological approach to studies of actual scientific practice using both cognitive-historical and contemporary ethnographic techniques. They have spent years observing, documenting, and talking to scientists as they do their day-to-day work (e.g., Osbeck et al. 2010). From these studies has emerged a clear sense that models are at the center of the day-to-day work of science; they are the functional units of scientific thought. As Nersessian explains, mental modeling is the underlying cognitive machinery that makes model-based reasoning so fundamental

to human sense-making. It is the general machinery that underlies our ability to engage in the more formalized scientific strategies of generating representations, using analogies and thought experimentation.

Building on the foundational works of Giere and Nersessian, there has been a proliferation of scholarship in science studies related to uncovering the role of models in science. For example, Morgan and Morrison (1999), in their edited volume, *Models as Mediators*, pulled together a range of articles that explored the ways in which models function in a variety of disciplinary contexts. And, numerous other scholars situated in biology, chemistry, physics, and economics have undertaken both historical and contemporary descriptions of model use in science.[5] Similarly, in the science education community, there is an emerging movement that acknowledges models and modeling as important aspects of scientific practice (e.g., NRC 2011; Windschitl et al. 2008b). Taken together, these studies provide a rationale for organizing science instruction around models and the primary motivation for this chapter: Models are central to scientific sense-making. They provide a way to organize our understanding of scientific practices and a way to understand the purpose of scientific activity.

Alternative organizing frameworks that centralize other aspects of scientific practice are certainly possible. To focus on models is a choice that, as we explore in this chapter, has particular affordances. Specifically, an explicit focus on modeling helps organize scientific practices such as representation, experimentation, and argumentation around the purpose of making sense of phenomena rather than as discrete activities. Although, this unification is seamless in actual scientific practice, in science education, unification can be more challenging. In the next section we draw on science studies to support the claim that models are central to the sense-making practices of scientists and examine the implications for science education.

36.2 Models in Scientific Practice and Science Learning

This section builds toward an understanding of models as context-dependent tools for making sense of phenomena by drawing on the work of philosophers and historians who emphasize the functional role of models in science. First, we address ontological questions about the nature and form of models, we then address epistemological concerns related to model construction and evaluation, and finally, we turn to a functional account of how models are used in scientific practice. What emerges from this account is a definition of models that emphasizes their utility as tools for sense-making as well as a description of the specific ways in which models

(1980); in physics see Cartwright (1997, 1999), Hughes (1999), and Nersessian (1999, 2002); in economics see Boumans (1999) and Morrison (1999). See also Auyang (1998) for comparison across biology, physics, and economics.

serve this function in science. This view of models, embedded in scientific practice, can provide a productive framework for organizing science education environments which is the focus of Sect. 36.3.

36.2.1 What Are Models? Ontological Concerns

> Few terms are used in popular and scientific discourse more promiscuously than "model." (Nelson Goodman 1976, p. 171, as cited in Odenbaugh 2009)

It can be challenging to define models in a concise way. Nevertheless, drawing on pragmatist philosophers, we identify several key attributes of scientific models:

1. *Models are defined by the context of their use.*
2. *Models are partial renderings of phenomena.*
3. *Models are distinct from the representational forms they take.*

In this section we discuss each of these features and discuss the implications of this definition of scientific models for education.

36.2.1.1 Models Are Defined by the Context of Their Use

Nersessian (2002) refers to the cognitive processes involved in deciding how to construct a model as mental modeling. Note that she makes a distinction between mental models, often described as knowledge structures stored in the long-term memory, and mental model*ing* as a *process* of human sense-making. We take up the latter view of model-based cognition as a flexible, context-dependent process whereby humans interpret and reason about situations by selecting and drawing together cognitive resources. Conceived of in this way, models are dynamic entities that are constructed and used as needed.

Although the word model is used to describe a wide range of entities in the sciences, one cannot actually provide a clear definition of what is and is not a model in an abstract sense. As Teller states:

> The point is that when people demand a general account of models, an account which will tell us when something is a model, their demand can be heard as a demand for those intrinsic features of an object which make it a model. But there are no such features. WE make something into a model by determining to use it to represent. (Teller 2001, p. 397, emphasis in original)

For these reasons we fall back on a very basic framework for a model, that models are sets of ideas about how some aspect of the world works. Models are entities that represent some aspects of a phenomenon to some degree. But which of those aspects and to what degree will not be uniform across contexts. Thus, while some philosophers have attempted to specify this relationship as an isomorphism between some source (the world) and some target (the model), we use the more relaxed

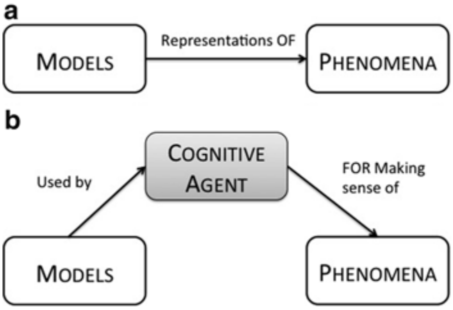

Fig. 36.1 From a dyadic to a triadic understanding of the relationship between models and phenomena. (**a**) The dyadic model focuses on defining the relationship between the model and some phenomenon. (**b**) The triadic model reframes the problem by shifting the focus to the cognitive agent who will ultimately be responsible for determining the nature of the relationship between the model and the phenomenon in a way that is useful given a particular aim

criterion of *similarity* (Giere 1988) to describe the relationship between models and phenomena. A slightly more precise version of the similarity criterion is proposed by Teller who describes similarity in terms of properties: Systems have properties, and some of these (depending on the objective of the modeler) will be part of the model (2001, p. 399).

Perhaps more important than defining what a model is defining what it is not. Appealing to similarity does not imply that any object that is similar to a natural phenomenon is a model. A globe, for example, is not a model of the Earth by default. It *becomes* a model when it is used to make sense of some puzzling pattern or answer some question. The same object can both be a model and not be a model depending on how it is being used.

Pragmatist philosophers, beginning with Giere (1988), have argued that the relationship between models and the world only makes sense in the context of their intended use *by some cognitive agent*. In defining models we cannot simply consider how the model relates to the phenomenon it represents; we must explicitly consider the role played by the cognitive agent (see Fig. 36.1, Giere 2004; Knuuttila 2005). By explicitly drawing attention to the cognitive agent in the system, we end up with a definition of models that foregrounds their function in reasoning. It is the cognitive agent, the modeler, who will decide how to bound, filter, simplify, and represent the phenomenon to generate a model. Which features need be shared and to what degree will depend on the way in which the model user wants to understand that phenomenon.

36.2.1.2 Models Are Partial Renderings of Phenomena

Understanding models in terms of their use can also help clarify the relationship between models and real-world phenomena. It is common to see models referred to as abstractions, simplifications, idealizations, or simply representations of phenomena. Specifying the exact nature of the relationship between models and the world has been a central point of debate in the philosophy of science literature (Downes 1992; Knuttila 2005). As Downes describes, the motivation for this debate has been to say something philosophically robust about models as knowledge structures—to answer the question what can models really tell us about the world? Many proponents of the semantic view have attempted to define the relationship between models and the world as isomorphic. However, for Downes and other pragmatists, the attempt to define a singular relationship between models and real-world phenomena misses the mark. Neither an account of models that focuses exclusively on isomorphism nor an account of models as purely analogical nor any other general account will apply in a universal sense to the variety of different kinds of scientific models that have been historically and continue to be used by practicing scientists (Downes 1992).

Cartwright (1999) similarly challenges the notion that phenomena can be mapped to general theories. Instead, she acknowledges that different phenomena may require models, which vary in the degree to which they make different simplifying assumptions. Cartwright's account is a rejection of the universalism of laws and an acknowledgement of the diversity of phenomena themselves, each of which require its own model formulation. Cartwright describes how a coin dropped from a height can perhaps reasonably be modeled using a simple Newtonian model. But the same model cannot help account for the motion of a dollar bill. The result is that reality is covered by a "patchwork" of models (see Fig. 36.2). This metaphor begins to complicate the possibility that there is a single way to characterize the relationship between models and the world.

Rather than attempt to map a one-to-one relationship between models and phenomena, Morrison and Morgan (1999) describe models as "partial renderings" that can differ widely in the extent to which they accurately represent real systems. They describe how a model of a pendulum can be simple and abstract when used as a means of making sense of simple harmonic motion but can be refined with a series of corrections that increase the complexity of the model as well as its success in making accurate predictions. There is no singular model of a pendulum; rather there are a group of overlapping models of a pendulum, each of which can be used to reason about a pendulum in a different way.

When the importance of a cognitive agent is recognized, a better metaphor for the relationship between models and phenomena is a geometric one proposed by Auyang (1998). As Auyang describes, attempts to a define a one-to-one correspondence between the world and our theoretical understanding of it necessitate a *finite geometry* in which our understanding maps onto the world like "a single global coordinate system covers an entire manifold" (1998, p. 74). As an alternative, Auyang proposes we think of science in terms of a *differential geometry,* in which the manifold is covered by overlapping local coordinate systems (see Fig. 36.2). Thus, Cartwright's patchwork is best understood not as a regular quilt with patches stitched together to create a complete understanding. Instead, the patchwork is much more irregular, with patches of different sizes and shapes overlapping with

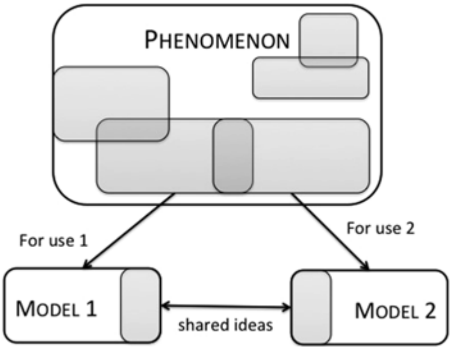

Fig. 36.2 Models related to phenomenon by an overlapping patchwork each of which is used for a slightly different purpose and makes different features of the phenomenon salient to the modeler (After Auyang 1998). *Grey boxes* represent different aspects of some phenomenon that a modeler has chosen to focus on for some particular use

one another, creating areas with many layers of coverage and possibly other areas with large gaps. It is the model user who decides which patch to apply to the world, depending on her aim.[6]

36.2.2 Models Are Distinct from the Representational Forms They Take

Just as there are potentially multiple models that can be used to make sense of a phenomenon, there are also multiple representational modes that any given model can take. Knuuttila (2005) describes modeling as involving two levels of representation. The first level involves choosing the attributes of the system that are relevant to include in a model. Such choices are dependent on the aim of the modeler as noted above. The second level involves making a choice about *how* to represent the relevant attributes of the system in some material form. Often these two levels cannot be separated—choices about what features are important will suggest a particular form just as the choice of a material form will afford or constrain what is attended to. Nevertheless it is worth pointing out that essentially the same ideas can be conveyed in a variety of representational modes including diagrams, equations, physical models, or written text. These different forms should not be conceived as different models per se; rather one should focus on the differences in representational mode.

---

[6] There are two recent books that develop the "patchwork" idea in quite rich directions for those readers who might want an even more sophisticated version of these ideas: Mark Wilson, *Wandering Significance*, Oxford Univ Press, 2006, and William Wimsatt, *Re-engineering philosophy for limited beings*, Harvard Univ Press, 2007.

Too great a focus on the material form of a model can be problematic because it tends to collapse the triadic relationship (between model, cognitive agent, and phenomenon) back into a dyadic one (model and phenomenon only) (see Fig. 36.1). A diagram of the cell is referred to as a "model *of* the cell," but this diagram by itself is merely a depiction of a physical object because it does not suggest what such a diagram is good *for*. Thus, despite the widespread usage in education circles of the word model as applied exclusively to physical objects (like Watson and Crick's tin and cardboard DNA molecule), it is not the material aspect or embodiment of the object that makes it into a model.

In the DNA example, the physical object was deployed to figure out something in the world; it was the physical manifestation of the key features of DNA that were relevant to understanding the mechanisms of inheritance. The material aspect of Watson and Crick's model was absolutely critical, but it was not the *materiality* that made it a model; rather it was how the abstract ideas about the structure and function of DNA along with Franklin's x-ray data were embodied in the material object and how it could then become a tool *for* reasoning about how the molecule functioned. The physical mode of representation was important because it allowed Watson and Crick to visualize precisely how the bond angles among atoms fit together and allowed them to feel confident that their structural understanding was correct. But, as the final line of their manuscript makes clear, that understanding was crucial for making sense of how DNA could possibly function in transmitting genetic information (Watson and Crick 1953).

To return to the of/for distinction made earlier, the three-dimensional structure of DNA is best understood not simply as a model *of* DNA but as a model that included the relevant structural elements of the molecule, thus allowing them to use it *for* developing a deeper understanding of its function. Educators tend to refer to the representational forms themselves as models (i.e., this is a 3-D model of DNA) rather than referring to representational systems as a whole (i.e., this is a physical representation of a DNA molecule that allows one to reason about how this molecule's structure relates to its function in biological inheritance). Unfortunately, this shorthand can promote confusion by foregrounding the form and backgrounding the intention. Being unclear about this issue can lead teachers to conclude that they are doing the scientific practice of modeling in their classrooms whenever they have their students working with physical objects. In fact, it is the cognitive activity—the sense-making—that should provide the primary criterion for determining if students are engaged in modeling. This kind of sense-making goes well beyond merely labeling parts and memorizing functions.

36.2.2.1 What Is a Model? Implications for Science Education

We can use this expanded understanding of models to gain some additional traction in defining models in science education: Models are not simply *of* phenomena, they are tools to be used *for* some reasoning about that phenomenon (Fig. 36.1). This distinction has important implications for decisions about what kinds of models to include in science curricula and for how we assess students' abilities as modelers.

A number of recent articles in the science education literature attempt to provide a typology of models in science toward a goal of finding a list that is inclusive and useful to educators for making decisions about what kinds of models to bring into science classrooms.[7] These typologies emphasize the importance of carefully considering the context when making decisions about the model form and content in instructional settings. However, one challenge of these lists is that they can be difficult to interpret on a philosophical level and use in science education because they do not distinguish models from their representational forms. For example, Harrison and Treagust (2000) present a typology that orders models from concrete scale models, through abstract theoretical models, to complex dynamic systems simulations. This ordering is meant to reflect conceptual demand; concrete scale models (e.g., a scale boat) are less challenging than process models (e.g., a chemical equation) and are therefore positioned lower in the typology (p. 219). Harrison and Treagust suggest a learning progression that first introduces students to concrete models and moves toward introducing more abstract models.

The general point that the models used in educational contexts must be chosen in accordance with the abilities of students is an important one but is made more clear when models and their representational forms are kept distinct. A scale model of a boat can be a less sophisticated reasoning tool than a chemical equation, but this has less to do with the representational form than it has to do with the ways in which the models are used. If the scale model of the boat is used to merely represent surface features of a boat, this is not very sophisticated, and indeed the cognitive demand may be relatively low. However, if the scale model of the boat is used to highlight how boat shape relates to buoyancy, then more intellectual challenge is introduced. A scalar representation *of* a boat is not a scientific model at all, whereas a scalar representation of a boat that can be used *for* reasoning about the phenomenon of floating by illustrating scientific ideas about displacement could be one way of representing a model for buoyancy. Thus, the cognitive demand of a particular model has less to do with the form it takes and more to do with the function it serves.

By defining models in the context of their use, the focus shifts to choosing a model that can be used to make sense of the target phenomenon in a way that is appropriate for the cognitive agent. This might mean that in some classroom contexts, a smaller set of constructs are introduced and simpler relationships are highlighted than are present in the model versions used in the scientific community. This point is made by Gilbert and colleagues in their discussion of curricular versus scientific models. Curricular models are simplified versions of scientific models that are specifically adapted for classroom use. Gilbert (2004) suggests that teachers must choose these curricular versions with an understanding of "the scope and limitations of each of these models: the purposes to which they can be put and the quality of the explanations to which they can give rise" (p. 126). That is, teachers and curriculum designers need to carefully select or construct versions of scientific models with which students can productively think.

---

[7] See, for example, Boulter and Buckley (2000), Coll and Lajium (2011), Gilbert (2004), and Harrison and Treagust (2000).

Introducing a model into a classroom also includes, as Harrison and Treagust (2000) suggest, the need to consider the representational form. However, because of the dual nature of the representational role of models, two sets of questions about what kinds of models to introduce to students must be asked: First, with what set of ideas do we want students to engage, and second, what representational mode or modes can support interaction with those ideas?

It is important to separate the notion of the model from the particular representational form it takes. One reason for this has been to keep students focused on the success of the model as a reasoning tool as opposed to particular features of the representational form that can sometimes distract them from the salient conceptual elements of the model. For example, when first graders were asked to design a physical object that "works like an elbow," they tended to focus on the surface features of the representation, adding details to the models that had only to do with physical resemblance between their replicas and real elbows (Penner et al. 1997). Part of the reason they did so seems to be because the task was purely a representational task—make the elbow—and students responded by making physical replicas *of* elbows.

Imagine if the task had been rephrased so that it foregrounded a sense-making aim and backgrounded the representation, e.g., how is it that an elbow allows you to pick up something? This could have been done by introducing some flexibility in the choice of representational form instead of requiring students to build a physical model or by reframing the task around explanation as opposed to design. In such a scenario, the task would have been framed such that the purpose—to understand something about how elbows work—would have been highlighted. A follow-up study by Penner and colleagues demonstrates a shift in this direction where the students began to explore ideas about the elbow as a fulcrum, introducing ideas about torque and distance. In this second study, the model was no longer seen as one *of* the elbow, it was *for* understanding how lever systems like the elbow actually work (Penner et al. 1998).

The reason the *of/for* distinction is so powerful for education is that, again, it situates the model in the context of its use. It highlights function over form. In addition, it helps to keep the focus on reasoning and making sense *with* the model rather than reducing models to just another thing to be learned by rote in the science classroom. Models should be deployed in science classrooms as dynamic entities that help organize and focus a class of cognitive activities toward a clear sense-making goal.

The second major implication of defining models in terms of their intended use is that there is no single model of any particular object or system but rather many possible models, each of which has different affordances and constraints for reasoning about that phenomenon. In the science education literature, mental models are sometimes used to refer to static representations of students' ideas stored in long-term memory. Students are often described as having models "of" particular phenomena. For example, Gilbert (2004) states that "[a]ll students of chemistry must have a mental model, of some kind, of an 'atom,' all those of biology of a 'virus,' all those of physics of a 'current of electricity'" (p. 117). Often students are asked to externalize their internal mental models as drawings (e.g., Coll and Treagust 2003; Gobert 2005). We have seen this work interpreted to mean that students have a singular view of a particular entity or process with the implication that if this view is incorrect, it must be replaced with the correct consensus model.

Defining models in terms of their purpose allows for the possibility that students, like scientists, have multiple sets of ideas about scientific phenomena. The ideas students have about an atom are likely to vary depending on how they are being asked to think about atoms. For this reason it is important when asking students to generate models to be clear about the purpose of the activity. Asking students to depict a generic model (e.g., "Draw me your model of an atom.") is an underspecified task because it does not help them, as cognitive agents, make informed decisions about which features and relationships are important to represent. Consider the difference in the salient ideas that the student would need to draw on if she was trying to reason about bonding versus nuclear radiation.

If instead models are defined as sets of ideas that are activated in the working memory in response to a particular aim, we shift the focus from whether or not students possess a correct mental model to helping draw out the productive ideas that students have for making sense of particular phenomena. This can help orient educators to drawing out and building on students' ideas rather than attempting to replace misconceptions (c.f. Hammer 1996). Modeling in the science classroom has the potential to draw upon the powerful learning and reasoning resources that all students bring to the classroom and to create an environment in which the students are active learners. This approach could result in students who develop their capacity to reason about the complex and interesting world and could go a long way toward addressing the rote approach seen in so many contemporary classrooms.

36.2.3 *What Makes a Good Model? Epistemological Concerns*

Given that models are defined only in the context of their use, it follows that there is no context-independent way to evaluate a model. Models are built with an understanding of the epistemological criteria that are relevant to the question at hand, and they are evaluated with an understanding of their intended use. This leads us to consider two epistemological concerns:

1. *A focus on models means merging the contexts of discovery and justification.*
2. *Models must balance trade-offs in epistemological criteria.*

36.2.3.1 Merging the Contexts of Discovery and Justification

Practice-based philosophers acknowledge that there is no meaningful distinction *in practice* between the model development and evaluation. In his 1999 chapter in *Models as Mediators*, Marcel Boumans explores the relationship between model building and model justification. He argues that "models integrate a broader range of ingredients" that include theory and empirical data but also metaphors, analogies, mathematical concepts, and techniques. The central claim of his chapter is that this integration is satisfactory when the resulting model can be (1) used as a solution to a theoretical problem, (2) an explanation of an empirical phenomenon, (3) an indication of some possibilities, and (4) a way to mathematically conceptualize a problem. This is an account of modeling that is situated in the context of function, aims, and cognitive payoffs.

Boumans' central thesis is that despite the way in which stories about model development get told, in practice, the "context of discovery" and the "context of justification" are completely intertwined. It is by simultaneously attending to both the theoretical/empirical world and the more pragmatic aims of the modeler that progress on model development is made and justified. The steps are not distinct. One does not build something and then check to see if it does what it is meant to do. Rather one builds something with ongoing and critical attention to the purposes it is supposed to serve. In this way, Boumans explains that "justification is built-in."

Similarly, Nersessian (1992, 2002), by focusing on the cognitive activities of scientists, combines the contexts of discovery and justification into the context of "development" where ideas are articulated and evaluated in a process that is fundamentally creative. New ideas arise in this context not completely de novo but in conversation with existing ideas. She describes how, for example, Maxwell's revolutionary ideas about electromagnetism were borne out of analogies with existing models in mechanics. Further, in the context of development, emerging ideas are not simply held up against a set of rigid standards of justification, but they can interact with those standards to change the rules of the game. Einstein's new framework of relativity fundamentally shifted the criteria against which models would be judged.

36.2.3.2 Models Must Balance Trade-Offs in Epistemological Criteria

Both the Boumans and Nersessian accounts point to the contingent and contextual nature of scientific reasoning and suggest that models will be subject to different epistemological criteria depending on how one intends to use them. They also suggest, as ecologist Richard Levins argued, that "[t]here is no single, best all-purpose model" (1966, p. 7). Levins argued that for both cognitive and methodological reasons, modelers must often choose among the desirable, but often conflicting, epistemic aims of realism, precision, and generality. For example, a fisheries biologist interested in population projections of a species of interest might choose to sacrifice generality in order to construct a model that can generate accurate predictions of population fluctuations, while an ecologist, like Levins himself, might forgo predictive precision in the interest of general explanatory power. The main point to take away from Levins' argument is that modelers will and should build different models depending on their particular aims. The implication is that there is not a single type of model or modeling that can address all biological problems equally well; depending on the question at hand, a biologist will want to choose the model that is the best tool for the particular job.

36.2.3.3 Implication: The Need to Contextualize Meta-modeling Knowledge

When engaging students in the context of model development (i.e., model construction and evaluation) it is important to make them aware of criteria used to judge models but also to help them develop the expertise to recognize which of these criteria are relevant for their purposes at a specific point. A recent study by Pluta et al. (2011) highlights the importance of helping students develop ideas about what makes models "good" in ways that make the context explicit. Without significant instruction, middle school students were able to generate a variety of epistemic criteria for evaluating scientific models. When prompted to list the features of a "good" model, students responded with criteria such as communication, explanatory power, and fit to data. However, the most common responses had to do with the amount of detailed information presented in the models, suggesting that students were thinking of models primarily as useful for conveying information, much as a textbook diagram would.

Looking closer at the nature of the task in this study, students were asked to evaluate a variety of static representations of models including diagrams, pictures, and text similar to what they might see in textbooks (Pluta et al. 2011, p. 500). The task was framed without reference to a particular problem, question, or aim. Given that in the context of this task students were interacting with static, final form models, it is not surprising that many students described models as tools that help communicate ideas, rather than objects to support scientific inquiry. Nevertheless, this study suggests that students do have some resources for thinking about using models in a variety of ways and it supports the argument that a goal of instruction should be to reinforce and refine these ideas with reference to particular scientific aims. We caution against teaching epistemic criteria to students as a normative list of characteristics of "good models" in an abstract and universal sense but instead advocate for instruction that helps students develop and attend to such criteria in the course of developing and using models in context.

36.2.4 How Are Models Used? Functional Concerns

The primary utility of the practice turn is that it has begun to specify, in more detail, the ways in which models function in scientific practice. Once one takes up the "models *for*" orientation, then a crucial next step is to consider what the cognitive agent is doing in more detail. In what follows we build on what has so far been a general argument that models are context-dependent tools for reasoning and now turn to a more specific account of the ways in which these tools can support sense-making in science.

Here the focus is on three scholars from the science studies literature who have taken up the challenge of elaborating a functional analysis of models in science. Jay Odenbaugh (2005) presents an argument from contemporary philosophy of biology for the legitimacy of modeling in biological practice and the range of uses they are put to in that discipline. Nancy Nersessian approaches the problem from the perspective of cognitive science, using cognitive-historical case studies of physicists and contemporary ethnographic methods to unpack the affordances of model-based reasoning. Stella Vosniadou (2001) considers how models function in scientific sense-making by examining similarities between the reasoning of young children/lay adults and scientists.

36.2.4.1 Odenbaugh: Cognitive Benefits of Modeling in Biology

Philosopher of biology Jay Odenbaugh (2005) presents an argument emphasizing the functional utility of modeling in ecology. He states, “model building is first and foremost a strategy for coping with an extraordinarily complex world” (p. 232). He unpacks the strategies of modeling in ecology and the associated cognitive benefits of engaging in these strategies. While, his analysis draws on work in biology, we find it useful for exploring the role of models in science more generally.[8]

Drawing on the work of Levins (1966), Odenbaugh explores five major pragmatic uses for models in biology and their associated benefits: (1) simple, unrealistic models help scientists explore complex systems, (2), models can be used to explore unknown possibilities (3) models can lead to the development of conceptual frameworks, (4) models can make accurate predictions, and (5) models can generate causal explanations. The focus of his argument is that the first three roles of models have been underemphasized in comparison to the latter two.

In his exploration of the first point, Odenbaugh describes how simplification is a purposeful strategy that scientists use in a number of different ways. For example, Odenbaugh describes how simplistic optimality models, which assume that natural selection is the only mechanism shaping natural systems, are used as a baseline from which to consider and explore deviations. That is, simple models can help scientists by allowing them to begin to unpack the reasons why a false model is wrong (see also Wimsatt 1987).

A simple model can be compared to successively more complex models as a systematic strategy for locating error. Odenbaugh illustrates this point with an account of how understanding the deficiencies in the simplest version of the Lotka-Volterra predator–prey model, which is empirically unrealistic, has led to a productive elaboration of increasingly detailed models. Importantly, these models not only make more sense empirically, they also include assumptions that are much more plausible given what is known about natural populations.

In posing a second role for models, Odenbaugh examines how models afford opportunities for exploring possibilities. Rather than representing what is, models can help scientists think about what might be. For example, Odenbaugh describes how ecologist Robert May explored the possible patterns that would emerge from a simple logistic model of population growth. His analysis revealed that increasing

---

[8] See Svoboda and Passmore (2011) for a much more thorough treatment of Odenbaugh’s framework.

the per capita rate of increase (R) could yield chaotic dynamics. The significance of this finding was that it oriented ecologists to the possibility that even relatively simple ecological systems could exhibit complex chaotic patterns for certain parameter values.

The third role for models is in leading to the development of new concepts. Odenbaugh (2005) describes how biologist Robert May chose to represent the overall number and degree of interactions in an ecological community in terms of a "connectance" parameter C, which he defined as the proportion of all pairwise species interactions that were not equal to zero. May's analysis suggested that C played a key role in the stability of the community over time. While May's model was later criticized, Odenbaugh describes how his attempt to operationalize and interpret the role of C opened up a discussion in the ecological community surrounding the appropriate ways to conceptualize community complexity and stability. This analysis marked the beginning of a proliferation of ideas in the ecological community as well as a marked increase in experimental work in community ecology that extended well beyond the original model.

In sum, the essence of Odenbaugh's argument is that matching reality is not the only role for models in biology. Making predictions and explanations are important roles for models, but there are others as well that do just as much to support sense-making. Odenbaugh wants to ensure that the utility of the *exploratory* role of models in generating new ideas and new ways of thinking is recognized as well.

36.2.4.2 Nersessian: Model-Based Reasoning in Physics

Nancy Nersessian and her colleagues have investigated the role of models in science both through cognitive-historical case study analyses (e.g., 1992, 1999, 2002) and more recently in laboratory settings (Osbeck et al. 2010). One of her primary aims has been to explore how models help scientists reason about phenomena by attending to the cognitive processes of scientists and how these processes are situated in scientific practice. In her work Nersessian has identified three types of modeling practices that commonly co-occur in case studies of scientific problem solving: (a) visual reasoning, (b) analogical reasoning, and (c) thought experimentation (simulative reasoning).

In a case analysis of the development of electric-field theory, Nersessian describes the strategies used by Faraday and Maxwell (for a detailed account see Nersessian 1992). Faraday and Maxwell were motivated by a desire to make sense out of a puzzling phenomenon: apparent attractions between objects at a distance. This phenomenon is easily observable by, for example, rubbing a balloon against some fabric and noting that it can now "stick" to the wall. Both scientists made extensive use of diagrams to organize and visualize their emerging understanding of how electric phenomena might work. These representations served to highlight the important structures and relationships between them and served as external objects that could be actively reasoned with. As Nersessian (2002) explains, visual representations do more than hold the ideas in a model—they help focus the reasoner on salient features. They also support simulative reasoning by helping create a visual image that can be animated in the mind. Finally, visual representations provide a way to share ideas with the community. Preparing for this sharing event can force the modeler to make ideas clear and the act of sharing such representations is a productive means of extending the reasoning process out to the larger scientific community. It is the interaction between these externalizations and the underlying model ideas that can lead to breakthroughs for the reasoner.

Analogical reasoning is a form of reasoning that is common in many of these analyses. In forming his understanding of the concept of electricity, Maxwell leveraged analogies from classical Newtonian mechanics. He reasoned that electricity could be analogous to other continuous-action phenomena such as heat, fluid flow, and elasticity (see 1992). For example, using a fluid flow model to map out a similar model of electricity was a crucial part of early work in developing understanding of electric forces.

It is also evident from Nersessian's analysis of his writings that Maxwell relied on simulative thought experimentation to reason through the consequences of his model. This strategy of imagining how a phenomenon might change if certain conditions are changed was also famously used by Galileo. As Nersessian describes:

> According to Aristotelian theory, heavier bodies fall faster than lighter ones. This belief rests on a purely qualitative analysis of the concepts of 'heaviness' and 'lightness'. Galileo argued against this belief and constructed a new, quantifiable representation through sustained analysis using several thought experiments and limiting case analyses…..He calls on us to imagine we drop a heavy body and a light one, made of the same material, at the same time. We could customarily say that the heavy body falls faster and the light body more slowly. Now suppose we tie the two bodies together with a very thin—almost immaterial—string. The combined body should both fall faster and more slowly. It should fall faster because a combined body should be heavier than two separate bodies and should fall more slowly because the slower body should retard the motion of the faster one. Clearly something has gone amiss in our understanding of 'heavier' and'lighter.' (Nersessian 1992, p. 28)

Galileo used this strategy to explore the meaning of the concepts of heavy and light and ultimately reveal the flaws in the Aristotelean model.

Nersessian's focus on model-based reasoning in science draws out some specific cognitive strategies that scientists have at their disposal for making sense of the world. Her analyses make clear that models and the suite of cognitive strategies that they support have helped scientists organize and extend their ideas in ways that have been extremely productive. Further, her account suggests that these same strategies can be productive for students of science (Nersessian 1989, 1995).

36.2.4.3 Vosniadou: Models and Learning Science

Stella Vosniadou has explicitly applied ideas about the cognitive utility of models to science learners. In her 2001 paper, she explores the analogous ways that children and scientists reason with models. Like others, she puts the mental models of children and lay adults on the same dimension as the models of practicing scientists. In her analysis she explores the functions that models play in children's reasoning.

She summarizes her findings with three related functions of models in reasoning: "(a) as aids in the construction of explanations, (b) as mediators in the interpretation and acquisition of new information, and (c) as tools to allow experimentation and theory revision" (p. 359).

In the first sense, Vosniadou notes that models serve a generative function in that they allow the cognitive agent to reason about situations or phenomena that are beyond his or her experience. In her studies of children and lay adults and their views of the shape of the earth, she found that the model served as the "vehicle through which implicit physical knowledge enters the conceptual system" (p. 361). Once this knowledge was articulated in the form of a model, most of her subjects answered questions using a consistent form of this model for the remainder of the study session and were observed to use the abstract ideas to answer specific questions about the earth and objects on it.

Just as the cognitive agent uses the model to generate explanations, so, too, does the model provide a strong filter through which new experiences or information is interpreted. In a study of children's ideas about the day/night cycle, Vosniadou found that the models children had clearly influenced how they interpreted the questions asked of them, just as scientists' models influence how new data are interpreted.

And finally, Vosniadou explores how existing models serve to inform and constrain new ideas and models. In her studies she found that children used their existing ideas to formulate new ones so that a clear connection could be drawn from initial ideas to how those ideas changed over time in the face of new information.

The importance of Vosniadou's contribution is to point out that reasoning with models "is a basic characteristic of the human cognitive system and the use of models by children is the foundation of the more elaborate and intentional use of models by scientists" (p. 367). The fundamental role of models in interpreting and generating new knowledge is central to science and from this premise more specific accounts of the function of models (as delineated above) are possible. Vosniadou's connections between the cognitive work of scientists and children imply that using a modeling framework in education is not only viable but desirable.

From these three scholars, there are a number of ways of describing how models function in science and how this functionality might extend into learning environments. In this final section, we synthesize across these ideas to propose a framework that demonstrates how models, modeling, and model-based reasoning can serve to organize classroom science and focus students' scientific reasoning on making sense of the natural world.

36.3 A Framework for Models in Science Learning

What follows from Sect. 36.2 is that what makes something a model and how a model is developed over time is inextricably linked to the ends it is put to. That is, at a fundamental level, the focus should not be on a model *of* something as an end in itself; rather models are *for* particular sense-making aims. Making sense of a

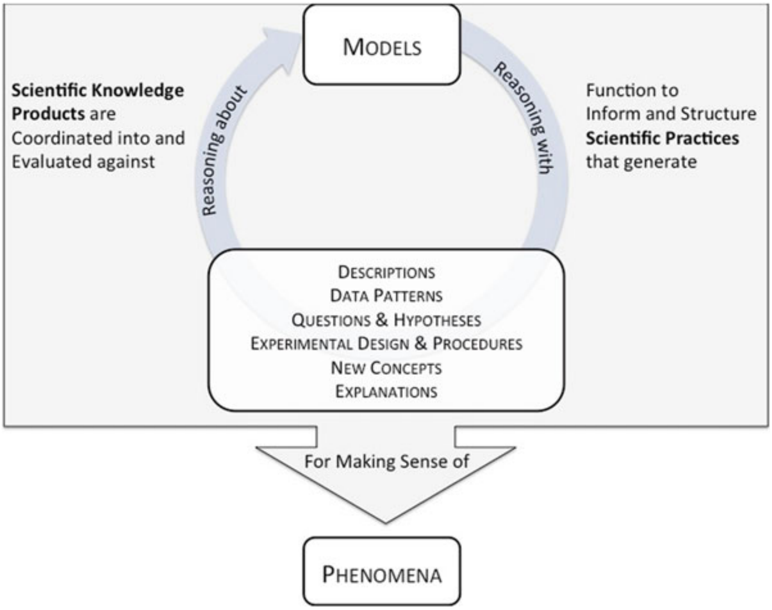

Fig. 36.3 Reasoning with and about models to make sense of phenomena

phenomenon does not typically happen all at once. Rather, one makes sense of a phenomenon by taking the problem in pieces. As these individual pieces come together to inform and constrain the model, both the model and the knowledge products that result from model use become more productive toward the ultimate aim of understanding how something in the world works. Thus, broadly conceived, we delineate two major classes of model-based reasoning. In Fig. 36.3, we have depicted the act of reasoning *with* the model to produce knowledge products and the act of reasoning *about* the model—developing and refining it—using these knowledge products, always toward the ultimate end of sense-making. Thus, the model is a means to an end, not an end in itself.

If models (whether explicit or not) serve as the basis for most, if not all, sense-making endeavors, then getting specific about the myriad ways that model-based reasoning plays out can productively inform science educators as they endeavor to craft more authentic learning experiences for students. Figure 36.3 above is one way to parse reasoning and the products of that reasoning. Of central importance in this figure is the idea that it is through *iterating* between reasoning *with* the model and reasoning *about* the model that one makes progress on coming to understand the phenomenon/phenomena of interest.[9]

---

[9] A major caution about the business of categorizing: We do this for the purpose of discussion and because we believe that a consideration of these different cognitive aims is potentially fruitful in the context of education. However, whenever something is presented in a list of categories, a

The challenge with depicting something as an iterative cycle is that it is difficult to know where to begin in discussing it. We do begin with an assumption from cognitive science that in general reasoning is "theory laden" or model based (Vosniadou 2001). Humans are incapable of interacting with ideas or other stimuli without simultaneously doing some level of integrating of those inputs into the cognitive architecture that is already present. In this sense, the cognitive agent does always begin with a model, although it is often implicit.

This does not imply, however, that instruction must always begin with an explicit model. Quite often instruction may begin with a puzzling phenomenon or an interesting data pattern. It may even begin with an explanation or prediction. However, at some point in the instructional sequence, the model must be drawn out in explicit ways so that its full potential as a reasoning tool can be realized.

36.3.1 Reasoning with Models

A major class of reasoning with models is to use them as filters on the world that serve to constrain and bound the problem space. This role of the model is in line with Odenbaugh's exploratory vision of model use (2005). What it is exactly that one finds intriguing about a particular phenomenon is wholly dependent on the model that the phenomenon is examined through. For example, when examining certain physical attributes of an organism, one may be interested in and attend to the genetic basis of a particular trait if the phenomenon is viewed through the lens of genetics models. Alternatively, one might be interested in the selective advantage of that trait in a particular environment if the phenomenon is viewed through the lens of evolutionary models.

An outcome of this kind of reasoning can be a particular description of the phenomenon. In one sense this is a representational task, but prior to any representation, the observer must bound and filter what it is that is worth noticing. This is done with regard to the model and is often the first stage in the sense-making process: defining what it is exactly that is of interest. In educational contexts, this stage is often done for the students prior to instruction in that the articulated learning goals imply a focus on specific models. To return to the example of organism traits, the way in which those traits are defined or described will vary depending on whether the students are supposed to be learning genetics or evolutionary models.

In the process of making sense of what is observed, one typically interacts with the world in particular ways. In figuring out how to manipulate and generate information from the world, one is guided by a current understanding of how the system functions. Interventions are based on models and an explicit attention to them can clarify what it is one wants to know more about and why that information may be

---

common interpretation is that that format implies an order. This is not our intention. The point here is that models organize a broad array of cognitive aims beyond representing and explaining which seem to be the two most commonly associated with models (Odenbaugh 2005; Knuuttila 2005).

useful in attaining a higher-order goal of sense-making. Reasoning with a model often points to areas that need further exploration and allows scientists to ask meaningful questions. From these questions, then, a scientist can derive and carry out investigative plans whether those involve data collection or simulations.

Two studies by Metz suggest that the degree to which there is an explicit focus on an underlying model may alter the degree to which students can productively engage in generating meaningful questions and investigations. Metz (2004) reports on a classroom study of elementary school children (second and fifth graders) designed to support the children in articulating and designing their own inquiries. Students had the opportunity to observe crickets and were able to generate many questions about them, but, according to Metz, few of them were scientific (e.g., What different crickets like different foods? What color do crickets seem to prefer? Where would crickets go on the playground?) (Metz 2004, p. 240). Metz does not interpret lack of scientific sophistication of these questions as attributed solely to students' age but rather to a lack of curricular support around question generation. In fact, some students did come up with potentially meaningful scientific questions (e.g., Where do crickets spend their time, in the shade or in the sunlight?) suggesting that students did have some scientifically interesting ideas about crickets but that they may have lacked the support needed to make those questions meaningful, reflecting "the failure of this initial version of the animal behavior curriculum to systematically scaffold theory-building" (Metz 2004, p. 267).

In contrast, Metz (2008) describes a classroom vignette in which students engage in thought experiments to explain the phenomenon that ants walk along the same line to get back to their nest. The focus of this activity was on generating plausible explanations for this phenomenon and then using those tentative explanations to develop a research question that could be tested. Students' tentative explanations were simple models with a relatively small number of constructs and relationships (e.g., ants are detecting some smell in the environment to lead them back to the nest). With these ideas explicitly articulated, the students could focus on attending to how they would collect evidence to support or refute various possibilities. For example, when one set of students devised a broom test that would sweep away the trail, other students could critically evaluate that suggestion in light of the emerging smell model by considering whether or not smell was something that could be removed with a broom. In these two studies, the difference between a focus on sensemaking and question generation in absence of a larger sense-making aim illustrates the potential importance of reasoning *with* a model and in making that explicit in the classroom.

When scientists reason with the model to carry out thought experimentation, they consider "how possibly" something might work. As Odenbaugh points out, this may involve adding particular conceptual elements to the broad framework which then find their way into the model itself. Scientists may then use their current models to develop explanations for how a system might work or to make predictions about the future behavior of that system.

In a study by Berland and Reiser (2011), students use simulation output of an ecological system containing organisms at three trophic levels (fox, rabbit, and grass) to determine the trophic level of a fourth unknown invading organism. In this report on the curriculum, it seems that the model that governed the simulation was largely implicit. This is an example where explicit attention to the underlying ecological models may have altered the student discourse during this activity. The students were engaged in sensemaking, but because the model was not made explicit, an important tool for that sensemaking aim was invisible in the classroom discourse. The primary resource the students had for defending claims was the data representation itself.

Berland and Reiser report on how students were engaged in trying to present arguments in support of their preferred claims. For example, one student countered another student's claim that the invader eats rabbits by explicitly referring to the graph: "you claim that the invader eats rabbits, right? Well, at the end of the graph when the rabbits are dead, how do the invader keep going up?" (Berland and Reiser 2011, p. 202). Underneath the first student's claim that the invader eats rabbits is a model in which the invasive organism shares a trophic level with the fox. Making sense of what this implies could have been supported by first developing a robust understanding of the three organism system and then reasoning through what could possibly happen if an invader was added to the system. This kind of thought experimentation with an explicit focus on the model at work behind the scenes of the simulation may have allowed the students to interpret the invader data more clearly. Such a model would explicitly link population numbers in the fox to the abundance of its food source, rabbit, and would make the prediction that if the rabbit population were to decrease, we would expect a decrease in the fox population as well. Being able to imagine how the system might change in response to changes in variables could help students make theoretically justified claims that they could then hold up against the simulation output.

The operations and outcomes of reasoning with models depicted in Fig. 36.3, collectively, are at the core of sense-making. That is, if a phenomenon is thoroughly described, investigated, and explained, then it has been reduced to some kind of order, or it has been made sense of in the broadest sense. Reasoning *with* a model is core to the scientific practices of observing, describing, asking questions, designing investigations, explaining, and predicting.

36.3.2 Reasoning About Models

Reasoning *about* models refers to the integrated practices of developing, evaluating, and revising models. In Fig. 36.3, reasoning *about* models means making decisions about how to synthesize ideas from a number of different sources in the service of more clearly articulating a model. Boumans (1999) makes the important claim that this work is done iteratively and concurrently with model use and so, again, recalls that these different cognitive strategies are teased apart in the diagram for the purposes of discussion.

Reasoning about a model involves making and justifying a number of decisions. One major class of model-based reasoning involves making representational decisions (Nersessian 2002; Knuuttila 2005). In order to share a model within a community of practice, the model must be externalized in some way. The types of things a scientist attends to in creating these externalizations are often central to the formulation of the model itself. For example, if one chooses to represent a model in mathematical form, there are a range of decisions one must make about how different aspects of the model are laid out and the precise ways that each model idea, as represented in a mathematical expression, relates to others. Then, once a mathematical model is analyzed or a computational model is run, the scientist must interpret the results using the initial framework, checking to see if the model output makes sense and is useful in figuring out something about the system under study.

In an undergraduate context, Svoboda and Passmore describe how the question and the model coevolved over time (2011). Specifically, students in this context were attempting to model vaccination-disease dynamics. The students never had a firm hypothesis that they were attempting to prove or disprove. Rather, the group was engaged in a creative and dynamic process of trying to make sense of a complex phenomenon. Throughout the course of their months-long inquiry, they spent a lot of time reasoning *about* the model with close attention to their initial intentions for modeling the system. They had been inspired to undertake this particular project after reading an article that described how media attention about a possible link between autism and the measles, mumps, and rubella (MMR) vaccine led to reduced vaccination and recent disease outbreaks in countries that have voluntary vaccination strategies.

As they went about their work, they continually returned to their initial goal of making sense of the phenomenon of disease-vaccine dynamics. This attention allowed them to make a series of decisions about what to include in their model, how to represent various aspects of the system, and how to interpret results of their modeling activities.

In the process of crafting a specific articulation of a model and communicating it to others, it is not uncommon to come across aspects of the model that need further expansion. Odenbaugh (2005) delineates this as a process of conceptual development. Deciding on, describing, and defining the working pieces of the model are all involved at this point.

Another class of reasoning *about* the model comes when one considers the relationship between particular phenomena and models. Often, a model is developed in the context of examining a very specific phenomenon. For example, one might model the relationships between a set of organisms in a particular environment. Doing so, by necessity, involves attending to the specific details of those organisms in that environment. The model may be deemed useful for explaining one very specialized situation, but from there one might wonder if the model could be applied to other similar phenomena. So, another way in which reasoning about the model occurs is to consider the generalizability of a particular model. One aspect of this may be to make representational decisions about how to broaden the model focus beyond a particular phenomenon to make it useful to explain a larger class.

To come back to the intertwined issues of "discovery and justification" (Boumans 1999), it is in the process of thinking explicitly *about* the model that model development and evaluation come together. Iterating between model use and meta-level processing about the extent to which the model is achieving one's aims is at the core of evaluating a model. The scientist reasons with a model to develop explanations and/or predictions and from there considers whether those knowledge products are useful or not. If not, it may be necessary to consider if the issue is related to the model itself, thus suggesting a need for revision, or if it is an issue of translating the model into an explanation that is at play.

In all cases, issues around reasoning about the model must be inextricably tied to the intention of the modeler. There is no context-free way to make reasonable decisions about the attributes and form of a model. These decisions, in practice, must always be made with regard to the purpose the model is put to in the context of its use.

A study by Hmelo-Silver and Pfeffer illustrates this point. They describe how students had trouble constructing models of aquaria that extended beyond superficial structural features, while experts tended to include deeper functional relationships (Hmelo-Silver and Pfeffer 2004). One way to understand this difference is to ask how each of these groups interpreted the purpose of this model development task. It is clear that experts brought a particular set of aims and purposes to the task. For example, expert aquarium hobbyists were concerned with the aim of maintaining healthy fish and tended to include variables and the relationships among variables in aquaria that are related to fish health. In contrast, ecologists constructed models that could be used to explain ecosystem stability over time.

That students attended to surface features suggests that they viewed the task as primarily descriptive (i.e., they were supposed to be building models *of* aquaria). Rather than propose that students are not as good as experts at attending to deeper features, this as an example where the students needed additional scaffolding around the purpose of model development.

While this work is important because it gave students the opportunity to take responsibility for model development, without an explicit aim, students had no way to productively bound what they were modeling or make decisions about what to include and what to leave out. If instructors do not make the purpose of a modeling activity clear to students, they will bring their own frame to it, and that framing, without explicit attention, may be idiosyncratic rather than shared across the group. If model development and justification cannot be decoupled, then there is simply no robust way to engage in model development in the classroom in the absence of a clear aim that can guide the evaluation/justification of the model.

In contrast, Smith and colleagues (1997) describe how groups of ecology students constructed models relevant to an aphid-wasp-fungus system. Crucially, prior to constructing models, the students were first asked to develop questions that they were interested in investigating. The students were then able to make decisions about the degree of detail and complexity to add into their models. Different groups of students, depending on the question they proposed and the aims they prioritized, then constructed very different models.

A growing number of scholars have written about the importance and utility of allowing students to construct and critique models.[10] What the science studies lens brings to such environments is the importance of coupling model development and evaluation to a clear sense-making aim. In order for students to make the appropriate decisions about how to bound and describe a system, they need to have a clear sense of what the model will ultimately used to do.

What these examples are meant to draw out is how, when contextualized in this way, the practices of constructing, representing, evaluating, and revising models can support productive sensemaking work. These examples highlight how reasoning about models is inextricably linked to considerations of what those models can then be used to do. Thus, reasoning *about* the model is done with critical attention to the output of reasoning *with* the model to achieve a particular aim. When these practices are not linked in instructional settings, then the outcome may not realize the full potential of model-based reasoning in supporting learning.

36.4 Major Implications and Recommendations

36.4.1 Implications

To consider a view of the various aims that a modeler can have and pay explicit attention to the two major classes of model-based reasoning identified above has implications for the way in which science educators approach science instruction and the degree of student ownership and autonomy. Moreover, a focus on models provides a framework in which the various practices of science can be organized and put to productive use in the classroom.

Much has been made over the past few decades about teaching for conceptual change. As part of this approach, many science educators have been involved in determining a canon of scientific ideas. What if the criteria for what counts as the canon were shifted? Obviously scientists do not undertake their cutting-edge work aiming at an established canon of models. To present the task in science classrooms as one in which the students are trying to uncover or guess the canonical model seems disingenuous at best. Maybe there is, however, a canon of classes of phenomena that a scientifically literate student should be able to explain, and those explanations are based on a developmentally appropriate set of models. In this way instruction could actually be crafted authentically, and the intellectual environment of the classroom could reflect the particular sensemaking aims of the community of learners at any given time while concurrently fostering deep understanding of important science concepts.

---

[10] See, for example, Baek et al. (2011), Clement (1989, 2000), Gilbert et al. (1998a, b), Hogan and Thomas (2001), Passmore and Stewart (2002), Schwarz et al. (2009), Svoboda and Passmore (2011), and White (1993).

As students engage in the kind of reasoning described here, they should develop a greater sense of ownership over ideas as they develop them iteratively to address specific reasoning aims that their classroom community has identified. Many of the studies cited above bear witness to the fact that students will engage in complex reasoning when tasks are designed that require it. By organizing these tasks in explicit ways with regard to reasoning with and about models, students may develop a sense of autonomy and begin to demand learning environments that are fundamentally about figuring things out about how the world works.

The framework presented here unites and organizes a number of practices that science educators have been focused on for the past several years (NRC 2007, 2011). The centrality of models to the practices of asking questions, designing investigations, developing explanations, and arguing from evidence becomes clear for both students and teachers. Sadly, higher-level goals of science do not seem to drive science education which tends to focus on the practices in ways that are potentially isolated from higher-order sensemaking goals of explanation (Metz 2006). Placing a model-based view of science at the center of the practices has the potential to counter the treatment of each practice as isolated and unite them in service of sense-making.

36.4.2 Research Recommendations

From the view of models in science presented here, there are a number of research avenues for investigating how models operate in learning science. In Sect. 36.3 we explored the real or imagined role of an explicit focus on models in learning environments that have been described in the science education literature. However, more detailed work is needed in this area to understand exactly how a focus on models and modeling interacts with learning both the conceptual content of particular scientific disciplines and how it may influence students' epistemological views. A recent article by Eve Manz (2012) is one example of this type of scholarship.

If the field can agree on a set of guiding principles for what modeling entails in science learning, then a series of deep investigations into learning environments will be possible that simultaneously attend to the particulars of each context and provide insights into a broader framework. As it stands now, there is a wide range of conceptualizations around modeling and its relationship to other scientific practices, and thus, it is sometimes difficult to understand how different studies speak to one another.

Further, there will need to be additional research on teacher conceptualizations and enactments around model-based inquiry. This work is underway,[11] but it is clear that teachers (both preservice and in-service) have had very little experience with a view of science as a model-based enterprise and thus may be challenged to enact

---

[11] See, for example, Danusso et al. (2010), Nelson and Davis (2012), and Schwarz and Gwekwerere (2006).

model-based curricula (Windschitl et al. 2008a). As researchers uncover and delineate some of the challenges teachers face in supporting students in model-based inquiry, additional resources can be developed to support teachers, including comprehensive curriculum.

36.5 Conclusion

This chapter was crafted to answer questions about the function of models in science and how that view could be translated for educators. The practice turn in science studies has been fruitful in focusing the scholarly community on the importance of models and in identifying the particular ways in which models function in the intellectual lives of scientists. The science studies' work has informed science educators and the time has come to more fully incorporate the findings from philosophical, historical, and cognitive studies of science into science education.

So, in the end we are hoping to make what may seem a subtle shift but one we find incredibly important and powerful in thinking about science education. Instead of listing the kinds of models there are and arguing about what the canonical set of target models for instruction might include, we suggest that the dialogue becomes one that is centrally about the context-dependent roles that models are playing in the students' reasoning/sense-making about phenomena. In making instructional and curricular decisions based on a "models *for*" orientation, we expect a more productive and hopefully authentic version of school science to emerge.

If it is relatively uncontested that models form the basis of most reasoning in science, then it seems obvious that they should form the basis of reasoning in science classrooms. And, although this is often the case when we examine productive classroom activity, the models are rarely made explicit. There may be much to be gained from changing this state of affairs, but ultimately that is an empirical question. The presence of and attention to models as used by cognitive agents *for* specific purposes both focuses and organizes the cognitive activity that is primarily aimed at sense-making. As science educators take seriously the "practice turn" and call for authenticity, it will be a central focus not only on models but also on what they are being used *for* in the sense-making process that will provide a way forward.

Cynthia Passmore is currently an Associate Professor specializing in science education in the University of California, Davis School of Education. She did her doctoral work at the University of Wisconsin, Madison and prior to that she was a high school science teacher. Her research focuses on the role of models and modeling in student learning, curriculum design and teacher professional development. She investigates model-based reasoning in a range of contexts and is particularly interested in understanding how the design of learning environments interacts with students' reasoning practices. She has been the principal investigator of several large grants and has coauthored several papers on modeling in science education that have been published in journals such as *Science & Education*, *The International Journal of Science Education* and *School Science and Mathematics*.

Julia Svoboda Gouvea received a Ph.D. in science education from the University of California, Davis. She also holds an M.A. in population biology from the same university and a B.A. in ecology, evolution, and behavior from Princeton University. Her dissertation work explored students' reasoning with mathematical models in the context of biology and how experiences with modeling influenced students' developing epistemologies of science. Her current research continues to explore the role that models and modeling play in supporting student reasoning and curriculum development in K-12-, undergraduate-, and graduate-level science education. Gouvea is currently an assistant project scientist at UC Davis and holds a concurrent position as a postdoctoral researcher at the University of Maryland, College Park.

Ronald Giere is a professor emeritus of philosophy and a member and former director of the Center for Philosophy of Science at the University of Minnesota. In addition to many papers in the philosophy of science, he is the author of *Understanding Scientific Reasoning* (5th ed 2006), *Explaining Science: A Cognitive Approach* (1988), *Science Without Laws* (1999), and *Scientific Perspectivism* (2006). His current research focuses on agent-centered accounts of models and scientific representation.

Chapter 37
Laws and Explanations in Biology and Chemistry: Philosophical Perspectives and Educational Implications

Zoubeida R. Dagher and Sibel Erduran

37.1 Introduction

The teaching of history and philosophy of science (HPS) in science education has been advocated for several decades.[1] In recent years, however, there has been increasing interest in the philosophical examination of biology and chemistry as distinct branches of science that differ epistemically from physics in significant ways. Philosophers of biology (Hull 1973; Mayr 2004; Ruse 1988) and philosophers of chemistry (Bhushan and Rosenfeld 2000; van Brakel 2000; Scerri and McIntyre 1997) have offered insights into the epistemologies of biology and chemistry. However, these insights have not been integrated sufficiently into biology and chemistry education research, curriculum materials and classroom practice. Research on the nature of science in science education could benefit from such insights in order to improve understanding of not only the disciplinary knowledge but also the meta-level characterisations of scientific knowledge at large.

As science educators we are concerned with the question of how philosophical insights into scientific knowledge can inform science teaching and learning. The goal is not to contribute to the debates in the philosophy of biology and chemistry,

but rather to draw out some aspects of these debates that are relevant for education in light of evidence from empirical studies in science education (e.g. Dagher and Cossman 1992; Erduran and Jimenez-Aleixandre 2008; Sandoval and Millwood 2005). In doing so, we problematise the current state of under utilisation of the epistemological aspects of disciplinary knowledge in science education and illustrate with examples how it can be practically addressed. It is hoped that the discussion will assist other science education researchers in exploring the philosophical literature for clarifying and justifying educational goals that relate to scientific knowledge claims.

According to Irzik and Nola (Chap. 30), science can be perceived as a cognitive-epistemic system and as a social system. Scientific knowledge, which constitutes one component of the cognitive-epistemic system, is the culmination of scientific inquiry and includes laws, theories and models. Focusing on these structural elements in the context of any single discipline would be necessary to understand the nature of that discipline. Among these elements, explanations and particularly laws have been understudied from an epistemological perspective in science education research. For instance, while there is a substantial body of literature focused on models (e.g. Justi 2000), the study of the particular epistemological aspects of models has been scarce (e.g. Adúriz-Bravo 2013; Adúriz-Bravo and Galagovsky 2001; Erduran and Duschl 2004). Similarly, despite the importance of laws and explanations in the science disciplines, relevance of their epistemic nature to educational practice is seldom explored (e.g. McComas 2003; Sandoval and Reiser 2004).

One often-cited misunderstanding of the nature of science (NOS) concerns scientific laws. Classified as the number one NOS myth by McComas (1998), many individuals tend to believe 'that with increased evidence there is a developmental sequence through which scientific ideas pass on their way to final acceptance as mature laws' (p. 54). Involved in this belief is the thought that science starts out with facts, progresses to hypotheses, then theories, then, when confirmed, to laws. Another myth pertains to the idea that scientific laws are absolute (McComas 1998). These beliefs represent only two of many other misunderstandings about the nature of scientific knowledge and pose challenges regarding the best approach to deconstruct them. Several approaches have been proposed for countering these and other nature of science misconceptions (Clough 1994; Khishfe and Abd-El-Khalick 2002; Schwartz et al. 2004), but it remains unclear whether efforts to enhance student understandings of the nature of science have resulted in significant or lasting improvements (Lederman 2007).

The context of laws provides a crucial and relevant nexus for promoting the epistemological aspects of biology and chemistry in the classroom. Focusing on the nature of laws in biology education, for example, not only serves to clear existing misconceptions (as the ones mentioned earlier) but offers insight into basic metaphysical and ontological aspects of the discipline which can enhance student understanding of the subject. The inclusion of 'laws' in chemistry education not only elaborates on this important philosophical thesis but also offers some insight into how students' interest in philosophical aspects of chemistry might be stimulated.

Scientific explanations on the other hand refer often to how and why something happens (Chinn and Brown 2000). Typically scientists explain phenomena by determining how and why they occur along with the conditions surrounding the observed events (Nagel 1961). Explanations are important components of scientific theories. They are the backbone of scientific claims and are consequently a central target for epistemological disputes. It is through the refutation or support of components of scientific explanations that the fabric of theories is woven. In science education, considerable emphasis is placed on developing students' ability to substantiate their explanations using reasons and evidence.

Despite the separation of laws and explanations for contrast in biology and chemistry in this chapter for educational purposes, the distinction of these concepts in the history of philosophy of science is not straightforward. For example, the covering laws in Hempel's positivistic framework function not only as core explanatory components (*explanans*) but also as the targets of explanation (*explananda*). In more recent work, lawlike regularities among properties are considered to be a kind of explanation in their own right. For instance, Bird (1998) calls them 'nomic explanations'. He argues that inferring a law from observation is a form of *inference to the best explanation* (IBE), a common form of scientific reasoning.

The task in this paper is not to articulate the distinctions between laws and explanations from a philosophical perspective. Indeed, as educators, it is beyond the scope of our engagement in philosophy of science to contribute to or resolve existing debates or to generate new knowledge in the field. This task is left to the professional philosophers. Rather, the purpose of this analysis is to draw out some themes around laws and explanations, discussed in philosophy of biology and philosophy of chemistry, in ways that are relevant for science education. For example, Mendel's Laws and the Periodic Law are chosen as examples because of their prominence in science curricula at the secondary school level, which is our primary area of interest. At times, the discussion will refer to some contentious characterisations of laws and explanations. Again, here the discussion is reflecting ongoing debates to inform the science education community of the sorts of issues that are of concern to philosophers of science. The implications for science education could include problematising the nature of laws, explanations or indeed the contrast itself. However, given the typically separate reference to laws and explanations in the science curricula, the goal in this chapter is to interrogate the existing literatures for particular and explicit references to either laws or explanations thus informing subsequent analysis of how they are depicted in science education.

Furthermore, while discussions of NOS in the science education literature typically focus on the relationship between laws and theories (specifically on how they are different), they tend to neglect the conceptual disciplinary-based features that pertain to them. Shifting the discussion in this paper from laws and theories to laws and explanations underscores the following key ideas/assumptions: (1) Explanation is a key purpose of science. Theories are developed not as ends in themselves but as powerful explanatory and predictive tools. (2) Laws express regularities that can serve predictive and/or explanatory functions. (3) Explanations are building blocks of scientific theories that can be explored pedagogically at multiple organisational levels. (4) explanations are pragmatic and contextual (de Regt 2011).

Focusing on explanations rather than theories in this paper allows for a nuanced and contextual discussion of their characteristics across disciplines and subdisciplines from philosophical and educational perspectives. The significance of explanations in science curriculum and instruction is recognised by science educators in a variety of ways. In some cases, concern is expressed about linguistic and epistemic aspects, as with Horwood's (1988) illustration of the lack of consistency between the terms 'explain' and 'describe' in teaching materials and Jungwirth's (1979) findings that high school students tend to equate anthropomorphic and teleological explanations with causal explanations. At the level of instruction, teachers are reported to use a wide range of explanatory types some of which are scientific and some are not, calling for further examination of the appropriateness of these explanations (Dagher and Cossman 1992). More recent work presents evidence for the difficulties experienced by students in generating and justifying scientific explanations (Sandoval and Millwood 2005). In addition, there have been ongoing efforts focused on designing instructional models for supporting student development of scientific explanations (Land and Zembal-Saul 2003; McNeill et al. 2006; McNeill and Krajcik 2012).

In summary, the purpose of this chapter is to discuss characterisations of laws and explanations in biology and chemistry and extract some implications for teaching, learning and curriculum. The goal is to demonstrate how some of the ongoing debates about the nature of laws and explanations in biology and chemistry can have useful contributions to teaching these disciplines without necessarily resolving these debates. Exploring the arguments in these debates allows the articulation of how laws and explanations as products of scientific knowledge might be addressed more meaningfully in educational settings by discussing current coverage of laws and explanations in typical biology and chemistry textbooks. The chapter concludes with recommendations for revising textbooks and instruction in ways that restore the grounding of subject matter knowledge in its epistemological context.

37.2 The Nature of Laws and Explanations in Science

Volumes have been written about the nature of laws and explanations in science, mostly using physics as a basis for analysis. Views about the purpose and nature of these entities have changed over time and some aspects of them continue to undergo some debate. Attempting to summarise this vast literature or represent the diversity of views in few paragraphs is impossible without doing grave injustice to the field. It is necessary, however, to highlight key ideas before discussing the characteristics of laws and explanations in biology and chemistry with the understanding that this brief overview is not exhaustive or representative of extant viewpoints.

What distinguishes a law of nature from any other regularity? Traditional definitions of a scientific law typically refer to 'a true, absolute and unchanging relationship among interacting elements' (Dhar and Giuliani 2010, p. 7). This traditional view has been challenged on several bases. Lange (2005) argues that the condition of truth alone does not help make this distinction since other regularities are true also. He proposes the following four criteria to aid in distinguishing laws of nature from other regularities: necessity, counterfactuals, explanatory power and inductive confirmations. Mahner and Bunge (1997) have argued that laws are said to be 'spatially and temporally boundless', where other laws may be 'bounded in space and time'. Cartwright's critique of 'the limited scope of applicability of physical laws' (Ruphy 2003) problematises the 'truth' aspect of laws. Giere (1999) on the other hand holds the view that what has come to be known as 'laws of nature' is in fact historical fossils, holdovers from conceptualisations first proposed in the Enlightenment. He proposes the consideration of models, which he argues are more reflective of how science is actually *practised*.

The significance of the debates about the nature of scientific laws becomes most relevant when discussing the role they play in supporting explanations in the specific sciences. Attempting a balanced description of scientific laws is a complex undertaking considering debates among philosophers about criteria invoked to distinguish between various types of laws such as strict versus *ceteris paribus* laws and empirical versus a priori laws. Such criteria include mathematical models, necessity, and explanatory and predictive potential. Some of these debates will be revisited in the context of the specific sciences later in this chapter.

In an insightful paper written more than five decades ago, Bunge (1961) classified lawlike statements from various philosophical standpoints into more than seven-dozen kinds. He concluded his detailed analysis with calling for less stringent philosophical restrictions regarding what could be classified as a law:

> There are as many classifications of law statements as viewpoints can be profitably adopted in their regard, and there seems to be no reason—save certain philosophical traditions—why most law statements should be regarded as nonlaw statements merely because they fail to comply with either certainty, or strict universality, or causality, or simplicity, or any other requisite found necessary in the past, where science seemed to concern itself exclusively…. That lawlike (*a posteriori* and general in some respect) statements be required corroboration and systematicity in order to be ranked as law statements, seems to fit contemporary usage in the sciences. (Bunge 1961, p. 281)

Bunge's pragmatic view regarding what constitutes scientific laws is a profound one. Continued debates about what counts as a scientific law, argued with core propositions of particular science disciplines, seem to be fundamentally grounded in normative or pragmatic standpoints and from this perspective cannot be said to have been fully resolved. Perhaps the most valuable context for such debates has been relative to the role of laws in generating or supporting scientific explanations (Press 2009).

Explanation is often hailed as one of the main goals of the scientific enterprise. Nagel (1961) articulates the central role of explanations in science when he states: 'It is the desire for explanations which are at once systematic and controllable by factual evidence that generates science; and it is the classification and organisation of knowledge on the basis of explanatory principles that is the distinctive goal of the sciences' (p. 4). While this stance towards explanation may seem obvious, it does not represent a united or a longstanding view. Logical positivists for instance, led by Ernest Mach, held that the aim of science is not to explain but rather to describe and predict phenomena (de Regt 2011). Discussions of the components that distinguish scientific explanation from other forms of explanation have spurred significant philosophical debate and led to a variety of accounts that have expanded understanding of their diversity.

The following discussion focuses on describing three main families or models of explanation. These are nomological explanation, causal explanation and functional explanation. According to de Regt (2011), these models are not mutually exclusive but can be used to explain the same phenomenon or explain phenomena in different disciplines.

The deductive-nomological (D-N) or covering law model of explanation proposed by Hempel and Oppenheim (1948) frames explanation as a logical argument in which the conclusion, or *explanandum,* follows from a set of premises, or *explanans.* The premises that constitute the *explanans* have to include at least one general law and other relevant preconditions. The general law in Hempel's account is a key component of the explanation process and has to be a 'true universal generalisation', allowing for the explanation and/or prediction of various events. One of the unresolved issues in the D-N model of explanation, pointed out by de Regt (2011), is that science is usually concerned with the explanation of laws, which necessitates the use of other more general laws. This proves to be problematic without 'giving an adequate criterion for the generality of laws' (p. 159). One derivative of nomological explanation is the inductive-statistical explanation (I-S), in which the law used in the *explanans* contains high probability that subsequently gives rise to an inductive (as opposed to deductive) support to the *explanandum.*

The Causal Mechanical (CM) model of explanation moves away from the conception of explanation as an argument (Salmon 1984). In generating this model, Salmon abandoned the attempt to characterise explanation or causal relationships in purely statistical terms. The CM model employs several central ideas. A causal process is a physical process, like the movement of a ball through space, that is characterised by the ability to transmit a mark in a continuous way. A mark is some local modification to the structure of a process. A process is capable of transmitting a mark if, once the mark is introduced at one spatiotemporal location, it will persist to other spatiotemporal locations even in the absence of any further interaction.

Causal processes contrast with pseudo-processes that lack the ability to transmit marks. An example is the shadow of a moving physical object. The other major element in Salmon's model is the notion of a *causal interaction.* A casual interaction involves a spatiotemporal intersection between two causal processes which modifies the structure of both—each process comes to have features it would not have had in the absence of the interaction. A collision between two cars that dents both is a paradigmatic causal interaction. According to the CM model, an explanation of some event *E* will trace the causal processes and interactions leading up to *E* (Salmon calls this the *etiological* aspect of the explanation), or at least some portion of these, as well as describing the processes and interactions that make up the event itself (the *constitutive* aspect of explanation). In this way, the explanation shows how *E* ‘fit[s] into a causal nexus’ (Salmon 1984, p. 9).

Functional explanations typically account ‘for the role or presence of a component item by citing its function in the system’ (de Regt 2011, p. 164). This type of explanation is commonly employed in the life and social sciences because these domains typically deal with ‘complex organized systems, the components of which contribute to the working of the system (organisms, human minds, societies and so forth)’ (de Regt 2011, p. 164). Achinstein (1983) presents three categories of functional explanations: the good-consequence doctrine in which the function confers some good on something or someone; the goal doctrine in which the function contributes to a goal that something, its designer or its user has; and the explanation doctrine in which the function includes causes or reasons or consequences. These categories probably make it easier to differentiate between functional explanations with teleological goal-oriented tendencies (the second doctrine) and other functional explanations. Achinstein further distinguishes between three types of functions: design functions, use functions, and service functions, allowing for a more nuanced and contextual differentiation between different functional explanations.

Philosophers of science have discussed a plethora of explanation models.[2] Additional contributions have came from philosophers of biology (e.g. Rosenberg and McShea 2008; Schaffner 1993; Sober 2008) and philosophers of chemistry (e.g. Goodwin 2008; Scerri and McIntyre 1997; van Brakel 2000) presenting and defending explanatory models that communicate the uniqueness of their disciplines. The following section describes the characteristics of laws and explanations in biology and chemistry focusing on aspects that have direct implications for science education.

37.3 The Nature of Laws and Explanations in Biology and Chemistry

37.3.1 Laws in Biology

There has been considerable discussion among philosophers regarding the appropriateness or meaningfulness of the concept of law in biology. Mayr takes the stance that ‘laws play a rather small role in theory construction in biology’. He attributes this ‘to the greater role played in biological systems by chance and randomness. Other reasons for the small role of laws in biology are the uniqueness of a high percentage of phenomena in living systems as well as the historical nature of events’ (Mayr 2004, p. 28). The fact that biological systems are governed by ‘dual causation’ imposed by natural laws and by ‘genetic programmes’ makes the

---

[2] For example, see Giere (1988), Harré (1988), Hesse (1970), Pitt (1988), Salmon (1987), and Scriven (1970).

theories that explain them distinct from those pertaining to physical systems (Mayr 2004, p. 30). For Mayr, the matter is not one of nomenclature but one of substance. He concedes that even though some of the important concepts in biology ‘can be phrased as laws, they are something entirely different from the Newtonian natural laws’ (Mayr 2004, p. 30).

Garvey (2007) takes a position similar to Mayr’s when he states that ‘Biology does not have strict mathematical laws of its own. There are, as in any science, generalisations. But these generalisations have a habit of proving to be: (i) not distinctive to biology; (ii) not strict, exceptionless, mathematical laws; or (iii) not laws at all. Put in more positive terms, the generalisations found in biology are: (i) laws that belong to other sciences, (ii) *ceteris paribus* laws[3]; or (iii) true by definition’ (p. 157–158). Others such as Uzman (2006) maintain that some biological observations tend to be presented as theories at a time when they should be considered laws of nature. He identifies four laws:

First law: “All phenomena of life are consistent with the laws of chemistry and physics.”
Second law: “The cell is the fundamental unit of life.”
Third law: “Life is continuous across generations.”
Fourth law: “Life evolves – populations of organisms change genetically and irreversibly through time.”

Örstan (2007) attributes to E. O. Wilson the claim that biology has 2 main fundamental laws: ‘1. All of the phenomena of biology are ultimately obedient to the laws of physics and chemistry, and 2. All of the phenomena of biology have arisen by evolution thru[sic] natural selection’. It can be argued, using Garvey’s criteria, that even these ‘laws’ constitute generalisations that are nonmathematical and/or true by definition.

Reasons advanced in support or opposition to the concept of laws in biology can be found in various subdisciplines (evolutionary biology, systems biology, molecular biology, ecology). While the complexity of biological systems is widely acknowledged, constant efforts are being undertaken to establish fundamental biological organising principles that exhibit lawlikeness. For example, Dhar and Guiliani (2010) present an approach for uncovering fundamental organising principles in systems biology. Dodds (2009) has identified 36 laws in ecology to minimise the perceived complexity in interpreting ecological systems. McShea and Brandon (2010) recently proposed a detailed account for a ‘Zero Force’ evolutionary law that they believe to be to biology what Newton’s first law is to physics. These efforts demonstrate that the complexity and contingencies inherent in biological systems have not discouraged biologists and philosophers of biology from trying different approaches to generating ‘fundamental organising principles’.

To attain the ideal status of a universal law, Dhar and Guiliani (2010) believe that what biologists need to do but is difficult to attain is to construct generalisations

---

[3] The Latin *ceteris paribus* stands for ‘all things being equal’: *ceteris paribus* laws are laws that have exceptions, often contrasted with strict or ‘real’ laws (Garvey 2007).

that connect all levels from atoms to ecosystems. From their perspective, Mendel's Laws provide a reasonable framework at the phenotypic level, but an equivalent framework is absent at the cell-cell level. They believe, however, that just because this framework is currently absent does not mean it is not attainable in principle. Thus, there is optimism about the possibility of identifying powerful generalisations at the different levels of organisation (Dhar and Giuliani 2010) or developing empirical biological laws (Elgin 2006). In Elgin's (2006) view, a 'distinctively biological law' is one in which 'two conditions must be met: (1) all non-biological concepts in it must be mathematical, (2) It must contain at least some biological concepts and these concepts must be essential to its truth' (Elgin 2006, p. 130).

Other philosophers of biology take a pragmatic approach that 'replaces a definitional norm with an account of the *use* of scientific laws' (Mitchell 2000, p. 259). From Mitchell's perspective, 'the requirements for lawfulness fail to reflect the reality of scientific practice. As a consequence, the traditional understanding of laws is incomplete and fails to account for how humans have knowledge of the complexity of the world' (Mitchell 2009, p. 53). Mitchell characterises the reasons used to deny the existence of laws in biology as rooted in a normative orientation that regard laws along the Popperian tradition: 'bold, universal, exceptionless' (Mitchell 1997, p. S473). Arguing against the privileging of a very special type of generalisation that meets very stringent conditions and occurs very rarely even in physics, she affirms that 'the contingency of generalizations in biology or other sciences does not preclude their functioning as 'laws' – generalizations that ground and inform expectations in a variety of contexts' (Mitchell 1997, p. S478).

Mendel's Laws of segregation and independent assortment are popular topics for debating the nature of biological laws. Briefly stated,

> Mendel's first law, the Law of Segregation, states that while an organism may contain a pair of contrasting alleles, e.g. Tt, these will segregate (separate) during the formation of gametes, so that only one will be present in a single gamete, i.e. T or t (but not both or neither). Mendel's second law, the Law of Independent Assortment, states that the segregation of alleles for one character is completely random with respect to the segregation of alleles for other characters. (Dictionary of Botany 2003)

However, neither their highly contingent nature (Mitchell 2009) nor the historical ambiguity surrounding their ascendance from principles to laws (see Footnote 2 and Marks 2008) is adequate for demoting them to accidental generalisations. Rather than deny the existence of biological laws, it is more useful in the context of the variation inherent in biological systems to provide "a better understanding of contingency so that we can state the many ways in which laws are not always 'universal and exceptionless" (Mitchell 2009, p. 63).

37.3.1.1 The Case of Mendel's Laws in Biology Textbooks

Mendel's Laws of segregation and independent assortment are often described in biology textbooks to various levels of detail with some reference to Mendel's profile and pea-plant experiments. Inheritance is a classic topic in middle and high school biology curriculum materials. A typical chapter in one high school biology book (BSCS 2003) begins with getting students to consider similarities of features between members of different generations in families. Starting with discussions about familiar experiences, the chapter invites students to read the tragic case of haemophilia in the family of the last Czars then leads them to work on different scenarios in order to predict inheritance patterns. Next, students are engaged in simulations, using beans, to help them understand the inheritance of one and two traits. The chapter explores inherited patterns, defines gametes, describes meiosis, tracks genes and chromosomes through meiosis by guiding students to construct a physical representation that tracks the genotype of the newly divided 'cells' and addresses the role of sample size in leading to more accurate predictions. Next the book introduces Gregor Mendel and a video segment that provides data for students to use to make predictions then compare their predictions with actual results provided by the teacher. Additional exercises pertaining to linked and sex-linked traits are offered to deepen and elaborate the concepts before the chapter ends with a discussion of the genetic basis for human variation.

Of particular interest to this paper is the text book's reference to Mendel's second law. The following excerpt represents one of two occasions in which it is mentioned in one chapter: 'When you follow the inheritance of 2 traits (a di-hybrid cross), more complex patterns result. In garden peas, the genes for the traits of pod color and pod shape are on different chromosomes. As a result, their inheritance conforms to Mendel's Law of independent assortment' (BSCS 2003, p. 438). The only other significant reference to this law appears later in the book in an essay at the end of the unit. The essay discusses the concepts of phenotype and genotype and concludes with an example that demonstrates the random inheritance of traits demonstrating how a baby rabbit may inherit different genes for particular traits from the father and mother like fur colour and eye colour independently of each other. The essay concludes with the following historical narrative:

> The principle of independent assortment was discovered more than 150 years ago in a small European monastery garden. A scholarly monk named Gregor Mendel used pea plants to study patterns of inheritance. Mendel experimented with many generations of pea plants. His insights later became the cornerstone for explaining basic patterns of inheritance. (BSCS 2003, p. 499)

As seen in these excerpts, the same concept is referred to as a law in one section of the book and as principle in another. It is not clear whether the shift in language is accidental or whether it refers to the historical evolution of this idea from 'principle' at the time of its inception to 'law' in later references to this idea.[4] While inconsistency in how textbook authors use categorisations of scientific knowledge has been already

---

[4] In his review of early textbooks, Marks (2008) notes that, initially, Mendel's Law was often presented in the singular in contrast to Galton's Law of Ancestral Heredity as evident in Punnett's 1905 textbook and most other genetics textbooks of the first generation. In his 1909 book, Bateson contrasted Galton's Law against the Mendelian ''scheme', 'principles', 'phenomena', 'methods', 'analysis', 'facts''. (Marks 2008, p. 250). First references to Mendel's Law of Segregation and Law of Independent Assortment appeared in Morgan's second book in 1916 and were further detailed in his 1919 book *The Physical Basis of Heredity*.

documented (e.g. McComas 2003), noting this inconsistency in this paper underscores what appears to be confusion or lack of clarity about the purpose that this law/principle serves, as demonstrated in both excerpts. The textbook provides no further details about what the 'law' or 'principle' of independent assortment entails or the role it plays in explaining phenomena. It is stated casually as a claim that explains some observations, no different than another claim in terms of its generalisability (or lack thereof) or ability to explain or predict. It is not made explicitly clear that this generalisation can be used to explain or predict phenotypes and genotypes of new generations of siblings that go beyond the specifics of the examples discussed in the chapter.

The main issues in the examples quoted earlier are (1) the striking lack of clarification about what a law entails, (2) the unexplained switch from 'law' in the chapter to 'principle' in the historical anecdote and (3) lack of explicit reference to the relative strong explanatory power (Woodward 2001) expressed that is qualitatively and quantitatively different from other concepts presented in the textbook.

In another high school biology book (SEPUP 2011), the discussion of Mendel's work is devoid of references to laws or principles. Some 60 pages after describing the historical work of Mendel, and only in the context of discussing genes and chromosomes, there is a brief reference to one of Mendel's Laws:

> When the chromosomes line up before division, the paternal and maternal chromosomes in the pair line up randomly and separate independently of each other. This is called independent segregation of the chromosomes. Independent segregation of chromosomes explains the behavior of genes that follow Mendel's law of independent assortment. It also accounts for the fact that genes that are linked on the same chromosome don't follow the law of independent assortment…. (SEPUP 2011, p. 356)

This passage illustrates how Mendel's Law of independent assortment exerts an explanatory function. But it is the only place other than the 'Glossary' section at the end of the book where this law is identified. The apparent retreat from explicit emphasis on Mendel's Laws in both textbooks either reflects a general trend of accidental nature or an outcome of authors' awareness of the philosophical controversy about laws in biology. In both cases, avoidance of explication of the significance of laws or principles in biology in the context of a specific content, such as the one explored here, reduces the likelihood that students will understand the usefulness of this aspect of scientific knowledge relative to its explanatory function. One way to rectify this matter is by using language consistently in textbooks, clarifying what the referents mean and educating readers about the distinctive nature of laws in biology, noting their relevance to explaining observations and predicting new ones. Alternatively, teachers can problematise terms like 'laws' and 'principles' and guide the students into a discussion that addresses their meaning and significance.

37.3.2 Laws in Chemistry

Until fairly recently, the status of laws in chemistry has received little attention within philosophy of science (e.g. Cartwright 1983). With the upsurge of philosophy of chemistry in the 1990s (Erduran & Mugaloglu, this handbook), there has been more focus on what might (or not) make laws distinctly chemical in nature. Some philosophers of chemistry (e.g. Christie and Christie 2000) as well as chemical educators (e.g. Erduran 2007) have argued that there are particular aspects of laws in chemistry that differentiate them from laws in other branches of science with implications for teaching and learning in the science classroom. A topic of particular centrality and relevance for chemical education is the notion of 'Periodic Law' which is typically uncharacterised as such:

> Too often, at least in the English speaking countries, Mendeleev's work is presented in terms of the Periodic Table, and little or no mention is made of the periodic law. This leads too easily to the view (a false view, we would submit), that the Periodic Table is a sort of taxonomic scheme: a scheme that was very useful for nineteenth century chemists, but had no theoretical grounding until quantum mechanics, and notions of electronic structure came along. (Christie and Christie 2003, p. 170)

A 'law' is typically defined as 'a regularity that holds throughout the universe at all places and at all times' (Salmon et al. 1992). Some laws in chemistry like the Avogadro's Law (i.e. equal volumes of gases under identical temperature and pressure conditions will contain equal numbers of particles) are quantitative in nature while others are not. For example, laws of stoichiometry are quantitative in nature and count as laws in a strong sense. Others rely more on approximations and are difficult to specify in an algebraic fashion. As a key contributor to philosophy of chemistry, Eric Scerri (2000a) takes the position that some laws of chemistry are fundamentally different from laws in physics (Scerri 2000a). While the emphasis in physics is on mathematisation, some chemistry laws take on an approximate nature:

> The periodic law of the elements, for example, differs from typical laws in physics in that the recurrence of elements after certain intervals is only approximate. In addition, the repeat period varies as one progresses through the periodic system. These features do not render the periodic law any less lawlike, but they do suggest that the nature of laws may differ from one area of science to another. (Scerri 2000a, p. 523)

Viewed from the perspective of physics, the status of the periodic system may appear to be far from lawlike (Scerri and McIntyre 1997). Significantly, the periodic law seems not to be exact in the same sense as are laws of physics, for instance, Newton's laws of motion. Loosely expressed, the Periodic Law states that there exists a periodicity in the properties of the elements governed by certain intervals within their sequence arranged according to their atomic numbers. The crucial feature which distinguishes this form of 'law' from those found in physics is that chemical periodicity is approximate. For example, the elements sodium and potassium represent a repetition of the element lithium, which lies at the head of group I of the periodic table, but these three elements are not identical. Indeed, a vast amount of chemical knowledge is gathered by studying patterns of variation that occur within vertical columns or groups in the periodic table. Predictions which are made from the so-called periodic law do not follow deductively from a theory in the same way in which idealised predictions flow almost inevitably from physical laws, together with the assumption of certain initial conditions.

Scerri further contrasts the nature of laws in physics such as Newton's Laws of Gravitation. Even though both the Periodic Law and Newton's Laws of Gravitation have had success in terms of their predictive power, the Periodic Law is not axiomatised in mathematical terms in the way that Newton's Laws are. Part of the difference has to do with what concerns chemists versus physicists. Chemists are interested in documenting some of the trends in the chemical properties of elements in the periodic system that cannot be predicted even from accounts that are available through contributions of quantum mechanics to chemistry. Christie and Christie (2000), on the other hand, argue that the laws of chemistry are fundamentally different from the laws of physics because they describe fundamentally different kinds of physical systems. For instance, Newton's Laws described above are strict statements about the world, which are universally true. However, the Periodic Law consists of many exceptions in terms of the regularities demonstrated in the properties and behaviours of elements. Yet, for the chemist there is a certain idealisation about how, for the most part, elements will behave under particular conditions. In contrast to Scerri (2000a) and Christie and Christie (2000), Vihalemm (2003) argues that all laws need to be treated homogeneously because all laws are idealisations regardless of whether or not they can be axiomatised. van Brakel further questions the assumptions about the criteria for establishing 'laws':

> If one applies "strict" criteria, there are no chemical laws. That much is obvious. The standard assumption has been that there are strict laws in physics, but that assumption is possibly mistaken . . . Perhaps chemistry may yet provide a more realistic illustration of an empirical science than physics has hitherto done. (van Brakel 1999, p. 141)

Christie and Christie (2000) indicate that taking physics as a paradigmatic science, philosophers have established a set of criteria for a 'law statement', which 'had to be a proposition that (1) was universally quantified, (2) was true, (3) was contingent, and (4) contained only non-local empirical predicates' (p. 35). These authors further argue that such a physics-based account is too narrow and applies only to simple systems. More complex empirical sciences do not necessarily conform to such accounts of laws:

> The peculiar character of chemical laws and theories is not specific to chemistry. Interesting parallels may be found with laws and theories in other branches of science that deal with complex systems and that stand in similar relations to physics as does chemistry. Materials science, geophysics, and meteorology are examples of such fields. (Christie and Christie 2000, p. 36)

The debates around the nature of laws in chemistry are ongoing and it is beyond the scope of this paper to contribute to this debate. However, it is important to problematise the complexity in the ways that philosophers of chemistry dispute the nature of chemical knowledge at large and the nature of laws in particular.

In summary, the suggestion offered by Christie (1994) is considered useful:

> Ultimately the best policy is to define 'laws of nature' in such a way as to include most or all of the very diverse dicta that scientists have chosen to regard as laws of their various branches of science. If this is done, we will find that there is not a particular character that one can associate with a law of nature. (Christie 1994, p. 629)

37.3.2.1 The Case of Periodic Law in Chemistry Textbooks

This section describes a case study of how a typical textbook covers the Periodic Table and how the discussion on the nature of the Periodic Law from a philosophical perspective could inform textbook revision. The purpose of this example is to illustrate how the philosophical dimensions of chemistry can be better captured in textbooks so as to ensure understanding of the epistemological aspects of chemistry. The coverage of the Periodic Table in chemistry textbooks has been highlighted to be problematic from a range of perspectives. For instance, Brito and colleagues (2005) argue that the important distinction of accommodation versus prediction in the context of Periodic Table is not covered in chemistry textbooks. In *A Natural Approach to Chemistry*, a textbook that is in current use in secondary schools in the USA, Hsu and associates (2010) dedicate a whole 31-page chapter to 'Elements and the Periodic Table'. The chapter begins with a section on the origin of elements in the universe. There are numerous occasions where the discussion on elements is linked to everyday contexts including the nature of metals on the hull of a boat, the human body and nutrition. A significant portion of the chapter is dedicated to the discussion on electronegativity, ionisation energy, the groups and series in the Periodic Table and an explanation of why compounds form using the Lewis dot notation. The chapter concludes with a set of open-ended and multiple-choice questions.

The coverage of the Periodic Table does mention the notion of patterns but not laws. In the section describing the development of the Periodic Table and the contributions of Dimitri Mendeleev, the authors state that he *'was trying to figure out if there was any kind of organisation to the elements, some kind of pattern he could use to help organize them in a logical way*' (p. 171). This reference is in contrast to the earlier discussion about the approximate nature of the Periodic Law. Indeed, predictions which are made from the so-called Periodic Law do not follow deductively from a theory in the same way in which idealised predictions flow almost inevitably from physical laws. In this respect, the reference to a 'logical way' in the textbook can be misleading in communicating the approximate nature of periodicity. The characterisation of the word 'periodic' is equally devoid of any specification of the approximate nature of the pattern: *'The Periodic Table is named for this because the rows are organised by repeated patterns found in both the atomic structure and the properties of the elements'* (p. 171). The explanation of the Periodic Table in terms of the atomic theory further stresses the logical ordering that the authors are emphasising throughout the text. In the discussion on the Modern Periodic Table, the authors state the following:

> At the time of Mendeleev, nothing was known about the internal structure of atoms. Protons were not yet discovered so the more logical ordering by atomic number was not possible. Today's table includes many more elements, and is ordered not by atomic mass, but by atomic number. However two things are still true of the periodic table, each column represents a group of elements with similar chemical properties, and each row (or period) marks the beginning of some repeated pattern of physical and chemical properties. While elements can be broadly categorized into metals, non-metals, and metalloids, an understanding that

> each column has similar chemical properties had lead to names for some of these element groups. (Hsu et al. 2010, p. 175)

What follows is the quantum mechanical models and the use of orbitals in explaining the organisation of the groups of elements. Considerable discussion is dedicated to establishing the role of valency in explaining periodicity including the introduction of the Lewis dot diagrams. The coverage of this textbook in terms of the viewing of the Periodic Table as a taxonomical tool and a scheme without any explicit emphasis on the character of periodicity as a lawlike feature of chemistry is consistent with observations of Christie and Christie (2003) mentioned earlier.

In his critique of Atkins' chemistry textbook coverage of quantum mechanical explanations, Scerri (1999) highlights a tendency among chemistry textbook writers to ignore the irregularities in the patterns in the Periodic Table:

> One is tempted to protest that in fact the proffered explanation does indeed require a new principle, namely the strange notion whereby the d- and f-subshells do not need to be complete for the shell itself to be classified as complete./…/Surely it would not have detracted from the triumph of science to admit at this point, or anywhere in the book, that the assignment of electrons to particular orbitals is an approximation. In fact, Atkins could have made his story of the Periodic Kingdom all the more interesting if he had stated that even though his discussion was based around an approximate concept, we are still able to use it to remarkable effect to explain so many macroscopic and microscopic features connected with trends in the periodic table. (Scerri 1999, p. 302)

When the textbooks do cover the peculiarities, they are left undiscussed, as exemplified in the textbook mentioned earlier. Consider, for instance, the following excerpt:

> The transition metals illustrate a peculiar fact: the 3d orbitals have higher energy than the 4 s orbitals!/../Energy is the real, physical quantity that determines how the electrons act in atoms. The real energy levels correspond to the rows of the periodic table. The quantum number is an important mathematical construction, but is not the same as the energy level. (Hsu et al. 2010, p. 179)

Here there is a missed opportunity to raise some philosophical insights into the role of empirical evidence in model building in contrast to the mathematical and theoretical grounds for quantum mechanical models in chemistry. Scerri highlights this issue by inviting textbook writers to consider the grounds on which orbital models are related to periodicity:

> In addition, the failure to provide an adequate explanation of the 4 s/3d question or a deductive explanation of the precise places where the elements appear to 'recur' should give us and Atkins grounds for suspecting that this model is not even all that empirically adequate. (Scerri 1999, p. 303)

So what would a revised chemistry textbook look like in light of this discussion so far? There are at least two issues that this coverage of the nature of the Periodic Law raises for consideration in textbook writing. First, the textbooks should elicit the approximate nature of the Periodic Law and specify the reference to the patterns in periodicity as an instance of law while highlighting the difference of interpretations of law in different branches of science. Second, the juxtaposition of the empirical versus theoretical dimensions of the orbital models should be teased out to clarify the different epistemological status of the Periodic Table in light of its historical and empirical foundation versus the incorporation of theoretical and mathematical characterisations since the advance of quantum mechanical models. Erduran (2007) has proposed that an argumentation framework could offer a useful pedagogical strategy for eliciting different characterisations of laws and suggested a potential activity could be structured as follows:

Claim 1: The Periodic Law and the law of gravitation are similar in nature. The term 'law' can be used with the same meaning for both of them.
Claim 2: The Periodic Law and the law of gravitation are different in nature. The term 'law' cannot be used with the same meaning for both of them.

These claims could be presented with evidence that would support either claim, both or neither. For example, the statement 'a law is a generalisation' could support both claims while 'the periodic law cannot be expressed as an algebraic formula while the law of gravitation can be' could support the second claim. The task for the students would be to argue for either claim and justify their reasoning. Further statements can be developed that would act as evidence for either, both or neither claim.

The inclusion of a framework that simulates the philosophical debate on the nature of laws in a comparative context between physics and chemistry will carry into the classroom the ways in which philosophers have conceptualised the nature of this particular aspect of scientific knowledge in these domains. Without a sense of a debate, textbooks reinforce the 'received view' of science that projects a perception of a consensus when there is none. In summary, the inclusion of meta-perspectives offered by philosophical accounts of laws can provide insights into textbook accounts of laws whereby the particular nuances of chemical knowledge are better framed in terms of consistency with epistemological accounts on chemical knowledge.

37.4 The Nature of Explanation in Biology and Chemistry

37.4.1 Explanation in Biology

Explanation in biology differs from explanation in physics in that it does not aim to provide the typical 'necessary and sufficient conditions'. Instead biological explanations aim to 'gain partial, but ever increasing insights into the causal workings of various *life processes*' (Brigandt 2011, p. 262). Mayr's (1961) distinction between proximate explanation and ultimate explanation provides a basic dichotomy between at least two ways of explaining biological systems. In asking about how a phenomenon happens, the proximate explanation would address physiological or other processes that underlie the cause, while the ultimate explanation would address the phenomenon based on the organism's evolutionary history. The explanations do not contradict but rather complement each other by adding a different dimension: one causal and another historical.

Further expansion of explanatory breadth can be found in Tinbergen's (1952, cited in Sterelny and Griffiths 1999) four explanatory projects in biology, according to which it is possible to address questions about any behaviour by proposing 4 different explanations: proximal, developmental, adaptive and evolutionary:

> Tinbergen distinguished four questions we could have in mind in asking why a bittern stands still with its bill pointed directly at the sky. (1) We could be asking for a *proximal* explanation: an explanation of the hormonal and neural mechanisms involved in triggering and controlling this behavior. (2) We could be asking for a *developmental* explanation: an explanation of how this behavior pattern emerges in a young bittern. (3) We could be asking for an *adaptive* explanation: an account, that is, of the role this behavior currently plays in the bittern's life. (4) Finally, we could be asking for an explanation of how and why this behavior evolved in this bittern and in its ancestors. (Sterelny and Griffiths 1999, p. 50)

Press (2009) suggests that one of the ways in which philosophers contrast physics and biology is by appealing to differences between their respective explanations as they relate to the covering law model. He describes divergent views among philosophers of biology, as represented by Sober, Kitcher and Rosenberg regarding the applicability of the covering-law model in the context of biological explanations. After analysing the different positions, Press (2009) concludes that there is a good fit between Hempel's covering law model and biological explanations, stating that 'the differences between biological and physical explanations are merely a matter of degree. …. biologists, who deal with extremely complex systems, will need to rely relatively heavily on various sorts of approximation if they are to explain anything at all' (Press 2009, p. 374).

Branching off of these distinctions, philosophers of biology have detailed a number of explanatory types that support the aim of gaining insights about the 'causal workings' of biological systems without limiting their discussion to causal explanations. Wouters (1995), for example, outlines five different types of explanation: Physiological, Capacity, Developmental, Viability and Historical/Evolutionary. These different types of explanation approach the same phenomena from different perspectives. To explain the circulatory system of a given organism, for example, Wouters argues that physiological explanations focus on the types of events in the individual organism's life history, whereas a capacity explanation focuses on underlying causal explanations having to do with the structure of the heart and valves. A developmental explanation would focus on the development of the system (heart and vessels), while a viability explanation would focus on why structural differences between systems occur in different organisms. Finally, an evolutionary explanation would focus on differences in systems between organisms in the same lineage.

More recently, Wouters (2007) has proposed a sixth type, design explanation, in which a system in a real organism might be compared to a hypothetical one. Calcott (2009) makes the case for an additional type of explanation that he names lineage explanation. This type of explanation aims to make plausible a series of incremental changes that lead to evolutionary change, focusing on a sequence of mechanisms that lead to the successive changes. Lineage explanations 'show how small changes between ancestral and derived mechanisms could have produced different behavior, physiology and morphology' (Calcott 2009, p. 74). Consequently, they provide an additional 'explanatory pattern' to account for evolutionary change.

Rose (2004) offers a fable that supports the discussion of how biological systems can sustain a variety of explanations. In this fable, five biologists are having a picnic when they noticed a frog jump into a nearby pond. Posing the question of what caused it to do so led to five different answers. The physiologist reasoned that impulses travelled from its retina to the brain and then to the leg muscles. The biochemist pointed out the properties of the proteins, actin and myosin, whose fibrous nature enable them to move in a predictable way. The developmental biologist attributed it to the ontogenetic processes that occurred during early stages of cell division. The animal behaviourist attributed the cause to the snake that was lurking by, whereas the evolutionist discussed the role of natural selection in favouring those frogs that escaped their prey due to their ability to detect them quickly and move fast in response, allowing them to survive and reproduce.

Of course, the question of legitimacy of teleological explanation in biology is important because of historical and pedagogical reasons. This is because attributing purpose to non-purposeful things or events or attributing human qualities to nonhumans can lead to questioning the credibility of the proposed explanation. The human tendency to assign purpose to everything seems to be nourished by the 'sheer efficiency of biological structures [which] reinforces the illusion of purpose' (Hanke 2004, p. 145). Use by some biologists in a metaphorical sense makes these explanations likely to be misunderstood by non-experts, especially in educational settings. Some philosophers of biology differ in their degree of opposition to the use of these explanations—perhaps because they are well aware of their semantic affordances and limitations. Few philosophers strongly object to their use as expressed in Hanke's (2004) viewpoint that teleology is 'bad not so much because it's lazy and wrong (which it is) but because it is a straightjacket for the mind, restricting truly creative scientific thinking' (p. 155).

The philosophical debates around these ideas have implications for educational settings but empirical findings can assist in making informed judgments regarding their use in educational contexts. Some science educators have cautioned against the use of anthropomorphic and teleological explanations in biology teaching out of concern for engendering misconceptions that can interfere with learning (Jungwirth 1979). However, a recent study called for the 'removal of the taboo' regarding teleological and anthropomorphic explanations, arguing that results of an empirical cognitive study has shown that high school students' use of anthropomorphic or teleological explanations is not indicative of teleological reasoning but seems to serve a heuristic value for learning as gleaned from the students' perspective (Zohar and Ginossar 1998).

The range of explanations described by Wouters (1995, 2007), Calcott (2009) and Rose (2004) illustrates the significance of invoking a diverse set of explanations for providing more comprehensive understanding of biological systems. Perhaps one of the overarching attributes of biological explanations is the notion of consilience in which different explanations need not be subsumed under one another and need not contradict with one another. The notion of consilience attributed to Wilson by Rose (2004) can perhaps be viewed as a pragmatic adaptation of the notion of 'consilience of inductions' developed by Whewell in his *Novum Organon Renovatum* (Morrison 2000). The diversity of explanatory types in biology is perhaps reflective of the 'epistemological pluralism' (Rose 2004, p. 129) that is characteristic of the study of biological systems. This diversity is often obscured in biology education, not because it is difficult to communicate, but mostly due to the way the school biology curriculum is chopped up and structured in ways that limit reference at a given point in time to one or two explanatory emphases. This in turn limits teachers' and students' ability to experience the value of epistemological pluralism as a powerful vehicle for explaining and understanding phenomena in the life sciences.

37.4.1.1 Explanation in Biology Textbooks

Topics typically covered in high school biology textbooks in the United States include evolution, genetics, cell biology and ecology. The approach to explicating these topics and the order in which they are presented varies significantly from one publisher to another.[5] For example, in the SEPUP (2011) book, the ecology unit, typically presented in other books as the last unit, is second to a first unit on sustainability, a topic rarely addressed so explicitly in biology textbooks. However, explanations in the three textbooks consulted (see footnote) are similar to one another in that they are not differentiated from the rest of the text, but are blended in the narrative, becoming rather 'invisible'. The explanations follow the topical narrative, but there is no discernible attempt to provide a broader synthesis, weave cross-topical themes, or illustrate the notion of explanatory consilience.

37.4.2 Explanation in Chemistry

In the *Stanford Encyclopedia of Philosophy*, Weisberg and colleagues (2011) review the recent developments in the formulation of chemical explanations. These authors state that from the nineteenth century onwards, chemistry was commonly taught and studied with physical models of molecular structure. Beginning in the twentieth century, mathematical models based on classical and quantum mechanics were applied to chemical systems. The use of molecular models has helped chemists to understand the significance of molecular shape (Brock 2000) and aided visual representation of structure and function of matter. One of the key scientific achievements of the twentieth century, the discovery of the double helical structure of DNA,

---

[5] The three textbooks reviewed in this section are BSCS (2003), Campbell et al. (2009), and SEPUP (2011).

was possible because of the use of physical models as explanatory tools (Watson 1968). The focus of chemical explanations entered a new phase with the advent of quantum mechanical theories and their applications in chemistry. The notion of 'explanation' in chemistry has centred in key debates involving not only models but also philosophical themes such as supervenience and reduction (Earley 2003) which will be referenced briefly later in the paper.

According to Weisberg and colleagues (2011), while exact solutions to the quantum mechanical descriptions of chemical phenomena have not been achieved, advances in theoretical physics, applied mathematics and computation have made it possible to calculate the chemical properties of many molecules very accurately and with few idealisations. This perspective is in contrast to those chemists who argue for employing simple, more highly idealised models in chemistry, which stem from the explanatory traditions of chemistry. In developing this point, Hoffmann illustrates two modes of explanation that can be directed at chemical systems: horizontal and vertical (Hoffman 1998). Vertical explanations are what philosophers of science call 'deductive-nomological explanations'. These explain a chemical phenomenon by deriving its occurrence from quantum mechanics. Calculations in quantum chemistry are often used to make predictions, but insofar as they are taken to explain chemical phenomena, they follow this pattern. By showing that a molecular structure is stable, the quantum chemist is reasoning that this structure was to be expected given the underlying physics.

In contrast to the vertical mode, the horizontal mode of explanation attempts to explain chemical phenomena with chemical concepts. For example, Weisberg and colleagues (2011) use the example of SN_2 reactions as an example of horizontal explanations. The first year organic chemistry curricula include the relative reaction rates of different substrates undergoing SN_2 reactions. They state that an organic chemist might ask 'Why does methyl bromide undergo the SN_2 reaction faster than methyl chloride?' One answer is that 'the leaving group Br^- is a weaker base than Cl^-, and all things being equal, weaker bases are better leaving groups'. This explains a chemical reaction by appealing to a chemical property, in this case, the weakness of bases. Vertical explanations demonstrate that chemical phenomena can be derived from quantum mechanics. They show that, given the (approximate) truth of quantum mechanics, the phenomenon observed had to have happened. Horizontal explanations are especially good for comparing and contrasting explanations, which allow the explanation of trends. In the above example, by appealing to the weakness of Br^- as a base, the chemist invokes a chemical property. This allows the chemist to explain methyl bromide's reactivity as compared to methyl chloride, and also methyl fluoride, methyl iodide and so on. Insofar as chemists want to explain trends, they make contrastive explanations using chemical concepts.

Apart from Hoffmann, earlier chemists argued that the nature of chemical explanations need not be overshadowed by quantum mechanical and reductive approaches. Consider, for instance, the perspective taken by Coulson:

> The role of quantum chemistry is to understand these concepts and show what are the essential features in chemical behavior. [Chemists] are anxious to be told … why the H–F

> bond is so strong, when the F–F bond is so weak. They are content to let spectroscopists or physical chemists make the measurements; they expect from the quantum mechanician that he will explain why the difference exists. … So the explanation must not be that the computer shows that [the bonds are of different length], since this is not an explanation at all, but merely a confirmation of experiment. (Coulson 1960)

Although both Coulson (1960) and Hoffmann (1998) defend the use of simple, idealised models to generate horizontal explanations, it is not clear that quantum calculations can never generate contrastive explanations (Weisberg et al. 2011). Although single vertical explanations are not contrastive, a theorist can conduct multiple calculations and, in so doing, generate the information needed to make contrastive explanations. However, the status of quantum mechanical explanations in chemistry is likely to be challenged for some time yet to come given the history of chemists' position on this issue. For example, Brown (2003) has drawn from cognitive sciences to illustrate that chemical explanations are metaphorical in nature and have a character that is distinguishable from representations employed in other fields of science: '…data are not explanatory in themselves. For the chemist to make effective use of powerful computational resources there must still be an underlying metaphorical model of what is happening in the conventional (chemical) sense' (p. 216). Even though chemical explanations involve the use of models and modelling (Erduran 2001), the meaning of the term 'model' or its function is not so straightforward particularly in relation to its import in chemical education. The presence of models in different disciplines related to chemical education, such as cognitive psychology and philosophy of science, makes it even more difficult to come up with a single definition for the term 'model' (Erduran and Duschl 2004).

A particular approach to chemical explanations includes the reference to 'structural explanations' (Harré 2003). Goodwin (2008) explains that in organic chemistry, the phenomena are explained by using diagrams instead of mathematical equations and laws. In that respect, the field of organic chemistry poses a difference in terms of the content of explanations from those in other physical sciences. Goodwin investigates both the nature of diagrams employed in organic chemistry and how these diagrams are used in the explanations. The diagrams particularly mentioned are structural formulas and potential energy diagrams. Structural formulas are two-dimensional arrangements of a fixed alphabet of signs. This alphabet includes letters, dots and lines of various sorts. Letters are used as atomic symbols, dots are used as individual electrons, and lines are used as signs for chemical bonds.

Structural formulas in organic chemistry are mainly used as descriptive names for the chemical kinds. Thus, a structural formula has a descriptive content consisting of a specification of composition, connectivity and some aspects of three-dimensional arrangement. Structural formulas are also used as models in organic chemistry. For example, a ball and stick model is used in explanations. After characterising some features of structural formulas, Goodwin presents a framework of explanations in organic chemistry and describes how both structural formulas and potential energy diagrams contribute to these explanations. Then he gives the examples of 'strain' and 'hyperconjugation' to support his idea about the role of diagrams in capturing the nuances of explanations through structures in organic chemistry.

Debates on reduction—i.e. 'reduction of axioms or laws of one science to the axioms and laws of a deeper putative science' (Scerri 2000b, p. 407)—have taken chemical explanations to its core in understanding what makes an explanation 'chemical'. Similar debates on reductionism have centred on issues related to philosophy of mind, particularly in the context of Multiple Realisability (e.g. Fodor 1974). Educational applications of such debates have been promoted though not yet realised at the level of schooling (e.g. Erduran 2005). One aspect of this debate has concerned the notion of supervenience. Two macroscopic systems that have been constructed from identical microscopic components are assumed to show identical macroscopic properties, whereas the observation of identical macroscopic properties in any two systems need not necessarily imply identity at the microscopic level. Chemical explanations have often been regarded as including microscopic, macroscopic and symbolic dimensions (e.g. Jacob 2001). The main position promoted in this debate is that the asymmetry in the way that properties and kinds of chemical entities are conceptualised suggests that chemical explanations cannot necessarily be reduced to explanations of physics—a realm of epistemology—even if ontologically chemistry might be reliant on physical principles.

37.4.2.1 Explanation in Chemistry Textbooks

Kaya and Erduran (2013) believe that structural explanations as discussed by Goodwin (2008) have relevance for chemistry textbooks. In their study of secondary chemistry textbooks across grade levels, they noted, for example, that for the 9th grade textbooks, topics such as 'development of chemistry', 'compounds', 'chemical changes', 'mixtures' and 'chemistry in our life' all included structural explanations. Similar ways of coverage are noted in the textbook by Hsu and colleagues (2010). In the chapter on organic chemistry, for example, there are sections that illustrate and define 'structural isomers'. The Appendix depicts the textbook reference to structural isomers of 2-pentane and isopentane. The description is 'When a molecule has the same number and type of atoms, but a different bonding pattern, it is a structural isomer' (p. 541). The rest of the text is similar in terms of providing definitions for the characterisation of isomers. There are two types of representations that are both two-dimensional but one represents the C and H atom balls, while the other does not. In this sense, there is potential for confusion for what counts as 'structure' when different levels of representations are superimposed.

37.4.3 Summary

This paper focused on the context, the definitions and the types of laws and explanations in biology and chemistry and described some emphases and patterns that illustrate a number of similarities and differences between biological and chemical laws and explanations. For example, when the types of explanation in chemistry and biology are contrasted, the result is a diversity of types that are distinctive to the science in question. While biological explanations include viability and developmental explanations that draw closely from the nature of biological content, chemical explanations focus on the structural and representational explanations that are based on either quantum mechanical or simple chemical models. The context of debates around the nature of biological and chemical laws and explanations are also rather particular. Whereas reference to principles is common in biologists' discussions of laws, the chemists are preoccupied with questions regarding axiomatisation and approximation.

37.5 Implications for Biology and Chemistry Education

This section provides some suggestions for how biology and chemistry education can be informed by investigations into the nature of laws and explanations. It illustrates the implications of the preceding discussion for teaching, curriculum and learning in biology and chemistry education. Design of instructional activities can exemplify more explicitly the role that variation and chance play in biological systems and enable students to explore the contribution of this uniqueness to shaping the formulation of biology's 'laws' or principles. Awareness of the function of generalisations and principles in biology allows students to appreciate their role in the construction of biological knowledge and enables them to realise that the scarcity of 'laws' does not diminish the 'power' of the generalisations/principles they study or reduce the status of biology to a 'soft science'.

In terms of chemistry teaching, the goals of teaching could include the broader aims of promoting students' understanding of how some chemical laws like the Periodic Law are generated and how they differ from laws in chemistry or other sciences. Lesson activities could acknowledge the observation that, for instance, the Periodic Law will be manifest in the classroom via comparative discussions about the trends in the chemical and physical properties of elements. Furthermore, engaging students in the process of the derivation of some of these trends is likely to give them a sense of how laws are generated and refined in chemistry. How can such discussions of laws, then, be manifested in the classroom? Earlier work has identified strategies such as questioning and discussion in chemistry teaching (Erduran 2007) that can be extended to biology teaching due to their broad pedagogical scope. For example, students could be presented with alternative accounts of scientific laws—those derived deductively and those that are derived with approximation and induction in mind—and asked to question, compare, evaluate and discuss them in relation to other products of scientific knowledge.

This review also has implications for the design of curricula for the inclusion of biological and chemical content knowledge. With respect to biology, curriculum materials should attempt to communicate more explicitly elements of 'epistemological pluralism' and how biologists search for consilience among a proposed family of explanations. Including these ideas in the curriculum should not be limited to presenting isolated narratives about how biologists work but should be reflected in developing more integrated and coherent content frameworks. This is necessary for promoting a more holistic and contextual understanding of structures and processes in biotic systems. Even though the chemistry curriculum typically covers structural explanations as described by Goodwin (2008) across various levels of schooling, the meta-perspectives on the nuances of these explanations are not typically part of either curriculum materials or textbooks (Kaya and Erduran 2013).

The discussion about the power and limits of biological and chemical laws can be initiated in curriculum resources by focusing more explicitly on what Mendel's Laws or the Periodic Law do and fail to do. Curricula and textbooks tend to cover laws in quite an ambiguous and limited manner (i.e. McComas 2003) and often present laws in different science fields on equal footing. That is, when certain generalisations are labelled as laws, textbook authors do not contextualise or explore what that label means. From the point of view of a teacher or student, a law in physics (e.g. Newton's) carries the same epistemic and ontological significance as a law in biology (e.g. Mendel's) or chemistry (e.g. Periodic). In some cases, neither Mendel's Law nor the Periodic law is introduced as laws, and consequently an opportunity to discuss the implications of these terms is lost. A study of Turkish chemistry curricula and textbooks, for example, revealed that there is little or no differentiation of the meta-perspectives on the nature of knowledge (Kaya and Erduran 2013). Other studies on textbooks (e.g. Niaz and Rodríguez 2005) point to the lack of attention to NOS features in general, let alone the nuanced distinctions addressed here. Understanding the relationship of laws and explanations to theories in biology and chemistry demands a deliberate undertaking from historical and contemporary perspectives.

Furthermore, chemistry curricula often contain conceptual mistakes and thus demand closer examination. For example, the notion 'one molecule, one shape' is widespread and results in students' construction of a misconception where molecules are static, not oscillating and taking on different shapes (Kaya and Erduran 2013). The dynamic nature of molecular shape is an inherent aspect of chemical explanations. Coverage of structural explanations with meta-level perspectives is likely to minimise misconceptions about the dynamic nature of molecules. Chemistry curricula also need to scaffold students' understanding of how chemical explanations can rest on structural models and how these differ from, for instance, historical or evolutionary explanations in biology. Design of instructional activities would, then, need to acknowledge the observation that explanations will be manifest in the classroom via discussions of the signs and symbols that make up the alphabet of structures represented in chemistry. Engaging students in the generation, evaluation and application of structural explanations in chemistry is likely to improve their understanding of how chemical language and explanation relate to each other.

There are important reasons for why biology and chemistry learning should be informed by the issues raised in the paper. Familiarising students with different *types* of explanation in biology may mitigate against straying into teleological sidetracks, favouring the capacity/causal type, or privileging some types of explanation over others (those dealing with the how over those dealing with the why). The tendency of students to favour experimental over historical explanations, for example, has been documented in the context of evolutionary theory (see, for example, Dagher and BouJaoude 2005). Thus, biology learning could focus on constructing and utilising a broad range of biological explanations for a given phenomenon and applying this kind of reasoning to multiple contexts/phenomena. In support of this kind of learning, there needs to be a restructuring of the content/curriculum, so that explanations addressing different aspects of the phenomenon under study are not isolated from each other as is typically the case (e.g. evolutionary and ecological concepts are rarely discussed in relation to each other or to physiological concepts in school science). With respect to chemistry learning, the articulation of structural explanations with meta-level perspectives is likely to assist in understanding the dynamic nature of molecules. As discussed earlier, a common problem in chemical education concerns the interpretation of molecular models and straying onto static notions of molecular structures as sidetrack in learning outcomes. Given the centrality of molecular structure and modelling in chemistry, improvement in the learning of the structural explanations is likely to have positive impact on understanding other related areas of chemistry.

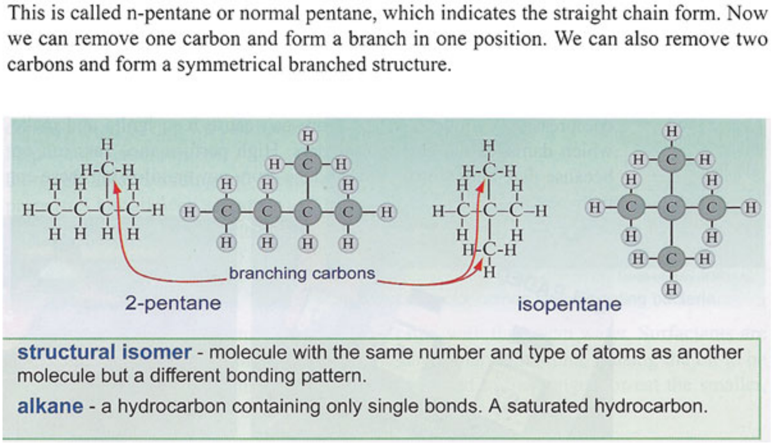
37.6 Conclusion

In summary, the aspects of laws and explanations in biology and chemistry emphasised in this paper are not exhaustive but are representative of the types of issues that concern us as science educators interested in improving students' understanding of science. This understanding will be enriched if students are provided multiple opportunities to develop meta-level understanding of how particular domains of science engage with some of the key aspects of scientific knowledge such as laws and explanations. There has been a long-standing criticism of science education in failing to enable students to understand the nature of science, scientific knowledge and scientific knowledge development. While science educators have acknowledged that perspectives from history and philosophy of science can promote a deeper understanding of the nature of science, the role of the nature of disciplinary knowledge has been under-investigated within the science education research community. The aim of this chapter was to articulate the nature of laws and explanations in biology and chemistry so as to extend and enrich the previous agendas for teaching the nature of science using domain-specific epistemologies to describe key debates and features related to disciplinary knowledge. Further research in this area is needed to further clarify, refine, challenge and expand some of the claims presented in this paper.

Acknowledgements The authors wish to thank the five anonymous referees who provided valuable feedback on earlier versions of this chapter.

Appendix

Source of potential confusion about structural explanations in a high school chemistry textbook (Reproduced from Hsu et al. 2010, p. 541).



This is called n-pentane or normal pentane, which indicates the straight chain form. Now we can remove one carbon and form a branch in one position. We can also remove two carbons and form a symmetrical branched structure.

structural isomer - molecule with the same number and type of atoms as another molecule but a different bonding pattern.

alkane - a hydrocarbon containing only single bonds. A saturated hydrocarbon.

Zoubeida R. Dagher is Professor at the School of Education, and a Faculty Fellow at the Center for Science, Ethics & Public Policy at the University of Delaware. She serves currently as President Elect of the International History and Philosophy of Science Teaching (IHPST) Group. She has been a Visiting Scholar at Curtin University of Technology, Perth, Australia, and the Lebanese University and the American University of Beirut in Lebanon. She also served as Deputy Dean in 2007–2008 at the College of Education at Qatar University, Qatar. Dr. Dagher has served as an elected member to the Board of Directors of the National Association for Research in Science Teaching (NARST) and as member of the Advisory Council of IHPST. She has also served as member of editorial review boards in lead science education journals. Dr. Dagher received her PhD in science education from the University of Iowa, USA, and her Masters and Bachelor degrees from the American University of Beirut and the Lebanese American University, respectively. She has taught science to middle and high school students in Lebanon. Her research interests include the nature of school science inquiry and representation of scientific epistemology in science curricula. Dr. Dagher has co-edited a book (BouJaoude and Dagher 2009, Sense) on science education in Arab states. She is currently co-authoring a book to be published by Springer on the nature of science in science education with Sibel Erduran.

Sibel Erduran is Chair of STEM Education at University of Limerick, Ireland. She has had Visiting Professorships at Kristianstad University, Sweden, and Bogazici University, Turkey. She has also worked at University of Pittsburgh and King's College, University of London and University of Bristol. She is an Editor for *International Journal of Science Education*, Section Editor for *Science Education* and serves as Director on the IHPST council. Her higher education was completed in the USA at Vanderbilt (PhD Science Education & Philosophy), Cornell (MSc Food chemistry) and Northwestern (Biochemistry) Universities. She has worked as a chemistry teacher in a high school in northern Cyprus. Her research interests focus on the applications in science education of epistemic perspectives on science in general and in chemistry in particular. She has co-edited a book (Erduran, S., and Jimenez-Aleixandre 2008, Springer) on argumentation in science education, an area of research for which she has received an award from NARST. In 2013, she guest edited *Science & Education* (Volume 22 Number 7) consisting of 17 articles with the editorial entitled 'Philosophy, Chemistry and Education: An Introduction'. She is currently co-authoring a book to be published by Springer on the nature of science in science education with Zoubeida Dagher.

Chapter 38
Thought Experiments in Science and in Science Education

Mervi A. Asikainen and Pekka E. Hirvonen

38.1 Introduction

When Albert Einstein was 16, he considered the following thought experiment. He imagined chasing after a beam of light with the velocity of c. He would then catch the light wave and be moving with it and the light wave would seem to be frozen. Einstein noted both his experiences and Maxwell's electromagnetic theory, which suggests that such a stationary wave does not exist. In addition, he noted that if an observer were to see him riding on a light wave with a velocity of c, Einstein himself would not be able to observe the velocity.

This example illustrates the essence of a thought experiment.[1] The thought experiment describes an imaginary, hypothetical situation. The thought experiment cannot always be performed as a physical experiment, in this particular case, because it is impossible for such a massive object (Einstein) to have the velocity of c. In several respects, however, the thought experiment resembles a physical experiment. Its premise of c as the velocity of light is an empirically measured theoretical result using Maxwell's theory of electromagnetism as a starting point. It rests on the hypothesis of riding a light wave, which inevitably fails as a result of the empirical observations and impossibilities contained in theories associated with physics.

The purpose of what follows in this chapter is to examine the role of thought experiments in science and science education. First, different definitions of the concept of thought experiment will be discussed. Second, it will be argued that TEs form an essential part of scientific methodology, a special case of scientific experimentation. Third, attention will be paid to the role played by TEs in the

---

[1] A scientific experiment can be either a thought experiment performed in thought or a physical experiment performed in the laboratory.

development of scientific theories. Subsequently, attention will also be paid to the pedagogical benefits of the use of thought experiments in science learning and the reported studies on the use of thought experiments in science teaching. It will be argued that, as a result of the various benefits of TEs, their use should be increased in science teaching. Finally, our discussion will focus on the challenges posed by TEs in the teaching and learning of science.

38.2 Descriptions of the Concept of the Thought Experiment

Thought experiments have a long history, starting from the time of pre-Socratics (Rescher 1991; Brown and Fehige 2010). It has been argued that during the Middle Ages, thought experimenting was one of the main methods used in science (King 1991). In the seventeenth century, Galileo Galilei and Isaac Newton used thought experiments (TEs) as part of their scientific methodology.[2] The rise of relativity and quantum physics would not have been possible without thought experiments, and famous thought experimenters include Niels Bohr, Erwin Schrödinger, and Albert Einstein (Brown 1986; Matthews 1988; Zeilinger 1999).

Modern science philosophers and scientists have attempted to frame a general description of the concept of thought experiment (TE). Roy A. Sorensen (1992) sees TEs in a broad light: the only difference between an actual experiment and a thought experiment is that a thought experiment attempts to achieve its aim without the benefit of actual implementation. However, as Galili (2009) has criticised, Sorensen's definition of an experiment goes beyond the realm of science. According to Sorensen, a scientific experiment is “a procedure for answering or raising questions about the relationship between variables by varying one (or more) of them and tracking any response by the other or others”. Galili states that physical experiments are based on certain theoretical assertions and this is how TEs are also used in science.

Sören Häggqvist (1996) claims that philosophers and scientists often see TEs as something different from “genuine”, “actual”, or “real” experiments but rather as or a species of experiments similar to “laboratory experiments” or “cyclotron experiments”. He characterises a TE loosely as an experiment that aspires to test some hypothesis or theory: it is performed in thought, but paper or pencil, encyclopedias, or computers may also be used (Häggqvist 1996, p. 15).

According to Irvine (1991, pp. 158–159), TEs have to possess at least several, if not all, of the characteristics of a scientific experiment. This means that not all varieties of hypothetical reasoning concerning the natural world can be considered to be TEs. A TE has to bear a special relationship both to previous empirical observations and also to the background theory of TE. A thought experiment cannot ever

---

[2] See, e.g. Newton (1728), Newton (1863), Gendler (1998), Palmieri (2003), Palmier (2005), Hall (2000), and Norton (1991).

replace observations or a physical experiment because a thought experiment rests on auxiliary presuppositions considered to be true but whose failure changes the result of the thought experiment per se.

Nancy Nersessian's view of TEs differs slightly from the views presented above in that she sees a TE as a mental model that enables the dissemination of a possible physical event that is often unrealisable in one's imagination (Nersessian 1989, p. 175). Nersessian claims that Galilei, for instance, acted in this way in the case of his TE concerned with falling bodies. According to Nersessian (1992, p. 27), mental simulation is needed for a thought experiment to be both thought and experimental. The original scientific thought experiment is executed by a scientist who imagines a sequence of events and constructs a mental model. Then she/he constructs it in a narrative form in order to describe the thought experiment to others.[3]

Nersessian's view is fascinating because it makes a connection between thought experiments and mental models. On the other hand, the connection makes her definition somewhat complicated because there is no consensus about how individuals possess their knowledge. Is it in form of models (Nersessian 1989, 1992; Nersessian and Patton 2009), "in pieces" (di Sessa et al. 2004; diSessa and Sherin 1998; diSessa 2002), or as coherent and organised naive theories related to particular topics (Vosniadou 1994; Vosniadou et al. 2008)? Some researchers even think that a mental model is an individual's inner, private model that cannot be expressed exactly; when an individual presents his/her model to an audience, the model is not a mental model but *an expressed model* (Gilbert et al. 1998).

Having analysed several definitions of thought experiment, Igal Galili proposes the following definition: "Thought experiment is a set of hypothetico-deductive considerations regarding phenomena in the world of real objects, drawing on a certain theory (principle or view) that is used as a reference of validity" (Galili 2009, p. 12).

Galili's (2009) definition is not concerned with the reality existing outside scientific theories, and it also excludes a pure, formal analysis manipulating with theoretical entities without addressing the real objects. The definition includes scientific TEs that are part of the scientific process and excludes philosophical TEs. Even if we mostly agree with Galili's definition, we do not think that phenomena should be restricted to include only the world of real objects because that would exclude from the definition Maxwell's demon or hypothetical entities, for instance, whose existence cannot be verified. The definition of a thought experiment should also include a more explicit statement about its mental implementation. In sum, TEs are an essential part of scientific methodology, a special form of scientific experiments. Like other scientific experiments, they are based on a particular background theory. The main difference between physical experiments and TEs is that TEs are performed in thought. In addition, TEs can also be devised with hypothetical entities that have not yet been verified or cannot even be verified at all.

---

[3] Racher Cooper (2005) and Tamara Szabó Gendler (1998, 2004) are also supporters of this kind of mental model account.

38.3 The Role of Thought Experiments in Science

Ernst Mach and Pierre Duhem were the first to consider the value of thought experiments in science. According to Mach, thought experiments are needed because they precede physical experiments by preparing for their actual implementation (Mach 1976). Duhem's view is the opposite: he considered thought experiments useless because they cannot be presented in symbolic form and hence they cannot replace scientific experiments (Duhem 1990).

Mach (1976) stated that the possibility of a thought experiment rests on our mental images, which are more or less copies of facts. When reminiscing, we may even find new properties of the physical facts that we had not noticed previously. Our mental images are easier and faster to use than the physical facts. Thus, it can be said that thought experiments precede physical experiments and prepare for them. This means that every experimenter has to be aware of the details of the experiment before its actual implementation.

Mach thought that if thought experiments are reported sincerely, they will be true even if two thought experimenters report different sequences. In addition, errors can only occur when the results of thought experiments are compared with the physical reality. Sorensen (1992) argues that Mach's account overemphasises the subjectivity of a thought experiment. Sorensen considers that thought experiments can also be fallacious in their reporting phase.

Sorensen also argues that if a TE always precedes a physical experiment, the concept of the thought experiment has to be so wide that it covers "any kind of forethought about an experiment". He thinks that it is not normal in science to perform the full experiment in thought, but the mental processing is more like the planning stage of a physical experiment. We agree with Sorensen with regard to both of his arguments. Thought experiments conducted by two different thought experimenters can lead to different results in the first stage of TEs, and as often as not they cannot both be true. In addition, experimental scientists undoubtedly plan their physical experiments mentally, but these thoughts are frequently more like schemes of action rather than being full thought experiments.

Mach argues that in some cases, the result of a thought experiment can appear so sure and final that its implementation as a physical experiment may even seem unnecessary (Mach 1976). Duhem sees the role of thought experiments differently than Mach. He considered that thought experiments could not replace physical experiments and that they should be forbidden in science and in science teaching (Duhem 1990). Duhem alleged that only mathematical argument was precise and unambiguous, while the language of concrete observation is not: "The facts of experience, in all their native brutality, cannot be used in mathematical reasoning. To feed such reasoning they must be transformed and put into symbolic form". Duhem's view is sometimes termed sceptical objection (see Brown and Fehige 2010).

This kind of sceptical view of thought experiment is not common amongst science philosophers, but critical views of thought experiments can be found (see, e.g. Brown and Fehige 2010). Hull (1998, 2001) argues, for instance, that TEs are nothing but simple illustration and they end up persuading people; but TEs often contain deficiencies, such as incoherence and missing details. Norton (2004b) agrees with Hull over the fallibility of TEs. In addition, he claims that TEs are simply arguments, and hence they cannot offer any kind of special information that could not also be uncovered by conventional argumentation.

Cooper (2005) argues that thought experiments are needed for several reasons. Some thought experiments are practically possible to implement as physical experiments, but there may be sound reasons (ethical reasons, e.g. or the monetary expense of physical experiment) for performing them only in the mind. Other thought experiments may be impossible to implement as real experiments because they involve idealisations. Cooper (2005, p. 344) argues that Galileo's TE demonstrating that bodies continue moving with constant velocity in the absence of a force – a ball rolling in a frictionless U-bend – includes an idealisation. In science, the idealisations are often similar to the limiting case imposed by extrapolation of the results of the physical experiment. Other thought experiments may be impossible to implement as real experiments because they involve the violation of a physical law. According to Cooper, these TEs resemble the computer simulations that scientists run to discover how phenomena may behave if the laws of nature are slightly different. Cooper states that simulations and thought experiments that cannot be implemented as physical experiments can nevertheless be used as potential sources of knowledge in science.

Buzzoni (2009) claims that thought experiments and real-world experiments form a dialectical unity: without thought experiments there would be no real experiments because we would not know how to ask about their nature, and without real experiments we would not find answers to these questions. According to Galili (2009), thought experiments play a heuristic role. They are free from the constraints imposed by reality (heat, friction, etc.), and the thought experimenter can also forget the technical restrictions (equipment, costs, availability, etc.). In a sense, a person conducting a thought experiment mentally models theoretical physics (Peierls 1980).

From the above it follows that a thought experiment is a special case of scientific experiment that can precede a physical experiment and help the experimenter to conduct it. In some cases, a physical experiment may not be possible and TE may then be the only way to experiment. TEs can also be used to idealise complex physical situations and remove constraints imposed by reality. The physical experiment may either confirm the results of a TE or show that the TE was fallible; both types of TEs are important in constructing an understanding of scientific knowledge. This view of thought experiments can then be used as a starting point in science teaching.

38.4 The Epistemological Role of Thought Experiments in Science

If we approve of TEs as one special part of scientific methodology, we need also to discuss whether TEs play a special epistemic role in the knowledge construction processes of science. The theoretical framework of TEs is of great importance because it determines the image of the nature of science that TEs convey when used in science teaching.

There are two different views of the epistemological status of TEs. The argument-based view states that knowledge comes only via sensory experiences, while the intuition-based (Platonic) view argues that TEs provide information beyond our senses. The argument-based views rely on the idea that TEs can be reconstructed as arguments or that they function via their connection to arguments, so they are unable to provide more information than argumentation in general. On the other hand, the intuition-based view argues that a special group of TEs, Platonic thought experiments, go beyond our senses to acquire a priori information about nature.

38.4.1 Argument-Based Views

Argument-based views rely on the idea that TEs are unable to provide more information than argumentation in general. The supporters of the argument-based view do not mean that TEs are meaningless in science; rather, they are meaningless in an epistemological sense.

John Norton is probably the best-known supporter of the view that thought experiments are basically arguments. He thinks that TEs are not epistemic wonders, but they do tell us about our world using our normal epistemic resources[4] (Norton 1996, 2004a). Norton (1996, p. 339) has formulated his claim in a more precise form, referred to as a *Reconstruction Thesis*, as follows:

> *Reconstruction Thesis:* All thought experiments can be reconstructed as arguments based on tacit or explicit assumptions. Belief in the outcome-conclusion of the thought experiment is justified only insofar as the reconstructed argument can justify the conclusion.

TEs draw on hypothetical and counterfactual situations that essentially separate them from physical experiments (Norton 1991, 1996). These unnecessary particulars are needed for the experimental nature of thought experiments; without them, TEs would not be experimental. These particulars can be psychologically useful, but they are unnecessary for the thought experiment itself.

Norton claims that the epistemological potential of TEs is the same as that of argumentation, since every TE can be reconstructed as an argument (Norton 2004a, b). Because TEs do not involve new empirical data, they can only reorganise or generalise the old data (Norton 1991, p. 335). This prior knowledge, based on our previous experiences, can enter into thought experiments as assumptions. Hence, thought experiments are devices that reorganise or generalise these assumptions to achieve the result of the thought experiment. Norton regards these “devices” as arguments.

If the TE simply reorganises, it is a *deductive* argument or a *reductio ad absurdum* argument, where the particular conclusion follows deductively from the premises.

---

[4] Epistemic recourses are processes and tools that we use to decide that we know something or to create knowledge (Redish 2004, p. 31).

For instance, thermodynamics includes some powerful TEs because the first, second, and third laws of thermodynamics can be formulated as "assertions of impossibilities" (Norton 1991, p. 131). The first law can be expressed as an assertion as follows: "It is impossible to design a perpetual motion machine of the first kind, that is, a machine whose sole effect is to produce more energy than it consumes". Norton explains that consequences can be derived from the assertions included in a *reductio* argument, which then almost automatically becomes a thought experiment.

If the TE generalises on a wider scale, it is an *inductive* argument. This kind of TE includes an inductive step that frees the conclusion of its particulars. Norton (1991) suggests that Einstein's magnet and conductor and Einstein's elevator thought experiments belong to this class. According to Norton (1991, p. 137), Einstein's elevator can be constructed as arguments as follows:

1. In an opaque chest, an observer will see free bodies move identically in the case where the box is uniformly accelerated in a gravitation-free space and where the box is at rest in a homogenous gravitational field.
2. Inductive step: (a) the case is typical and will hold for all observable phenomena and (b) the presence of the chest and observer are inessential to the equivalence.
3. A uniformly accelerating frame in gravitation-free space and a frame at rest in a homogenous gravitational field are observationally identical but theoretically distinguished, which is self-contradictory.
4. The verifiability heuristic for theory construction (version 2[5]).
5. A uniformly accelerating frame in a gravitation-free space and a frame at rest in a homogenous gravitational field are the same thing (which becomes a postulate of a new theory).

According to Norton, the inductive step (2), which proceeds from a finite number of specific facts to a general conclusion, is quite problematic but "masked by the thought experiment format". He continues: "The extension from the motion of bodies in free fall to arbitrary processes is quite a leap, especially in view of the bizarre consequences that follow". Based on this example, it seems that constructing a thought experiment as arguments may also contain challenging phases that may not be unambiguous.

Brown and Fehige (2010) present three objections to Norton's claims. First, they consider Norton's view too vague. Second, they argue that Norton reaches far ahead of established facts: every real-world experiment can be represented as a thought experiment but nobody claims that thought experiments are unnecessary. Furthermore, Norton's view does not tell where the arguments come from. Brown and Fehige (2010) admit that a thought experiment can be an essential phase in the building of Nortonian reconstruction, but a thought experiment expressed as an argument loses its power. Arthur (1999) also disagrees with Norton by arguing that

---

[5] States of affairs that are not observationally distinct should not be distinguished by the theory (Norton 1991, p. 135).

if TEs are constructed as arguments, there will be an epistemic loss: the original thought experiment is not epistemically similar to the constructed arguments.

Nersessian (1992, p. 27) argues that a Nortonian reconstruction cannot be performed before the actual thought experiment has been executed. This means that TEs really have experimental power. By claiming that a TE contains particulars irrelevant to the conclusions, Norton fails also to see the constructive function of the narrative form in which thought experiments are presented.

Häggqvist (1996) claims that thought experiments are not arguments because something that is a process, an event, or a procedure cannot, by its nature, be an argument; TEs function, however, via their connection with arguments. He argues that thought experiments work in the same way as experiments in general, by affording premises for their associated arguments. For a successful experiment, the premises are true. Only arguments as truth-valued, linguistic entities matter when the truth-value of a scientific or philosophical theory or hypothesis is evaluated.

The argument-based view of TE as presented by Norton (1991, 1996, 2004a, b) seems to be problematic with regard to its potential use in science teaching. The reconstruction process, in particular, would be rather demanding for students because, in practice, students would already need to understand the original TE quite well in order to be able to perform the reconstruction. This does not mean that we do not appreciate the basic skills of scientific argumentation that constitute important learning goals in science education. The argument view may, however, be useful for science educators and science teachers in regarding the nature of the counterpoint of the argument-based view, i.e. Brown's destructive and constructive TEs, which will be examined next.

38.4.2 Brown's Destructive and Constructive TEs

James Robert Brown (1991) classified TEs according to their role in building scientific theories as destructive and constructive TEs. *A destructive TE* is an argument against a theory; it destroys or at least indicates serious problems in the particular theory. According to Brown, Einstein's chasing the light beam, presented in the introduction to this chapter, and Schrödinger's cat are examples of this kind of TE. Erwin Schrödinger presented a cat paradox where a cat in a box exists in a superposition of two states: dead and alive (Schrödinger 1935). His aim was to question the limitations and conceptual difficulties of quantum mechanics.

In contrast, *constructive* TEs break down into three further types: *direct*, *conjectural*, and *meditative* TEs. *A meditative TE* helps in the drawing of a conclusion from a specified, well-articulated theory. It may illustrate some counter-intuitive aspects of the theory, making it seem more satisfying, or it may act like a diagram in a geometrical proof that helps to support understanding, or even in the discovery of, the formal proof. Brown uses Maxwell's demon as an example of meditative TE.

The demon sits between the chambers of a gas vessel, which are filled with gas. The demon opens a trapdoor between the chambers by allowing the faster molecules to move to one side and the slower molecules to the other side. The TE shows that if this kind of demon existed, it would decrease the entropy of the gas system and cause a violation of the second law of thermodynamics. James Clerk Maxwell used this thought experiment to discuss the second law of thermodynamics at molecular level and to show that it possessed only statistical certainty (Schlesinger 1996; Radhakrishnamurty 2010). According to Schlesinger, Maxwell's intention was to use the demon to dramatise his claim concerning the statistical nature of thermodynamics.

A *conjectural TE* establishes some phenomenon and hypothesises a theory to explain the theory thereafter. The events of conjectural TEs have a presumed explanation. A *direct TE* begins with an unproblematic phenomenon and ends with a well-articulated theory. Brown considers Newton's bucket to be a prime example of a conjectural TE. Newton suggested that the existence of absolute space could be substantiated by hanging a bucket of water from a rope and spinning it. The concave shape of the water's surfaces caused Newton to assume that it was spinning with respect to something. Furthermore, according to Brown (1991), Stevin's inclined plane[6] and Einstein's elevator[7] belong to this class of TEs.

A small group of TEs are both destructive and constructive at the same time. These thought experiments are termed Platonic TEs (Brown 1991, p. 34). According to Brown (1991), in a few special cases we may go well beyond existing data to obtain a priori information about nature. Brown and Fehige (2010) explain that this information is a priori information about nature since, because the thought experiment does not contain new information, the conclusion does not draw on old data and it is not some sort of logical truth. This view of thought experiments can be further developed by combining a priori epistemology to recent views about the laws of nature, according to which laws consist of objectively existing relations between abstract entities. This view is, therefore, Platonic.

According to Brown, Galileo's free fall and the EPR (Einstein, Podolsky, Rosen) paradox may be regarded as examples of Platonic TEs. Brown argues that Galileo's free fall extinguished Aristotle's view and generated a new view, while EPR seriously challenged the Copenhagen interpretation and established the incompleteness of quantum mechanics. Brown and Fehige (2010) have characterised Brown's view as an intuition-based view.[8]

Galileo's free fall TE indeed revealed an inconsistency in the Aristotelian view, but it could not say anything about the actual descent of objects, which indeed fall at different rates of acceleration relative to the ground. According to McAllister (2004), Galileo's TE merely verified that if the rate of fall of simple and compound bodies was simply a function of their mass, then the rate of fall of bodies would be

---

[6] Stevin's TE discusses the forces that are needed to keep a weight on an inclined plane (see, e.g. Gilbert and Reiner 2000).

[7] If a man is in a windowless elevator, he cannot tell whether the sensation of weight is due to gravity or acceleration.

[8] Intuition can be defined as a capacity for attaining direct knowledge or understanding without the apparent intrusion of rational thought or logical inference (Sadler-Smith and Shefy 2004).

independent of mass. This is an important point that needs to be grasped in physics education (Lehavi and Galili 2009). Hence, Galileo's free fall TE is not actually a Platonic TE. Furthermore, Albert Einstein, Boris Podolsky, and Nathan Rosen attempted to show that quantum mechanics is incomplete, but, instead, a definition of nonlocality was found (Einstein 1918). Quantum mechanics is, however, generally regarded as complete. Bokulich (2001) has discussed both the essence and also further modifications of EPR.

Our view is aligned with that of Arthur (1999), who does not agree with the epistemological power of Platonic TEs but thinks that TEs can go beyond arguments by offering an effortlessly understandable imaginative reconstruction of the phenomenon. According to Arthur (1999, p. 27), there are no pre-existing concepts but rather some sort of presentiment or intuition of them. This does not mean that such ideas would really exist and that we could not yet understand them. Rather, we have not succeeded in formulating them.

Norton (2004a) has questioned the reliability of the use of those TEs that are supposed to be "the glimpsing a Platonic world". Brown's counterargument is that even ordinary vision can be mistaken (1991, p. 65–66). Norton sees this differently: the TE that fails is simply an argument that contains an erroneous assumption. Brown's Platonism has also been criticised for not presenting criteria for good and poor thought experiments (Brown and Fehige 2010). Brown and Fehige argue that this objection will be weak if the intuitions do the work in thought experiments, since rationalists and empiricists do not have a theory of the validity of intuitions.

Brown's (1991) categorisation of TEs as constructive and destructive has already been used in the analysis of thought experiments in physics textbooks and popular physics books by Velentzas, Halkia, and Skordoulis (2007). When they analysed 25 books to discover how the 11 most essential thought experiments in the domains of relativity and quantum mechanics are presented, they found all of the thought experiments contained in the books to be constructive.

The use of Brown's categorisation shows that it has potential in science education. We believe that it could also be used in science teaching as a theoretical framework of thought experiments for understanding how scientific knowledge is constructed. In the following section, thought experiments are discussed from the perspective of science education.

38.5 Thought Experiments in Science Education

In the course of the past 10 years, there has been a slight increase in research activities related to thought experiments in science education, and thought experiments have received more attention in scientific discussions. Here we argue why and how TEs might be used in science teaching in supporting student learning and offering an authentic image of science. In addition, the possible challenges involved in the teaching and learning of TE will form part of the discussion.

38.5.1 Pedagogical Benefits of Thought Experiments

Ernst Mach was the first to realise that thought experiments might have a high didactical value (Mach 1976). He emphasised in particular the role played by students in thought experimenting (Matthews 1988, 1990). By using thought experiments as a teaching method, a teacher can keep students guessing. In addition, this method provides a significant support to the teacher in coming to know his/her students better. Some students are able to guess the next phase immediately, while some will present extraordinary guesses. Through thought experiments, students will learn to distinguish solvable from unsolvable concerns.

The use of TEs introduces an authentic image of the culture of science (Galili 2009; Reiner et al. 1995; Reiner and Gilbert 2008). TEs can be used to address the essential characteristics of physical theories (Galili 2009). They often employ representative models that eliminate technical details, errors, and impeding factors such as heat or friction. By introducing TEs before real experiments, students may develop an ability to appreciate real experiments and perceive the focus of the experiments, which is otherwise frequently difficult to see because of the sheer quantity of details. Naive observers' difficulties in differentiating between non-relevant and relevant details may impede them from finding out the aimed observations, results, and conclusions (see, e.g. Kozma and Russell 1997; McDermott 1993). Klassen (2006) believes that by devising their own thought experiments, students are mentally engaged in the concepts to be learned, and this, in turn, may help them to construct a deeper understanding of science. Nersessian (1992) claims that "the historical processes provide a model for learning activity itself" and may assist students in constructing representations of scientific theories. Social discussions of TEs may lead students to conceptual refinement and construction of reliable knowledge, as would be the case in science itself (Reiner and Gilbert 2008).

Reiner and Burko (2003) claim that both the TEs devised by physicists and also those formulated independently by students are important in the learning of physics. Scientifically correct TEs constructed by famous physicists enable students to familiarise themselves with the potential of TEs and to see them as a special mode of argumentation. In contrast, incorrect TEs prepare them for the existence of logical and conceptual stumbling stones, the temporary state of knowledge in physics, and the meaning of self- and peer criticism in the construction of physical knowledge. By working on thought experiments independently, students also work through the processes that underlie erroneous reasoning and learn to negotiate over the processes and conclusions with their peers in a relevant form of social interaction (Reiner et al. 1995). Procedures such as these all contribute to the clarification of concepts.

It has also been claimed that the use of TE in teaching stimulates students' interest (Lattery 2001; Velentzas et al. 2007; Velentzas and Halkia 2011) and helps their imaginations to develop (Galili 2009). By introducing situations that are impossible to reproduce despite the sophistication of the available equipment, TEs also become an irreplaceable tool of teaching. According to Galili (2009), this applies especially in the teaching of relativity and quantum physics, where real experiments are not widely used in the classroom, and the use of the multimedia often fails to promote enhanced understanding. Encouragement is also given to the use of thought experiments in teaching if the aim of the teaching is to activate students' cognitive processes with situations that would otherwise be beyond their everyday experiences (Velentzas and Halkia 2010).

38.5.2 The Use of Thought Experiments in Science Textbooks

It has been noted that in some domains of physics such as relativity and quantum mechanics, thought experiments are the main method of presenting the concepts in physics textbooks and popular physics books (Velentzas et al. 2007). Because science teachers often base their teaching on textbooks (Levitt 2002; Yore 1991), textbook studies are an important method for understanding the premises of science teachers' use of thought experiments. In addition, it would appear that studies concerned with teachers' use of TEs are still absent from in the literature.

The extent to which thought experiments are used in science textbooks and the ways in which they have been exploited have been studied by Gilbert and Reiner (2000) and Velentzas, Halkia, and Skordoulis (2007). Gilbert and Reiner's study focused on popular physics textbooks[9] while Velentzas and colleagues looked at both popular science books and physics textbooks.[10]

Gilbert and Reiner (2000) discovered that textbooks often miss opportunities to develop thought experiments suitable for teaching even though there were numerous suitable opportunities to do so. Thought experiments in textbooks frequently turn into thought simulations that lack two essential elements of thought experiments: recognition and approval of the imposed problem and conclusions based on the results. Instead of drawing on the six elements of TEs,[11] the textbook thought simulations typically consisted of the following parts:

i. Statement of the conclusion reached
ii. Creation of the imagined world
iii. Conflation of the design and running elements
iv. Statement of the results obtained, often with an optional restatement of the conclusions reached (Gilbert and Reiner 2000, p. 279)

---

[9] The books analysed were Breithaupt's *Understanding Physics for Advanced Level* and Ohanion's *Physics* and *Conceptual Physics* by Hewitt.

[10] The books were either written in Greek or translated into Greek from English. The study aimed at finding out how the books represented the 11 most essential thought experiments in the domains of relativity and quantum mechanics. A total of 25 books were included in the study.

[11] The six elements of a TE: (1) posing a question or a hypothesis, (2) creating an imaginary world, (3) designing the TE, (4) performing the TE mentally, (5) producing an outcome of the TE, and (6) drawing a conclusion.

According to Gilbert and Reiner (2000), this may be the result of the textbook writers not understanding the actual potential of using thought experiments. Indeed, thought experiments can be a successful way to enhance students' cognitive engagement, which is the key to developmental success. Thought experiments offer opportunities for creating new ontological entities, developing reasoning skills, and adopting epistemological engagements. These skills are claimed to be essential for gaining an understanding of physics (Driver et al. 1994). It might also be asked whether this kind of one-sided deductive approach to thought experiments is pedagogically valid.

Velentzas, Halkia, and Skordoulis (2007) observed that all of the thought experiments that they had found in the physics textbooks and popular physics books in their study were constructive. In addition, the authors had modernised numerous thought experiments: for example, Einstein's chest TE was examined in the form of a spaceship thought experiment. The authors had also invented thought experiments independently. The mathematical level of thought experiment was low and the terminology, language, and abstraction level were all modified to match their readers' perceived skills. The use of narratives was typical of the popular textbooks, whereas the other textbooks tended to avoid narratives by using scientific language and terminology.

38.5.3 Studies on the Use of Thought Experiments in Teaching

Thought experiments have been used in science teaching in different ways, and some of the possibilities have been reported. In the following we describe a few of these: using written tasks to help students to understand well-known TEs,[12] constructing historical physics experiments as thought experiments in narrative form (Klassen 2006), and students' own TEs in the context of experimental work (Reiner 1998).

Velentzas, Halkia, and Skordoulis (2007) used the famous TE known as Einstein's elevator thought experiment to introduce the concepts of the equivalence principle to 9th grade students. A group of six students studied the thought experiment as it was presented in a selected popular physics book[13] and replied to related questions, first individually and then as a group. The results indicate that the pupils achieved a reasonable understanding of the concepts. They were also surprisingly enthusiastic about performing the given task. The researchers supposed that this reaction may have been a consequence of the nonmathematical, narrative representation of the task. It seems, then, that popularised thought experiments can be used to inspire pupils in the case of concepts and principles that are discussed in greater depth later in the teaching process.

---

[13] Stannard, R. (1991). *Black Hole and Uncle Albert*. London: Faber and Faber Ltd.

Velentzas and Halkia (2011, 2012) have also successfully used thought experiments as a teaching tool in physics teaching for upper secondary students. They studied the ways in which the uncertainty principle and the basic concepts of the theory of relativity could be taught to upper secondary school students. The uncertainty principle was introduced via Heisenberg's microscope thought experiment (Velentzas and Halkia 2011), while the theory of relativity was approached via Einstein's train and Einstein's elevator thought experiments (Velentzas and Halkia 2012). In the case of the uncertainty principle, the students were able to derive the uncertainty principle, and by the end of the teaching, they understood it as a general principle in nature (Velentzas and Halkia 2011). Furthermore, Einstein's TEs concerning relativity enabled students to realise situations related to the world beyond their everyday experiences and to gain a basic understanding of the theory of relativity (Velentzas and Halkia 2012).

Lattery (2001) used Galileo's TE Law of Chords (rates of descent along certain curves) as a basis for a student project at the university level. A group of three students discussed the TE and made predictions, following which they tested the predictions experimentally. Subsequently, they wrote a paper, prepared a poster, and made an oral presentation for their peers and the faculty concerned with the project. Lattery concludes that it offered a positive learning experience for the students themselves, for their peers, and for faculty in general.

Klassen (2006) argued that thought experiments could be expressed as stories. To test his hypothesis, he wrote a story about Benjamin Franklin's life and experiments in a form that invited students to render Franklin's experiments as thought experiments. He believed that this kind of narrative construction would help students to become mentally engaged in the concepts to be learned and that this, in turn, would them help to construct a more profound understanding of science. Even if a method of this kind seems to be rather interesting, its effectiveness should still be assessed scientifically by examining students' learning processes before further conclusions.

Reiner (1998) studied grade 11 students' self-devised thought experiments. A total of 12 students were given the following task. Using a computer-based simulator and hands-on equipment, they were required to design a periscope with a wide visual field. To solve the task, the students worked in groups of three. Analysis of the processes produced by one group showed that the students' thought experiments developed because of a collaborative problem-solving process in which the students used the computer system to validate potential events and results. The system helped the students to make their intentions visible to their peers and also to test hypothetical events. Furthermore, the four different student groups displayed a considerable variety of thought experiments, e.g. the logic and contexts that the students used and the conclusions that they drew varied considerably. It was also typical of the four groups that the students' thought experiments were partial and incomplete; they did not contain all three parts of the typical thought experiment: hypothesis, results, and conclusions. Reiner claims, however, that the results show that the thought experiments, which consisted of episodes, were general rather than random, even if they missed out one or two of the three parts. According to Reiner, a collaborative environment helps students to construct thought experiments as a shared construction that is based on individual students' contributions.

These examples of the implementation of thought experiments in teaching are illustrative; but in actual classroom teaching, some limitations may occur. Teachers need to take into account the fact that students' cognitive processes may lead to erroneous conclusions (Velentzas and Halkia 2011). In analysing some of the famous TEs of physics, Reiner and Burko (2003) have discovered cognitive processes that also lead to erroneous conclusions. At least three of this kind were found: strong *intuition* of a kind that induces the abandonment of theory-based reasoning, *incompleteness* of the basic assumption of the thought experiment, and *irrelevance* of the system's properties in the thought experiment.

Reiner and Burko (2003) claim that the processes that are characteristic of physical thinking are likely to be found in physics learning as well. The use of intuition instead of logical, theory-based reasoning is even stronger in the case of naive physics learners than amongst famous physicists in the history of physics. In addition, research has shown that students more often apply concrete, experiential knowledge rather than using logical reasoning (e.g. DiSessa 1993; Gilbert and Reiner 2000). The incompleteness of the students' TEs relates to the narrowness of the learners' physical world. Their readiness to conclude is insufficient because assumptions integrated into knowledge structures are partial instead of being comprehensive; the learners may not have sufficient knowledge of the physical world to make sense of the TE. Reiner and Burko (2003) argue that the use of TEs in physics learning is important, because it allows students to experience the destructive and constructive role of physical intuitions, incompleteness, and the importance of relevancy.

We agree with Reiner and Burko and Velentzas and Halkia (2011), who recommend the use of TEs in cases where the performance of a physical experiment is impossible, harmful, and dangerous or has nothing to offer in the end for the result. They also suggest the use of TEs in situations that require students to mentally surpass their everyday experiences.

In sum, thought experiments can be used in science teaching to help students to develop their conceptual understanding of science.[14] Thought experiments may increase students' interest in learning science[15] and to activate and support their thinking processes.[16] In addition, the construction of students' own thought experiments can be supported by creating a collaborative environment that enables students to construct thought experiment together with their peers (Reiner 1998). Students' erroneous conclusions should, however, be taken into account in teaching; they can be used as a basis for discussion about the destructive and constructive intuitions in thought experimenting (Reiner and Burko 2003).

38.6 Conclusion

This article has examined the role played by thought experiments in science and science education. It has been argued that TEs are a natural part of scientific methodology, a special type of scientific experimentation that may play either a constructive or a destructive role in the construction of scientific theories. The important role played by TEs in science should also be discussed in science teaching. In addition, TEs have been used in science education in various ways to foster the development of students' reasoning, mental modelling, and conceptual understanding; to teach them about the nature and processes of science; and to stimulate their interest in science. Thought experiments also provide opportunities for focusing on the epistemology and ontology of science in the teaching of science.

TEs are a special variety of scientific experiment that can, at its best, precede a physical experiment and help the experimenter in conducting it. In some cases, physical experimentation may not yet be possible and the TE can be the only way to experiment; TEs are free from the constraints imposed by the learning environment and by technical restrictions (Cooper 2005; Galili 2009). In addition, a physical experiment may be considered useless if it is unlikely to substantially improve understanding gained from a TE (Sorensen 1992). These statements also hold true in science education: TEs can be used as an effective tool for teaching. By performing a TE before the physical experiment per se, students may develop their ability to see the focus of the physical experiment (Galili 2009). At times, the experiment can only be made mentally as a TE for practical reasons: the school may not have certain equipment or the experiment is too laborious to be conducted during a lesson. In some cases, thought experimenting is the only way to experiment because the situation cannot be performed as a physical experiment, regardless of the sophistication of the equipment available (Galili 2009). TEs also frequently involve idealisations such as technical details, errors, and impeding factors such as heat or friction; these factors can be eliminated by using TEs (Cooper 2005; Galili 2009). This particular use of TEs in school teaching may already be more common than might be expected.

TEs in science can be fallible, but the mistakes can also teach important lessons that help scientists to develop scientific theories. For instance, erroneous conclusions in famous TEs can be explained in terms of three different cognitive processes: strong *intuition*, which induces the abandonment of theory-based reasoning; the *incompleteness* of the basic assumptions of thought experiment; and the *irrelevance* of the properties of the system in the thought experiment (Reiner and Burko 2003). This kind of erroneous reasoning is also likely in the case of students; teachers should also be prepared to take it into account in their teaching (Velentzas and Halkia 2011). Teachers should also be prepared to encourage students to experiment mentally. As Ozdemir's (2009) results have shown, even physics graduates may tend to think that mental simulations cannot be used correctly to explain the phenomena of physics. Hence, teachers should be ready to help their students to become more open-minded and to be undaunted by errors in their reasoning. Teachers need to help their students to gain an insight into the value of thought experiments in scientific reasoning since they may otherwise remain unaware of it (Reiner 2006).

Thought experiments can be used in science teaching to allow students to see that scientific intuitions can play both destructive and constructive roles. It has, however, been observed that authors of science textbooks and popular science books may be in the habit of using only constructive TEs (Velentzas et al. 2007). This rather one-sided use of TEs may bias the image of science that the books attempt to convey. If the authors of textbooks aim at conveying an image of the processes of science, then the use of TEs in textbooks should be carefully designed to include both destructive and constructive TEs.

It must also be emphasised that, when conceptually demanding thought experiments have been simplified for teaching a particular student group, it has been noted that thought experiments stimulate the students' interest (Velentzas et al. 2007). Our own approach tends to agree with that of other researchers who acknowledge that this use of TEs works well if the concepts are taught in greater detail at a later stage. Reconstruction of historical physical experiments as thought experiments has also been reported to enhance students' interest (Klassen 2006).

The role played by a skilful teacher is pivotal in the use of thought experiments in science teaching. Students' own thought experimenting needs to be supported by the teacher by means of the selection of suitable resources, the structuring of the learning activities, and guidance of the students' experimentation (Hennessy et al. 2007). A skilful teacher is able to observe instances of erroneous reasoning and knows how to guide students' learning processes in the right direction. To be able to evaluate thought experiments in science textbooks and also thought experiments implemented by students, a teacher should present or formulate the theoretical background and criteria for the elements of a TE. Gilbert and Reiner (2000, p. 268) provide a system of categorisation for thought experiments that appears to be promising for understanding the use of TEs in science teaching. The categorisation is briefly as follows. An *expressed thought experiment* is a TE that has been placed in the public domain by an individual or a group of researchers. A *consensus thought experiment* is a TE accepted by at least some of the scientific community and one that has been scientifically justified, that is, published in a scientific journal.

In addition, a *historical thought experiment* is a TE that has already been replaced in science but may still be used to explain particular phenomena economically. A *teaching thought experiment* contains "the criterion by the teacher (or, indeed, the taught) of the TE based on the situations familiar to or imaginable by the students, through which to develop an understanding of a given consensus TE". Gilbert and Reiner emphasise that all of the different types of TEs include the six elements of TEs described by Reiner (1998).

As Gilbert and Reiner (2000) point out, although different types of thought experiment exist in science, they all have a certain structure. Hence, thought experiments devised and conducted by students should also include these common elements in order to qualify as genuine thought experiments; if some of the elements are missing, then the exercise should be termed a thought simulation rather than a thought experiment (Gilbert and Reiner 2000). According to some studies, historical TEs have sometimes been modernised in textbooks to be more readily understandable (see, e.g. Velentzas et al. 2007). This reconstruction may, however, lead to another problem: textbooks do not always include all of the necessary elements of thought experiments, with the result that TEs that have been reduced as thought simulations will lead to loss of the necessary cognitive engagement (Gilbert and Reiner 2000). Such thought simulations may nevertheless be used to some extent in science teaching if the primary goal of the teaching is not the actual subject matter or to foster students' understanding of the processes of science but rather to stimulate the students' interest in the science per se. Naturally, it would be unreasonable to assume that, for instance, secondary students would be able to perform thought experiments as effectively as, say, university students. It is perhaps self-evident that the science teacher should have the freedom to decide just how accurate students' mentally performed experiments need to be for them to fulfil the criteria of a thought experiment.

Undoubtedly, TEs need to be considered carefully in the context of science teacher education, and in-service education would need to be organised for practicing teachers. Both pedagogical and subject-matter departments could introduce TEs to students as part of the history and philosophy of science teaching. In addition, many subject-matter courses, such as mechanics, thermodynamics, and quantum physics, offer good opportunities for the use of TEs in the teaching of subject matter. In this way, TEs could become better integrated into the knowledge structures of future science teachers, who could then use thought experiments flexibly in their own science teaching. As Matthews (1992, p. 28) suggests, "A historically and philosophically literate science teacher can assist students to grasp just how science captures, and does not capture, the real, subjective, lived world".

Systematic research into the use of TEs in science teaching is, however, definitely needed so that we can acquire further research-based, valid information on their effective use at various educational levels. In particular, the notion of a *teaching thought experiment* is interesting from the perspective of science teaching as conducted in schools. It would be interesting to discover the kind of TEs that teachers use and how they use them, and whether teachers use thought simulations (TSs) rather than TEs. It is likely that consensus and historical TEs are not widely used in teaching at secondary school level, but teaching TEs may nevertheless prove to be more common than is thought. Thus far, the groups participating in the studies have been small and they have varied from lower secondary school pupils to university students. In consequence, the results cannot be readily compared; and hence our recommendations for the use of TEs in teaching are inevitably still rather loosely based. Nevertheless, analysis of students' thought experiments has interesting possibilities that may help us to understand better the challenges posed by science learning. There is undoubtedly a need for further studies of how science teachers actually use TEs in their teaching. This gap in the literature deserves to be filled.

Acknowledgements We wish to thank Mick Nott, Tarja Kallio, John A. Stotesbury, and also the anonymous reviewers for their helpful critical comments.

Mervi A. Asikainen is a Senior Lecturer at the Department of Physics and Mathematics, University of Eastern Finland. She is a key person in the Physics Education Research Group of the University of Eastern Finland (PERG-UEF). She is responsible for the methodological issues of physics and mathematics education research in the group. She has M.Sc. in physics and a competence to teach physics, mathematics, and chemistry in secondary schools. Her Ph.D. thesis in physics focused on the learning of quantum phenomena and objects in physics teacher education. She has taught physics in various in-service teacher education courses for both primary and secondary school teachers and worked as a school teacher. At the moment, she teaches courses Basic Physics II, Basic Physics IV, and Quantum and Atomic Physics. Her main interests are the methodology of science education research, teacher knowledge in physics and mathematics, and teaching and learning of university physics. She has published in *European Journal of Physics*, *American Journal of Physics*, *Research in Science Education*, and *Journal of Science Teacher Education*.

Pekka E. Hirvonen Associate Professor Hirvonen is the leader of the Physics and Mathematics Education Research Group of the University of Eastern Finland and the education unit of the Department of Physics and Mathematics. He received his Master's degree in 1996 with the pedagogical studies of the subject teacher, Licentiate degree in 1999, Ph.D. in physics in 2003, and the title of docent in 2010. He has published in journals such as *Science & Education*, *European Journal of Physics*, *American Journal of Physics*, *Research in Science Education*, and *Journal of Science Teacher Education*. The research concentrates on two main themes: teaching and learning different topics of physics and mathematics and research-based development work of physics and mathematics teacher education.

Part X

Theoretical Studies: Teaching, Learning and Understanding Science

Chapter 39
Philosophy of Education and Science Education: A Vital but Underdeveloped Relationship

Roland M. Schulz

> *It was through the feeling of wonder that men now and at first began to philosophize. … but he who asks and wonders expresses his ignorance … thus in order to gain knowledge they turned to philosophy.*
>
> —Aristotle *(Metaphysics)*

39.1 Introduction

This chapter examines the relationship between the two fields of science education and philosophy of education to inquire about how philosophy could better contribute to improving science curriculum, teaching, and learning, above all teacher education. The value of philosophy *for* science education in general remains underappreciated at both pedagogical levels, whether the research field or classroom practice. While it can be admitted that philosophy has been an area of limited and scattered interest for researchers for some time, it can be considered a truism that modern science teacher education has tended overall to bypass philosophy and philosophy of education for studies in psychology and cognitive science, especially their theories of learning and development (which continue to dominate the research field; Lee et al. 2009). A major turn encompassing philosophy would thus represent an *alternative approach* (Roberts and Russell 1975).

Science education is known to have borrowed ideas from pedagogues and philosophers in the past (e.g., from Rousseau, Pestalozzi, Herbart, and Dewey; DeBoer 1991); however, the subfield of *philosophy of education* has been little canvassed and remains on the whole an underdeveloped area. At first glance such a state of affairs may not seem all too surprising since science education is mainly concerned

M.R. Matthews (ed.), *International Handbook of Research in History, Philosophy and Science Teaching*, DOI 10.1007/978-94-007-7654-8_39,

with educating students about particular science subjects or disciplines. But this necessarily implies a tight link between content and education. Hence, if education is to mean more than mere instructional techniques with associated texts to encompass broader aims including ideals about what constitutes an educated citizen (i.e., defining "scientific literacy") or foundational questions about the nature of education, learning, knowledge, or science, then philosophy *must* come into view (Nola and Irzik 2005). As is known, an *education in* science can be, and has been, associated with narrow technical training, or with wider liberal education, or with social relevance (STSE), or lately with "science for engineers" (US STEM reforms), an updated version of the older vocational interest.[1] Yet all these diverse curricular directions imply or assume a particular educational philosophy which is rarely clearly articulated (Matthews 1994a/2014; Roberts 1988; Schulz 2009a).

At second glance then, and viewing science education in a broader light, being principally at home in education unavoidably implies an excursion into philosophy of education. In fact, it avoids this subfield of philosophy at its own peril, as argued elsewhere (Matthews 2002; Schulz 2009a, b). Equally, there are lessons to be learned from its own past, yet most science teachers and too many researchers seem little aware, or even concerned to know, about the rich educational philo-historical background of science education as it has developed to the present, whether in North America, Europe, or elsewhere (some examples are Mach, Dewey, Westaway, and Schwab; DeBoer 1991; Gilead 2011; Matthews 1990b). In fact recent critical reviews insist educators must acknowledge and respond to how past historical developments have molded science education while continuing to adversely shape the current institutionalization of school science (Jenkins 2007; Rudolph 2002). A central concern of this chapter is to emphasize the value of philosophy in general and philosophy of education in particular. It will be claimed an awareness of the worth of these fields can have positive results for further defining the *identity* of both the science teacher as professional (Van Driel and Abell 2010; Clough et al. 2009) and science education as a research field (Fensham 2004). The perspective to be taken on board is that to teach science is to have a philosophical frame of mind—about the subject, about education, and about one's identity.

39.2 Philosophy of Science Education Framework

To be clear from the start, there is no attempt made here at formulating a particular philosophical position thought appropriate for science education, in contrast to such discussions having taken place in mathematics education for some time. In that field

---

[1] The prominent US *National Science Teachers Association* (NSTA) has made STEM a central reform emphasis: www.nsta.org/stem. References for the other more common science classroom curricular emphases are Aikenhead (1997, 2002, 2007), Carson (1998), DeBoer (1991), Donnelly (2001, 2004, 2006), Pedretti and Nazir (2011), Roberts (1982), Schwab (1978), Witz (2000), and Yager (1996).

several educators have articulated and debated the notion of a "philosophy of mathematics education," for example, Platonism and foundationalism versus social constructivism and fallibilism (Ernest 1991; Rowlands et al. 2011). On the other hand, it will be stressed that the development of a "philosophy *of* science education," that is, an "in-house philosophy" for the field, could be significant for reforming science education. It can be acknowledged that math educators have been in the forefront of attempting to establish a "philosophy of" for their educational discipline, while science educators in the main have not yet come to consider or value such an overt evolution in their field. Such an endeavor urges exploration of new intellectual territory.

The sign of the times seems ripe for such an investigation ever since the science educational field became staked out by opposing, even irreconcilable positions "from positivism to postmodernism" (Loving 1997).

In the past constructivism was once seen by many educators as a kind of "philosophy" (though not expressed as such) which was to serve the role as a "new paradigm" of science education. Today, however, this view is considered mistaken, although the topic is divisive (Matthews 2002; Phillips 1997, 2000; Suchting 1992).[2] This judgment has come about largely because many supporters at the time did not reflect seriously enough about the philosophical underpinning of its various forms—cognitive, metaphysical, and epistemological.[3] Constructivism remains a dominant and controversial topic in education, but one lesson to be had from the heated debate of the past three decades is that absence of philosophical training among science educators became apparent (Matthews 2009b; Nola and Irzik 2005). Another lesson learned is the absence of any explicit discussion regarding educational philosophy, even though constructivism in some corners was brashly substituted for one. In hindsight it surprises that constructivism—which after all still finds its principal value as learning theory (and perhaps teaching method)—could be mistaken as a dominant kind of "philosophy of" science education at the neglect of broader aims and concerns relevant to educational philosophy, as to what it *means* to educate someone in the sciences. And science education once again showed unawareness of its own history, since Dewey (1916, 1938, 1945) and Schwab (1978) had previously addressed such concerns. At minimum the case of constructivism had illustrated—although not widely recognized—how interwoven, if not dependent, science education in the academy had become with certain psychological ideas and philosophy of science (notably its Kuhnian version; Matthews 2003a).

In light of this background, it will be of some interest to teachers and researchers to raise anew the question of developing a "philosophy of" science education (PSE),

---

[2] "Regrettably, much of the constructivist literature relating to education has lacked precision in the use of language and thereby too readily confused theories of knowledge with ideas about how students learn and should be taught" (Jenkins 2009, p. 75).

[3] The literature on constructivism is vast. Critiques are found in Davson-Galle (1999), Phillips (2000), Grandy (2009), Kelly (1997), Matthews (1998b, 2000), and Scerri (2003). Also see chapter 31 in Handbook.

by asking here what that could *mean* and could *offer* the discipline. The intent is to address these concerns and help sketch out contours. With this project in mind, one can draw attention to two useful aspects pertaining to philosophy in general which can come to our aid and contribute to improving science education and developing such a philosophical perspective: the ability of philosophy to provide a synthesis of ideas taken from associated disciplines with their major educational implications and providing what can be called “philosophies of.” In this way it will be shown how philosophical thought can be brought to bear directly on educational ideas and practice.

39.2.1 The Synoptic Framework

The role and value that philosophy itself and its two important subdisciplines of *philosophy of science* (PS) and *philosophy of education* (PE) can have is illustrated by the representation below. Note that “philosophy of science education” (PSE) can then be understood as the *intersection* or *synthesis* of (at least) three academic fields. For each respective field of study, some individual points are stressed which comprise core topics of interest to science education pertinent to each, but is meant to be illustrative not exhaustive:

The framework in itself assumes neither prior philosophical positions (e.g., metaphysical realism or epistemological relativism) nor pedagogical approaches (e.g., constructivism, multiculturalism, sociopolitical activism). As a graphic organizer it does provide science teachers and researchers a holistic framework to undertake analysis of individual topics and perhaps help clarify their own thinking, bias, and positioning with respect to different approaches and ideas. The main point is to show that any particular PSE as it develops for the teacher or researcher should take into consideration, and deliberate upon, the discourses pertinent to the three other academic fields when they impinge upon key topics in science education. At minimum it should contribute to helping develop a philosophic mind-set.

In sum (as Fig. 39.1 shows), any philosophy of science education (PSE) is foremost a *philosophy* (“P”) and as such receives its merit from whatever value is assigned to philosophy as a discipline of critical inquiry. (This value may not appear at all obvious to science educators.) Furthermore, such a philosophy would need to consider issues and developments in the philosophy, history, and sociology of science (“PS”)[4] and analyze them for their appropriateness for improving learning *of* and *about* science. Finally, such a philosophy would need to consider issues and developments in the philosophy of education and curriculum theory (“PE”) and analyze them for their appropriateness for education in science, as to what that can *mean* and how it could be conceived and best achieved. A fully developed or

---

[4] This component is meant to include the associated disciplines and not just the philosophy discipline itself.

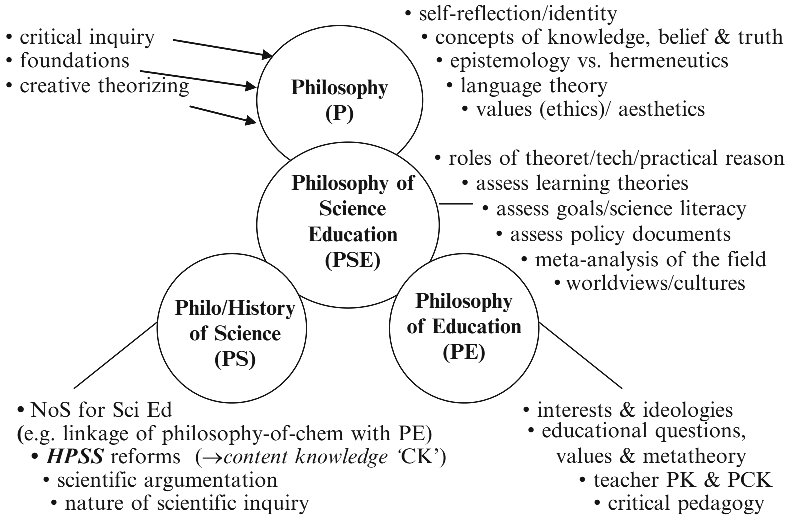

Fig. 39.1 Philosophy of science education (PSE)

"mature" PSE can be understood as an integration of all three fields. It ultimately aims at improving science education as a research field as well as assisting teachers in broadening their theoretical frameworks and enhancing their practice.

39.2.2 *Providing "Philosophies of"*

Philosophy today has evolved into several specialized subdisciplines. These include philosophy of science, of education, of mathematics, of technology, of history, of religion, and others, which can collectively be called "philosophies of." It is especially the first two that are of immediate concern to us when developing one for ourselves, as Fig. 39.1 illustrates. And yet this conceptualization is not as new as it may appear. Over 40 years ago, the philosopher Israel Scheffler summarized the value of these "philosophies of" for science educators:

> I have outlined four main efforts through which philosophies-of might contribute to education: (1) the analytical description of forms of thought represented by teaching subjects; (2) the evaluation and criticism of such forms of thought, (3) the analysis of specific materials so as to systematize and exhibit them as exemplifications of forms of thought; and (4) the interpretation of particular exemplifications in terms accessible to the novice. (Scheffler 1970, p. 392)

He understood these "philosophies of" would provide invaluable components to a science teacher's identity and preparation, in addition to the common three of (i) subject matter competence, (ii) practice in teaching, and (iii) educational methodology. Especially the inclusion of philosophy of science (PS) topics he considered vital to allow teachers to be "challenged to reflect deeply on the foundations" of their subjects and "to relate their reflections to the task of teaching" (p.388).

Matthews (1994a, b, 1997) is known to have helped popularize Scheffler's earlier vision, whose call for inclusion of PS has been broadly acknowledged today though unfortunately little implemented worldwide in teacher education programs.[5] He has expanded upon Scheffler's line of reasoning to include additional pedagogical and professional arguments. An improved pedagogy, for example, should include several aspects: wisely evaluating constructivism and the educational aims of curricular documents, integrating HPSS topics, developing critical thinking, allowing science courses to show a "human face," and at minimum making science more interesting and understandable. Enhancing professionalism requires teachers to develop a wider perspective of their subject and its role in education, including becoming versed with topics and questions associated with science and society concerns. These would include religion and science, "multicultural science," feminism, techno-science, environmental ethics, animal rights, and others.

In short, philosophical questions concerning both education and science are at the heart of the science education profession, many of which have kept, and continue to keep, teachers, researchers, and curriculum developers engaged. Broadly speaking, they encompass essential concerns immediately identifiable with the two fields of philosophy of education (PE) and philosophy of science (PS):

> … educational ones about the place of science in the curriculum, and how learning science contributes to the ideal of an educated citizen and the promotion of a modern and mature society. The questions also cover the subject matter of science itself. What is the nature of science? What is the status of its knowledge claims? Does it presuppose any particular worldview? The first category of questions constitutes standard philosophy of education (PE); the second category constitutes philosophy of science (PS) or history and philosophy of science (HPS). (Matthews 2002, p. 342)

The teacher's professional role today has in some cases also come to include cocreating, advising, and assessing so-called national science "standards" documents. Since the 1990s several countries around the world have sought to define curriculum "standards," which harbor considerable agreement on nature-of-science policy statements (McComas and Olson 1998). "Clearly all these curricular exhortations depend on teachers having philosophical acumen and knowledge in order to understand, appraise, and enact them. This requires a mixture of philosophy of science (to understand the substantial claims), and philosophy of education (to interpret and embrace the objectives of the curricula)" (Matthews 2002, p. 343). The same arguments and considerations apply to mathematics education where philosophy *of* mathematics is integral to what, why, and how mathematics is taught and assessed and how teachers understand their professional role and responsibilities.

In the sections below, the intention is to further elaborate on the worth of philosophy as a subject in general, but especially philosophy of education since

---

[5] Whether or not science students themselves should be presented with PS ideas and controversies is still being debated among researchers (Hodson 2009). One philosopher of education has reversed his earlier standpoint (Davson-Galle 1994, 2004, 2008a).

this topic is usually overlooked. Philosophy of science for educators will only be glossed (above all its newer subspecialties) as this topic has been an active area of research.

39.3 The Value of Philosophy

Philosophy is an academic discipline that seeks to establish a systematic reflection on reality however it may be construed. Its analytic function, often termed rational inquiry, involves critical appraisal of different topics, beliefs, and schools of thought.[6] Because of the complexity of the world around us (both natural and artificial), philosophy has been traditionally divided into separate major fields of study (first accredited to Aristotle) such as metaphysics, epistemology, logic, ethics, aesthetics, and politics. These fields individually have either major or lesser bearing on science education directly. The *first two* have played a significant historical role pertaining to our understanding of the nature of reality, of knowledge, and of science:[7]

- ***Ontology***: the branch of philosophy (metaphysics) that concerns itself with the most general questions of the nature or structure of reality: what "is" or "what is *being*?" and existence. It examines natural and supernatural claims and asks about the feature of essences (e.g., are natural kinds, like species, universal or nominal?). Questions regarding *scientific* ontology are concerned with ascertaining the status (or validity) of the products of human creativity or discovery; included are scientific models and theoretical entities (e.g., gene, field, black hole, tectonic plates), evaluated as to their truth (realism) or merely useful (fictive) construct to solve problems and "fit" experimental data (empirical adequacy).
- ***Epistemology***: the branch of philosophy that studies the nature of knowledge, its scope, foundations, and validity; it deals with theories of knowledge, distinctions between believing and knowing, and justification. *Scientific* epistemology is concerned with describing and ascertaining the nature of both the body of known scientific facts and theories (degree of certainty) *and* the production of new knowledge (i.e., scientific inquiry). *Personal* epistemologies are commonly taken to include individual beliefs, views, and attitudes about a particular subject; hence, they can be considered a "personal knowledge framework"

---

[6] It has also been historically associated with particular schools of thought (e.g., idealism, rationalism, empiricism, existentialism); hence, particular *philosophies* which themselves are often associated with individual philosophers (e.g., Plato, Kant, Marx, Nietzsche).

[7] This is not meant to discount the next three. Logic has made a renewed appearance in science education under the guise of critical thinking and scientific argumentation; those in ethics intersect with discussions of values and socio-ethical issues (Allchin 2001; Corrigan et al. 2007; Witz 1996; Zeidler and Sadler 2008); even aesthetics has been considered for the field (Girod 2007).

(i.e., "what do you know about 'X', and how do you know (it)?"). Two competing views of epistemic justification are *foundationalism* and *coherentism*.[8]
